ESHG PLENARY LECTURES

PL1.1

Understanding the Influence of Conditional Host-Karyome-Microbiome Interactions in Health and Disease

J. K. Nicholson;

Department of Biomolecular Medicine, Imperial College, London, United Kingdom.

Post-genomic technologies are being widely applied to improve the understanding of adverse drug reactions and the molecular basis of human disease. Metabonomics is an approach that enables multivariate profiling of the integrated metabolic responses of complex systems to patho-physiological stress, and so involves understanding the way the whole metabolic regulatory system varies with interventions thus providing complementary information to genomics and proteomics. Mammalian biochemistry is strongly influenced by the host karyome (genome) and gut microbiome symbionts that can alter drug metabolism and toxicity; the study of these transgenomic interactions is termed "global systems biology". Because these interactions are mediated by a large number of co-metabolic processes the system state integrity can be evaluated via metabolic profiling of biofluids. With the growing desire to apply systems biology tools to understanding human disease processes at the population level where massive cohorts need to be investigated, it is necessary to use analytical and statistical methods that report on *whole system state* non-invasively, hence the attraction of biofluid analyses described here.

NMR spectroscopy and chromatographic linked MS methods have been applied to characterize and quantify a wide range of metabolites in biological fluids and tissues to explore the biochemical consequences of drug-induced toxicity and human disease. In disease or toxicity states metabolic profiles and NMR and mass spectra are changed characteristically in different toxicity or disease conditions according to the exact site and mechanism of the lesion. The use of chemometrics allows interrogation of spectroscopic data and can give direct diagnostic information and aid the detection of novel biomarkers of disease and the integration of metabolic data with other omics sets. Such diagnostics can be extremely sensitive for the detection of low level damage in a variety of organ systems and is potentially a powerful new adjunct to conventional procedures for disease assessment and can help explain environment-gene interactions that give rise to idiosyncratic toxicity of drugs in man. Examples of the application of metabonomics to personalised healthcare (1) and population screening to detect new "Metabolome-Wide Associations" with disease risk factors (2).

PL1.2

Cell competition, apoptosis and tumour progression in *Drosophila*

G. Morata;

Centro de Biología Molecular Severo Ochoa, CSIC-UAM - Campus de Cantoblanco, Madrid, Spain.

Larvae homozygous for mutations at the tumour suppressor genes of *Drosophila* lethal giant larvae (lgl), scribble (scribb) or disc large (dlg) develop extensive neoplastic tumours that affect principally the central nervous system and the imaginal discs. Thus the lack of any of these products is sufficient to transform normal imaginal cells into tumorous cells. However, imaginal cells mutant for any of these genes are unable to develop a tumour if they are surrounded by non-tumour cells. We have been studying the behaviour of clones of lgl mutant cells in the wing disc to study the interactions between tumour and non-tumour cells. We find that as a rule lgl clones are eliminated from the wing disc by a process akin to cell competition: they enter apoptosis mediated by the JNK pathway and the interactions leading to the disappearance of the mutant cells take place at the border of the clones. We have also found that when these cells contain an additional factor conferring a high proliferation rate, the lgl mutant cells are transformed into "supercompetitors", which are able to eliminate surrounding non-

tumour cells and give rise to invasive neoplastic tumours that colonise the entire disc

PL1.3

Human evolution: palaeontology and ancient DNA

J. L. Arzuaga;

Centro de evolución y comportamientos humanos, Instituto de salud de la Universidad Carlos III, Madrid, Spain.

PL2.1

Mutations in the pericentrin (PCNT) gene cause primordial dwarfism

A. Rauch¹, C. T. Thiel¹, U. Wick¹, Y. J. Crow², D. Schindler³, A. Ekici¹, C. Zweier¹, A. J. van Essen⁴, T. O. Goecke⁵, L. Al-Gazal⁶, K. H. Chrzanowska⁷, H. G. Brunner⁸, K. Becker⁹, C. J. Curry¹⁰, B. The growth of an individual grossly depends on regulation of cell size and cell division and dysfunction of the pathways involved not only results in somatic undergrowth but contributes to a wide variety of pathological conditions.

Using positional cloning, we found in a total of 25 patients that biallelic loss-of-function mutations in the pericentrin (*PCNT*) gene cause microcephalic osteodysplastic primordial dwarfism type Majewski II (MOPD II, MIM 210720). Adults with this rare inherited condition belong to the shortest of the short having a height of about 100 centimeters and a brain size comparable to that of a three-month old baby, but are of near-normal intelligence. Truncal obesity, type 2 diabetes and a high risk of stroke have been noted in older individuals with MOPD II.

PCNT is known to mediate nucleation of microtubules by anchoring the γ -tubulin ring complex, thus initiating the assembly of the mitotic spindle apparatus. We show that PCNT mutations cause absence of the protein resulting in disorganized mitotic spindles, premature sister chromatid separation and missegregation of chromosomes in patient cells. Our findings thus characterize MOPD II as a distinct clinical entity linking a key protein of the centrosome to dwarfism and a high risk of diabetes and stroke.

Similarities between MOPD II individuals and the Late Pleistocene hominid fossils from the island of Flores, Indonesia, also known as "hobbits", suggest that these do not represent a diminutive, small-brained new species, *Homo floresiensis*, but are pathological modern humans.

Rauch et al. 2008, *Science* Feb 8, 319:816-9.

PL2.2

Meta-analysis of genome-wide association data and large-scale replication identifies several additional susceptibility loci for type 2 diabetes

E. Zeggini¹, R. Saxena², L. J. Scott³, B. F. Voight⁴, for the DIAGRAM Consortium;

¹University of Oxford, Oxford, United Kingdom, ²Harvard and Massachusetts Institute of Technology, Cambridge, MA, United States, ³University of Michigan, Ann Arbor, MI, United States.

Genome-wide association (GWA) studies have identified multiple new loci at which common variants modestly but reproducibly contribute to risk of type 2 diabetes (T2D). However, established variants, common and rare, explain only a small proportion of the heritability of T2D. To increase the power to discover alleles of modest effect, we performed

meta-analysis of three T2D GWA scans (DGI, FUSION, WTCCC) encompassing 10,128 European-descent individuals (4549 cases and 5579 controls) and ~2.2 million SNPs (directly genotyped and imputed). Even after excluding known type 2 diabetes loci, we saw a strong enrichment of highly associated variants (426 with $p < 10^{-4}$ vs. 217 expected by chance). Sixty nine SNPs were taken forward to an initial round of replication in up to 22,426 individuals, and 11 SNPs with replication $p < 0.005$ were tested in additional individuals from the deCODE, KORA, Danish and HUNT T2D studies with an effective sample size of up to 18,066. Multiple new loci with strong evidence for association were observed, including the *JAZF1* (OR[95%CI]: 1.11[1.08-1.14], $p = 8.8 \times 10^{-12}$), *CDC123/CAMK1D* (OR1.10[1.07-1.14], $p = 5.6 \times 10^{-9}$), *ADAMTS9* (OR1.10[1.07-1.14], $p = 9.5 \times 10^{-9}$), and *THADA* (OR 1.17[1.11-1.23], $p = 4.5 \times 10^{-8}$) gene regions. These loci provide additional biological clues about the inherited basis of T2D, and the relatively small effects point to the need for large discovery and follow-up samples.

PL2.3

G protein-coupled receptor P2Y5 and its ligand LPA are involved in maintenance of human hair growth

S. M. Pasternack¹, I. von Kügelgen², K. Al Aboud³, Y. Lee^{4,5}, F. Rüschemeyer⁶, K. Voss⁶, A. M. Hillmer⁷, G. J. Molderings⁸, T. Franz⁹, A. Ramirez^{2,10}, P. Nürnberg^{10,11}, M. M. Nöthen^{1,7}, R. C. Betz¹;

¹Institute of Human Genetics, Bonn, Germany, ²Department of Pharmacology, Bonn, Germany, ³Department of Dermatology, Makkah, Saudi Arabia, ⁴Department of Pediatric Pneumology and Immunology, Berlin, Germany, ⁵Max Delbrück Center for Molecular Medicine, Berlin, Germany, ⁶Department of Human Genetics, Würzburg, Germany, ⁷Department of Genomics, Bonn, Germany, ⁸Department of Anatomy, Bonn, Germany, ⁹Institute of Human Genetics, Cologne, Germany, ¹⁰Center for Molecular Medicine Cologne, Cologne, Germany, ¹¹Cologne Center for Genomics, Cologne, Germany.

Hypotrichosis simplex (MIM 146520 and MIM 605389) is a group of hereditary non-syndromic human alopecias that affects men and women equally. The hair loss is diffuse and progressive, and usually begins in early childhood. We mapped an autosomal recessive form of this disorder to chromosome 13q14.11-13q21.33, and identified homozygous truncating mutations in *P2RY5*, a gene which encodes an orphan G protein-coupled receptor. We analysed expression-patterns of *P2RY5* in various human and mouse tissues and performed western blot and immunofluorescence analyses to characterize the protein. Furthermore, we identified oleoyl-L- α -lysophosphatidic acid (LPA), a bioactive lipid, as being a ligand for P2Y5 in reporter gene and radioligand binding experiments. Homology and studies of signalling transduction pathways suggest that P2Y5 is a member of a subgroup of LPA receptors, which also includes LPA4 and LPA5. As *P2RY5* is expressed in human hair follicle cells, but LPA4 and LPA5 are not, a loss of P2Y5 function will not be compensated for, and will ultimately lead to pathological changes and hair loss.

Our study is the first to implicate a G protein-coupled receptor as being essential for and specific to the maintenance of human hair growth. With the functional characterization of the P2Y5 receptor, we identify the missing link which is required for the transmission of the LPA signal through the cell membrane in hair follicle cells. This finding may provide opportunities for new therapeutic approaches to the treatment of hair loss in humans.

PL2.4

X-linked protocadherin 19 mutations cause female-limited epilepsy and cognitive impairment

J. Gecz^{1,2}, L. Dibbens¹, P. Tarpey³, K. Hynes¹, M. A. Bayly¹, I. E. Scheffer⁴, J. Boma⁵, L. Vandeleur¹, C. Shoubridge¹, Z. Afaw⁶, M. Y. Neufeld⁶, S. Kivity⁷, D. Lev⁸, T. Lerman-Sagie⁹, G. R. Hospital, Belfast, United Kingdom.

EFMR (Epilepsy and Mental Retardation limited to Females) is a disorder with an X-linked mode of inheritance and unusual expression pattern. Disorders arising from mutations on the X chromosome are typically characterized by affected males and unaffected carrier females. In contrast, EFMR spares transmitting males and affects only carrier females. Unraveling the biology of this conundrum depends upon the identification of the molecular defect underlying EFMR. Aided by systematic re-sequencing of 737 X chromosome genes we identified different protocadherin 19 (*PCDH19*) gene mutations in seven families. Five mutations result in the introduction of a premature termination codon. Study of two of these demonstrated nonsense mediated decay of *PCDH19* mRNA. The two missense mutations are predicted to affect adhesiveness of PCDH19 through impaired calcium binding. *PCDH19* is expressed in human and mouse developing brain and is the first member of the cadherin superfamily to be directly implicated in epilepsy or mental retardation. To explain the reversed, sex-limited expression pattern for EFMR, we propose rescue in males by a human specific Y chromosome gene protocadherin 11Y (*PCDH11Y*).

PL2.5

Genomic structural variation profiles of world human populations

L. Bassaganyas^{1,2,3}, M. Garcia^{1,3}, M. Montfort^{1,4,3}, L. Armengol^{1,3}, X. Estivill^{1,4,3};

¹Center for Genomic Regulation (CRG), Barcelona, Catalonia, Spain, ²Pompeu Fabra University (UPF), Barcelona, Catalonia, Spain, ³Public Health and Epidemiology Network Biomedical Research Center (CIBERESP), Barcelona, Catalonia, Spain, ⁴National Genotyping Center (CeGen), Barcelona, Catalonia, Spain. Genomic variants can contribute to genetic disease, and are potential substrates for natural selection resulting in phenotypic differences between individuals. The use of genome-wide molecular methods have revealed the existence of Copy Number Variants (CNVs), genomic segments ranging in size from one kb to several megabases, that are present at variable copy number in comparison with a reference genome. The aim of our study was to determine the existence of population-specific genomic structural variation and to identify genes located in these regions that might contribute to phenotypic differences as well as to differential susceptibility to common disease and environmental exposures of human populations. We have selected 343 individuals from 11 populations from the HGDP-CEPH panel (Biaka- Mbuti Pygmy, Bantu, Mozabite, Bedouin, Brahui, Hazara, Yakut, Papuan-Melanesian, French, Pima and Maya) and 134 individuals from the three populations of the HapMap collection (YRI, CHB and CEU). To detect structural variation we have used array-CGH (Agilent 244K) and array-based comparative genome intensity (Illumina). We have observed differences between populations in 179 loci. 122 of these were already described in the Database of Genomic Variants and 58 coincide with segmental duplications. Interestingly, a number of genes involved in different common disorders or to have phenotypic differences between population groups were found to be variable in copy number among human populations (i.e. RHD, CFHR1, CFHR3 and PRSS1). These loci and others could explain differences in disease predisposition among individuals from different populations and could provide important clues on the adaptation of humans to different environments.

PL2.6

Acetylcholine receptor pathway mutations explain various fetal akinesia deformation sequence disorders

A. Michalk¹, S. Stricker², J. Becker³, R. Rupps⁴, T. Pantzar⁵, J. Miertus⁶, G. Botta⁷, V. G. Naretto⁸, C. Janetzki¹, N. Yaqoob⁹, C. Ott¹, D. Seelow¹, D. Wiczorek¹⁰, B. Fiebig¹¹, B. Wirth³, M. Hoopmann¹², M. Walther¹³, F. Koerber¹⁴, M. Blankenburg¹⁵, S. Mundlos^{1,2}, R. Heller³, K. Hoffmann^{1,2};

¹Charite University Medicine, Berlin, Germany, ²MPI Molecular Genetics, Berlin, Germany, ³Institute of Human Genetics, University Hospital, Cologne, Germany, ⁴Departments of Medical Genetics and Pathology, BCCH Children's Hospital, Vancouver, BC, Canada, ⁵Charite University Medicine Departments of Medical Genetics and Pathology, BCCH Children's Hospital, Vancouver, BC, Canada,

⁶Medical Genetics Dept., St. Elizabeth Cancer Institute, Bratislava, Slovakia, ⁷Azienda Ospedaliera San Giovanni Battista, Torino, Italy, ⁸Dept. of Pathology, „OIRM-S.Anna“ Hospital, Torino, Italy, ⁹Consultant Histopathologist, King Abdul Aziz Specialist Hospital, Taif, Saudi Arabia, ¹⁰Institute of Human Genetics, University of Duisburg-Essen, Essen, Germany, ¹¹Centre for Human Genetics, University hospital, Regensburg, Germany, ¹²Prenatal Medicine, Department of Gynecology and Obstetrics, University Hospital, Cologne, Germany, ¹³Medical Centre of Rheumatology, Berlin-Buch, Germany, ¹⁴Department of Paediatric Radiology, University Hospital, Cologne, Germany, ¹⁵Department of Neuro-pediatrics, Vestische Kinder- und Jugendklinik, University of Witten/Herdecke, Datteln, Germany.

Impaired fetal movement causes growth retardation, fetal hydrops, polyhydramnios, pulmonary hypoplasia, multiple joint contractures with or without webbing (pterygia), and other features, summarized under the term fetal akinesia deformation sequence (FADS).

We sequenced 75 patients with severe FADS and found mutations in the γ , α 1 and δ subunit of the AChR as well as in the receptor associated protein of the synapse, rapsyn.

Our major conclusions are that

- FADS is a frequent genetic condition.
- Doctors in pre- and neonatal care are often confronted with FADS but are not as aware of possible involvement of AChR pathway mutations as a neurologist would be.
- More awareness of the potential involvement of the AChR pathway will save the lives of some newborns.

Our findings are important to the understanding of cellular biology, genetics and clinical relevance of AChR mutations especially in pre- and neonatal care. Early neonatal diagnosis in one of our families helped to start effective treatment for the second affected child, whereas the first affected - undiagnosed - died in infancy. One major conclusion is that the inclusion of clinical and molecular data from prenatally deceased siblings is crucial to elucidate severe phenotypes of AChR pathway mutations.

We suggest that the AChR pathway contributes to a broad spectrum of intrauterine phenotypes and should be examined functionally and genetically in patients with recurrent spontaneous abortions, fetal akinesia, hydrops, pterygia, or inborn contractures.

PL2.7

Plastin 3 protects against spinal muscular atrophy (SMA) - the first report of a fully protective modifier of a Mendelian disease

Brunhilde Wirth^{1,2,3}, Sandra Kröber^{1,2}, Michelle L. McWhorter⁴, Wilfried Ros-solf⁵, Stefan Müller⁶, Michael Krawczak⁶, Gary J. Bassell⁶, Christine E. Beattie⁴, and Gabriela E. Oprea^{1,2,3};

¹Institute of Human Genetics, University Hospital, Cologne, Germany, ²Institute of Genetics and ³Center for Molecular Medicine Cologne, University of Cologne, Cologne, Germany, ⁴Centre for Molecular Neurobiology, The Ohio State University, Columbus, OH, USA, ⁵Emory University School of Medicine, Department of Cell Biology, Atlanta, GA, USA, ⁶Institute of Medical Informatics and Statistics, Christian-Albrechts University of Kiel, Kiel, Germany.

Homozygous deletion of *SMN1* leads to spinal muscular atrophy (SMA), the most frequent genetic cause of early childhood lethality. In rare instances, however, individuals carrying the same *SMN1* mutations as their affected siblings are found to be fully asymptomatic, thereby suggesting the action of modifier genes. By comparing the transcriptomes of lymphoblastoid cell lines from unaffected and affected *SMN1*-deleted siblings, we identified plastin 3 (*PLS3*, localized on Xq23) to be abundant in unaffected, but not affected counterparts. We showed that *PLS3* expression in blood is rare, occurring in only 5% of controls. Interestingly all eight unaffected *SMN1*-deleted individuals were female. Despite extensive research, the molecular cause for this gender-specific protective effect still remains unknown. We found that *PLS3* is highly expressed in spinal cord, associates with *SMN*, and that both proteins are part of a large multi-protein complex in spinal cord. Both *PLS3* and *SMN* are present at similar subcellular locations in primary motor neurons and increase in expression during neuronal differentiation. As an actin bundling protein, *PLS3* influences the F-actin level known to be important for axonal outgrowth and guidance. *PLS3* knock-down in neuronal differentiated PC12 cells severely affects axonal growth whereas *PLS3* over-expression induces axonal growth. Most importantly, over-expression of *PLS3* rescues the axonal growth defect caused by reduced *SMN* levels in neuronal differentiated PC12 cells, in primary motor neurons of SMA mouse embryos

and in an *in vivo* zebrafish SMA-model. Our data strongly support the view that the involvement of *SMN* in axonal outgrowth and pathfinding is the major pathogenic defect in SMA. The discovery of *PLS3* as a protector against SMA provides the opportunity to identify novel regulatory mechanisms that may act specifically in motor neurons, and which may be useful for understanding the molecular pathogenesis of other motor neuron diseases as well. The results may also help to identify novel targets for SMA therapy. Our discovery signifies a major breakthrough in medical genetics and represents the first report ever of a fully protective modifier for a Mendelian disorder in humans.

PL3.1

Systematic resequencing of the coding exons of the X chromosome in X-linked Mental Retardation

M. Stratton;

Cancer Genome Project, Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Mental retardation (MR) affects 1-3% live births and has both genetic and non-genetic causes. A proportion of cases with genetic abnormalities are attributable to mutations of genes on the X chromosome. Although several X-linked MR (XLMR) genes have been reported, identification of more by conventional approaches is problematic because mutations of many genes cause MR and their associated phenotypes are similar. Here, we have implemented a new strategy in which the coding exons of X chromosome genes (~1Mb DNA per sample) have been systematically resequenced for disease-causing variants in individuals from more than 200 XLMR families. The strategy has yielded several new XLMR genes. However, many families remain to be explained. The study also indicates that loss of function of ~1% of X-genes is compatible with apparently normal existence. To our knowledge, this is the largest resequencing study to identify human disease genes thus far conducted. The results highlight issues that will be faced in the future by whole genome screens for rare disease-causing variants.

PL3.2

Cap-Analysis Gene Expression (CAGE) analysis of transcriptional complexity and regulation

P. Carninci, Y. Hayashizaki;

Functional Genomics Technology Team, Omics Science Center, Omics Science Center, Yokohama, Kanagawa, Japan.

The genome sequence is an invaluable resource, yet it is still hard to identify all its encoded RNAs and regulatory regions. Despite there are about 20,000 protein coding genes, 63% to 93% of the mammalian genomes is expressed, mainly producing non-coding RNAs, starting from more than 230,000 core promoters. These are identified with CAGE (cap-analysis gene expression), resulting in a finely redefinition of the promoter structure.

The development of novel generation of sequencing instruments allows addressing the RNA complexity at a much higher definition. We are using multiple platforms (454 Life Science, Illumina/Solexa and ABI-SOLiD sequencers) to produce hundreds of millions of functional sequencing tags, with particular focus on CAGE and short RNA libraries. Sequencing of deep-CAGE libraries, which contain 1 to more than 10 millions tags, produces much detailed and sensitive data than microarrays at a progressively decreasing cost. We are broadening the CAGE applications to the ENCODE project and have also miniaturized the protocol, to work with RNA extracted from less than 1000 cells (neurons).

CAGE analysis allows correlating promoter elements to transcriptional control, as demonstrated by reconstructing the transcriptional network of differentiation of THP-1, a human myeloid leukemia cell in the Fantom 4 project in an integrated approach. We provide the first description of the dynamics and architecture of a human transcriptional network undergoing transition from a proliferating to a differentiated state

PL3.2

High-throughput SNP genotyping and ultra-high-throughput sequencing for genome-wide association studies

I. G. Gut;

CEA - Institut de Genomique, Centre National de Genotypage, Evry, France.

In the course of the last 2 years the Centre National de Genotypage (CNG) has run numerous genome-wide association (GWA) studies us-

ing its high throughput genotyping platforms. We have widely applied different formats of Illumina Infinium and Affymetrix arrays. The CNG genotyping platforms are embedded in a system of highly standardized DNA handling and QC, LIMS, data QC, statistical analysis and OPERON, a bioinformatic knowledge database. Our studies have delivered many striking results, such as ORMDL3, a strong candidate gene associated with childhood asthma, PTGER4 a candidate gene associated with Crohn's disease, BCL11A a strong candidate gene associated with sickle cell disease and β -thalassemia, and others. The identification of associated genes was accelerated by a database of genome-wide association of global gene expression. Recently we managed to identify an intriguing group of genes that constitute subunits of a nicotinic acetylcholine receptor on 15q25 associated with lung cancer susceptibility.

To gain better understanding of the regions of the genome that show association with a phenotype we are currently using a 2nd generation DNA sequencing platform based on Illumina Genome Analyzers. We have adapted efficient methods for the enrichment of regions of interest. The 2nd generation DNA sequencing methodology is well suited for the analysis of DNA samples enriched for particular genomic regions of interest. Due to the technical limitations of these technologies, their application for capturing structural variation such as short range length polymorphisms (microsatellites and minisatellites), duplications and inversion requires work arounds. We believe that a further paradigm shift to a 3rd generation of DNA sequencing technology will be required for cost-effective whole genome sequencing. This technology will have to be able to analyze clonal DNA molecules over long distances (5 - 30 kb). The European Community is funding an effort to develop such a technology through its FP7 programme READNA.

PL4.1

Distinguished Speaker Lecture: Systems Biology and Systems Medicine

L. Hood;

President, Institute for Systems Biology, Seattle, WA, United States.

The grand challenge for biology and medicine in the 21st century is complexity. A currently emerging paradigm change is the idea that

biology is an informational science and that most biological information is mediated by dynamical biological networks. The systems approach to biology and medicine is a general category of approaches that appear to be very effective in dealing both with biological circuits and hence with biological complexity. Systems approaches require a truly cross-disciplinary environment and the effective integration of biology, technology and computation/mathematics. I will discuss my views of systems biology. Then I will discuss a systems approach to one disease, prion disease in mice, and demonstrate how it profoundly alters our views of disease with regard to understanding disease pathophysiology as well as new approaches to diagnosis, therapy and eventually prevention. Then I will talk about the emerging measurement technologies that are the foundation of P4 medicine, as well as some of the pioneering computational and mathematical tools that will be necessary to usher in this revolution in medicine. The view of biology as an information science, the systems approach to disease, the new measurement and visualization technologies and the evolving mathematical/computation tools will catalyze this paradigm change in medicine. I will make five predictions: 1) our current largely reactive medicine will be transformed to a predictive, preventive, personalized and participatory (P4) medicine over the next 10 to 20 years, 2) this will lead to the digitalization of medicine (extracting information from single cells, single molecules and single individuals) with even more profound implications for society than the digitalization of communications and information technologies, 3) systems medicine and its digitalization will dramatically turn around the slope of ever increasing healthcare costs to the point that the developed world will be able to export its P4 medicine to the developing world, 4) P4 medicine will necessitate fundamental changes in the business plans of virtually every sector of the healthcare industry and 5) this new world of medicine will be propelled forward by carefully chosen strategic partnerships across all sectors of science_academia, industry, government laboratories, independent research institutes, etc_and that these partnerships will be international. ISB hopes to play an important role in catalyzing a series of these strategic partnerships.

ESHG CONCURRENT SYMPOSIA

S01.1

Dissection of structural variation in common human disease

X. Estivill;

Genes and Disease Program, Center for Genomic Regulation (CRG), Barcelona National Genotyping Center (CeGen), Public Health and Epidemiology Network Biomedical Research Center (CIBERESP), Pompeu Fabra University (UPF), Barcelona, Spain.

CNVs represent a new common source of genetic variability in individuals (recognized by Science as the breakthrough of 2007), which might constitute susceptibility factors for the onset, progress and severity of complex diseases. CNVs could directly affect the dose of certain genes or modify loci that regulate the expression of relevant genes, therefore providing important clues for disease and phenotype variability. We are using and implementing multiple technologies to further analyze CNVs potentially involved in several complex disorders, mainly psychiatric diseases, neurodegenerative diseases and inflammatory disorders. Functional validation of CNVs with respect to disease needs: a/ verification that the genomic variants are associated to changes in the expression of a gene product at the mRNA and protein levels; and b/ characterization of the physiological consequences associated to changes in the dose of a gene, which might contribute to specific traits of the disease. We have identified several genomic regions that contain CNVs that are common in the population and that could have an enormous impact in disease predisposition. We have preliminary results on the identification of CNVs for several neurological, neuropsychiatric and inflammatory disorders, and we are characterizing such genomic regions and performing genome scans to uncover the variability landscape of these disorders.

S01.2

Gene copy number variation and common human disease

T. J. Aitman;

Physiological Genomics and Medicine Group, MRC Clinical Sciences Centre and Imperial College, London, United Kingdom.

Gene copy number variation is now well recognised as a source of sequence variation in the genome of humans and other mammals. During positional cloning studies to identify genes for insulin resistance and autoimmune glomerulonephritis in the rat, we showed that gene copy number variants, at the *Cd36* and *Fcgr3* gene loci respectively, contributed to disease susceptibility in the rat model. In humans, we went on to show that low copy number of *FCGR3B*, an orthologue of rat *Fcgr3*, was associated with glomerulonephritis in the autoimmune disease systemic lupus erythematosus (SLE). More recently we found that low *FCGR3B* copy number predisposes to development of SLE itself and to development of the systemic autoimmune diseases microscopic polyangiitis and Wegener's granulomatosis. These studies provide direct evidence for the importance of heritable variation in gene copy number in the evolution of genetically complex phenotypes, including susceptibility to a range of common human diseases.

S01.3

Beta-defensin copy number variation: measurement, diversification and association with psoriasis

J. A. L. Armour;

Institute of Genetics, Nottingham, United Kingdom.

In the current excitement surrounding the recent discoveries from case-control association studies, it is essential to avoid overenthusiastic interpretation of error-prone data. Although this is still an important consideration for SNP typing, it is of particular concern in assessing the role of copy number variation, for which the development of typing technology satisfactory for case-control association studies is still in its early stages. I will address the importance of accuracy (as well as throughput) in measuring copy number, with reference to our own PRT methods applied to beta-defensin variation on 8p23.1. This copy number variation involves a cluster of seven defensin genes, presumed to act as antimicrobials, but which may have a wider spectrum of functions; copy number variation is commonly over the range between 2 and 7 copies per diploid genome. The accuracy of the typing methodology has been essential in discovering an association between beta-defensin copy number and psoriasis, as well as in revealing an unexpected and highly unusual mechanism for generating variation in the copy number of these genes.

S02.1

Mutation specific therapy: The CF experience

E. Kerem;

Hadassah University Hospital, Jerusalem, Israel.

CFTR mutations cause defects of CFTR protein production and function by different molecular mechanisms. The mutations can be classified according to the mechanisms by which mutations disrupt CFTR function. This understanding of the different molecular mechanism of CFTR dysfunction provides the scientific basis for development of targeted drugs for mutation specific therapy of CF. Class I mutations are nonsense mutations that result in the presence of premature stop codon that leads to the production of unstable mRNA or the production of a short truncated protein that is not functional. Drugs such as the aminoglycoside antibiotics and PTC124 can suppress premature termination codons by disrupting translational fidelity and allowing the incorporation of an amino acid, thus permitting translation to continue to the normal termination of the transcript. Class II mutations cause impairment of CFTR processing and folding in the Golgi. As a result the mutant CFTR is retained in the ER and eventually targeted for degradation by the quality control mechanisms. Chemical and molecular chaperons can stabilize protein structure, and allow it to escape from degradation in the ER and be transported to the cell membrane. Class III mutations disrupt the function of the regulatory domain. CFTR is resistant to phosphorylation or ATP binding. CFTR activators can overcome the affected ATP binding through direct binding to a nucleotide binding fold. In patients carrying class IV mutations, phosphorylation of CFTR results in reduced chloride transport. Increases in the overall cell surface content of these mutants might overcome the relative reduction in conductance. Activators of CFTR at the plasma membrane may function by promoting CFTR phosphorylation, by blocking CFTR dephosphorylation, by interacting directly with CFTR, and/or by modulation of CFTR protein-protein interactions. Class V mutations affect the splicing machinery and generate both aberrantly and correctly spliced transcripts, the level of which vary among different patients and among different organs of the same patient. Splicing factors that promote exon inclusion or factors that promote exon skipping can promote increase of correctly spliced transcripts, depending on the molecular defect. Inconsistent results were reported regarding the required level of corrected or mutated CFTR that has to be reached in order to achieve normal function.

S02.2

Synthetic lethal approaches to the development of new therapies for cancer

A. Ashworth;

Breakthrough Breast Cancer Research Centre, The Institute of Cancer Research, London, United Kingdom.

About one in nine women in the Western world develop cancer of the breast and at least 5% of these cases are thought to result from a hereditary predisposition to the disease. Two breast cancer susceptibility (*BRCA*) genes have been identified and mutations in these genes account for most families with four or more cases of breast cancer diagnosed before the age of 60. Women who inherit loss-of-function mutations in either of these genes have an up to 85% risk of breast cancer by age 70. As well as breast cancer, carriers of mutations in *BRCA1* and *BRCA2* are at elevated risk of cancer of the ovary, prostate and pancreas. The genes are thought to be tumour suppressor genes as the wild-type allele of the gene is observed to be lost in tumours of heterozygous carriers. Both *BRCA1* and *BRCA2* have significant roles in the maintenance of genome integrity via roles in the repair of DNA damage via homologous recombination. The specific DNA repair defect in *BRCA*-mutant cells provides opportunities for novel therapeutic approaches based on selective inhibition of functionally interacting repair pathways, in particular by inhibition of the enzyme PARP. Here I will describe recent work defining determinants of sensitivity and resistance to PARP inhibitors, as well as the application of the synthetic lethal approach to other cancer types.

S02.3**Small-molecule therapy for Cystic Fibrosis****A. S. Verkman;***Departments of Medicine and Physiology, University of California, San Francisco, San Francisco, CA, United States.*

The Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) is a cAMP-activated chloride channel expressed in epithelia in the lung, intestine, pancreas, testis and other tissues, where it facilitates transepithelial fluid transport. In the intestine CFTR provides the major route for chloride secretion in certain diarrheas. Mutations in CFTR cause the hereditary disease cystic fibrosis, where chronic lung infection and deterioration in lung function cause early death. CFTR is a well-validated targeted for development of inhibitors for therapy of secretory diarrheas and polycystic kidney disease, and activators for therapy in cystic fibrosis. Our lab has identified and optimized small molecule inhibitors of CFTR, as well as activators of deltaF508-CFTR, the most common mutant CFTR causing cystic fibrosis. High-throughput screening of small molecule collections utilizing a cell-based fluorescence assay of halide transport yielded thiazolidinone and glycine hydrazide CFTR inhibitors that block enterotoxin-mediated secretory diarrhea in rodent models, including a class of non-absorbable inhibitors that target the CFTR pore at its external entrance. Nanomolar-potency benzothiophene, phenylglycine and sulfonamide potentiators were identified that correct the defective gating of deltaF508-CFTR chloride channels, restoring their function to that of wildtype CFTR. Several classes of correctors of defective deltaF508-CFTR cellular misprocessing were discovered, including bisaminomethylthiazoles, that improve mutant CFTR folding and facilitate its stability and targeting to the cell plasma membrane, restoring cAMP-stimulated chloride permeability. Small-molecule modulators of CFTR function are in development for the treatment of cystic fibrosis, secretory diarrhea and polycystic kidney disease.

S03.1**Is the era of genetic counseling over?****S. Kessler;***Department of Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA.***S03.2****Medical genetic services in developing nations****A. Christianson;***Division of Human Genetics, National Health Laboratory Services & University of the Witwatersrand, Johannesburg, South Africa.*

An expert advisory group of the WHO recognized in the early 1980's that health (epidemiological) transition would require developing countries, within the foreseeable future to develop medical genetic services. To that end the expert advisory group developed an approach cogent for developing nations that focused on community based medical genetic services integrated into primary health care and closely linked to secondary and tertiary health care services.

In the latter half of the last century these approaches were refined, to an extent based on services that were being established in a few developing countries. This decade several middle-income nations have recognized the need to develop medical genetic services, initially for the care and prevention of birth defects. Following the approach proposed by the WHO these nations are developing medical genetic services, some with assistance from the March of Dimes and the World Alliance of Organizations for Prevention and Treatment of Genetic and Congenital Conditions (WAO). Numerous barriers to the establishment of these services still exist, but are being overcome.

S03.3**Personalized Medicine and Genetic Services: The US Model****M. Aspinall;***Genzyme Corporation, Westborough, MA, United States.*

A revolution is underway in the life sciences and health care industry. Fueled by the mapping of the human genome and a deepening understanding of human genetic variation and ongoing advances in diagnostics are expanding our understanding of the molecular basis of disease. Health care delivery is beginning to shift from trial-and-error medicine to patient-centric medicine. Patient care is becoming focused on highly targeted and individualized diagnostic and treatment regimens. The use of genetic services is expanding in all areas. This revolution is known as personalized medicine.

Personalized medicine is a movement away from defining diseases by their symptoms and locations within the body, and toward understanding them through their underlying genetic causes. With a successful transition to this model, more specific disease diagnoses will occur, resulting in a personalized treatment plan for individual patients. Costs will be reduced through more accurate diagnosis, improved drug efficacy with fewer adverse drug reactions as well as improved patient drug compliance. This trend to personalized medicine and increased use of genetic services is occurring today in the field of oncology and will expand to all areas of medicine.

The field of genetics services - both testing and counseling - is essential to the implementation of personalized medicine. Without these services, physicians and other healthcare providers will not be able to access the information necessary to make the most informed choices for patients.

Personalized medicine, however, must overcome multiple challenges if it is to be fully adopted. There are significant challenges involving physician and patient education and acceptance. An expanded understanding of genetics and diagnostics and its impact on patient care will be necessary for all healthcare providers. A health information infrastructure must be able to accommodate the accumulation and analysis of expanding patient and pharmacogenomic data.

In this talk, I will review the current status of personalized medicine in the United States including examples of its current impact on patient care. I will also describe the current United States diagnostic market including the current distribution systems and infrastructure design.

S03.4**The Clinical Use of Genetic and Molecular Biomarkers: A Public Health Perspective****R. Zimmern;***PHG Foundation Cambridge, Strangeways Research Laboratory, Cambridge, United Kingdom.*

Advances in genomic science have led to a much greater knowledge of disease mechanisms and the development of novel technologies such as genetic tests and molecular biomarkers. Unlike the well-trodden pathway that exists for pharmaceutical products, we do not have within Europe (or anywhere across the developed world) an effective framework for their clinical evaluation. The absence of mechanisms for generating the necessary data, or of institutions that focus on their analysis, and the lack of policy about the respective responsibilities or the public and commercial sectors for their establishment and funding are major concerns for the practice of medicine and for public health.

The lecture will argue that an approach to the introduction of tests into clinical practice based on clinical judgement is longer sustainable. The complexities of modern diagnostics will require a more formal and innovative approach. Tests will require explicit evaluation to identify the clinically valid and useful. Biomarkers that are predictive of complex disease before its development, in contrast to diagnostic or prognostic markers or to genetic tests for high penetrance single gene disorders, pose a particular challenge. The low relative risks that these show, and the fact that each individual biomarker will be neither necessary nor sufficient for the development of disease suggests that a different approach to their assessment will be needed.

S04.1

microRNA Regulation of Cardiac Development and Disease

D. Srivastava;

Gladstone Institute of Cardiovascular Disease, UCSF – Dep. of Pediatrics and Biochemistry & Biophysics, San Francisco, CA, United States.

Gradients of signaling and transcription factors result in distinct cellular responses during organ formation suggesting that the precise dose of major regulatory proteins must be tightly controlled. MicroRNAs (miRNAs) are phylogenetically conserved small RNAs that regulate translation or stability of target messenger RNAs providing a mechanism for protein dose regulation. Studies in our lab of multiple cardiac-enriched miRNAs reveal that they coordinate decisions of cellular proliferation, differentiation and response to stress via intricate transcriptional and translational networks. In addition to our previous work demonstrating the role of miR-1 in differentiation of mouse and fly cardiac progenitors, we found that targeted deletion of miR-1-2 in mouse causes defects in cardiac morphogenesis as well as cardiac conduction and cell cycle abnormalities. Consistent with this finding, manipulation of miR-1 and the co-transcribed miR-133 in mouse and human embryonic stem cells revealed that these miRNAs can be used to guide pluripotent stem cells into mesodermal cells and ultimately into the cardiac lineage, while repressing neuroectodermal and endodermal differentiation. Finally, novel approaches of miRNA target identification to explain the mechanisms underlying the described effects of cardiac miRNAs will be discussed.

S04.2

A rapidly evolved RNA gene may have played a role in the evolution of the cerebral cortex

D. Haussler;

Center for Biomolecular Science & Engineering, University of California, Santa Cruz, CA, United States.

We have scanned the human genome for segments that have been under negative selection during most of mammalian evolution, but experienced a burst of changes during the last few million years of human evolution. The most dramatic such segment occurs in a previously unstudied RNA gene expressed specifically in the Cajal-Retzius neurons in the developing cerebral cortex, during the time these neurons guide the development of the 6-layer cortical structure. Examples like this demonstrate the power of computational reconstruction of the evolution of the human genome, and argue that changes in non-coding functional regions may have played a significant role in the molecular events that forged our species.

S04.3

The RNAi strategy in Cancer: Towards the Achilles Heal of Cancer

R. L. Beijersbergen;

The Netherlands Cancer Institute, Division of Molecular Carcinogenesis and NKI Robotics and Screening Center, Amsterdam, Netherlands.

The development of the RNA interference (RNAi) technology has changed the way how we approach target discovery and validation in cancer research. The potential to study the consequence of the inactivation of each individual gene is a very effective tool to identify novel targets. In addition, high content imaging allows us to identify novel components of cellular pathways involved in complex cellular phenotypes in a high throughput manner. The combination of RNA interference and high content imaging will lead to the discovery of a new class of targets that can be used for development of novel cancer therapies or to improve existing therapies.

We have constructed a large set of retroviral vectors encoding more than 50,000 shRNAs, which target 15,000 different human or mouse genes for suppression. This RNA interference library has been used to identify genes involved in major cellular pathways such as the p53 tumor suppressor pathway. In particular we have focused on genes that modulate the cytotoxic response to small molecules that target the MDM2-p53 interaction. In addition we have developed novel screening methods with the use of shRNA libraries and DNA micro-arrays to be able to rapidly screen large numbers of shRNA vectors. This technology is applied to identify the mechanism of action of novel anti-cancer drugs and to identify genes involved in resistance to anti-cancer drugs.

Recently, we have extended our efforts into synthetic siRNA screens to

allow genome wide single well high throughput screening with the goal to study more complex phenotypes and, importantly, to identify targets that upon inhibition would only affect tumor cells where normal cells would remain unaffected. The concept that a particular mutation has deleterious consequences under specific conditions is known as synthetic lethality. Two genes are defined as synthetic lethal when cells die if they have both genes mutated but can survive if either gene alone is mutated. The approach of exploring synthetic lethal gene-gene interactions is attractive because it turns a hallmark of cancer cells, specific mutations, into a weakness that can be explored therapeutically. We explore the existence of synthetic lethal interactions with tumor specific genetic alterations and large scale siRNA screens.

These approaches illustrate the power of RNAi to gain insight in the mode of action of novel cancer drugs with the goal to accelerate their development and as a powerful way to identify a whole new class of more specific and more efficient anticancer drugs.

S05.1

Guidelines for the clinical management of Lynch syndrome and adenomatous polyposis

H. F. A. Vasen;

Department of Gastroenterology & Hepatology, Leiden University Medical Centre, Leiden, Netherlands.

The Lynch syndrome (LS)(HNPCC) is characterized by the development of colorectal cancer (CRC), endometrial cancer and various other cancers and is caused by a mutation in one of the mismatch repair (MMR) genes: *MLH1*, *MSH2*, *MSH6* or *PMS2*. Familial adenomatous polyposis (FAP) is a well-described inherited syndrome, characterized by the development of hundreds to thousands of adenomas in the colorectum. The syndrome is caused by mutations in the *APC*-gene or the *MUTYH*-gene. Both syndromes (LS, FAP) are responsible for at least 5-7 % of all cases of CRC. Since 2006, annual workshops were organized by a group of European experts in hereditary gastrointestinal cancer (the Mallorca group) aiming to establish guidelines for the clinical management of hereditary CRC syndromes. Thirty-one experts from nine European countries participated in these workshop. Prior to the meeting, various participants prepared the key management issues of debate according to the latest publications. A systematic literature search using Pubmed and the Cochrane Database of Systematic Reviews, reference lists of retrieved articles, and manual searches of relevant articles was performed. During the workshop all recommendations were discussed in detail. Part of the guidelines will be discussed. Moreover, the results of recent studies on cancer risk and experience of longterm surveillance for CRC in the Lynch syndrome will be presented.

Evaluation of breast and ovarian cancer screening programmes in BRCA1 and BRCA2 mutation carriers: the UK, Norwegian and Dutch experience

D. G. Evans¹, K. N. Gaarenstroom², D. Stirling³, A. Shenton¹, L. Maehle⁴, A. Dørum⁴, M. Steef⁵, F. Lalloo¹, J. Apold⁶, M. E. Porteous³, H. F. A. Vasen⁷, C. J. van Asperen⁸, P. Moller⁴;

¹Medical Genetics Research Group and Regional Genetics Service, University of Manchester and Central Manchester and Manchester Children's University Hospitals NHS Trust, St Mary's Hospital, Manchester, United Kingdom, ²Department of Gynaecology, Leiden University Medical Center, Leiden, Netherlands, ³South East of Scotland Genetics Service, Western General Hospital, Edinburgh, United Kingdom, ⁴Section for Inherited Cancer, Department of Medical Genetics, Rikshospitalet Radiumhospitalet Clinical Center, Oslo, Norway, ⁵University of St Andrews, Bute Medical Buildings, St Andrews, United Kingdom, ⁶Centre of Medical Genetics and Molecular Medicine, Haukeland University Hospital, and Institute of Clinical Medicine, University of Bergen, Bergen, Norway, ⁷The Netherlands Foundation for the Detection of Hereditary Tumours and the Department of Gastroenterology, Leiden University Medical Center, Leiden, Norway, ⁸Center for Human and Clinical Genetics, Department of Clinical Genetics,

Leiden University Medical Center, Leiden, Norway.

The management of the high risk of breast and ovarian cancer in female BRCA1/BRCA2 mutation carriers remains a vexing issue. In order to provide alternatives to risk reducing surgery, surveillance programmes have to detect the disease sufficiently early to provide a very high likelihood of cure. In particular there have been substantial doubts about the ability of routine annual mammography and ovarian ultrasound plus serum CA125 to meet this goal. Collaborative research between the UK, the Netherlands and Norway has enabled us to provide a more accurate assessment of the likelihood of cure within these programmes. Additionally the benefits of MRI screening for breast cancer have been demonstrated by National studies in each country.

To assess the effectiveness of annual ovarian cancer screening (transvaginal ultrasound and serum CA125 estimation) in reducing mortality from ovarian cancer in women at increased genetic risk. A cohort of 3532 women at increased risk of ovarian cancer was screened at five centres between January 1991 and March 2007. Survival from diagnosis of ovarian cancer was calculated using Kaplan-Meier analysis and compared for proven BRCA1/2 carriers with non-carriers and whether the cancer was detected at prevalence or post prevalent scan. Screening was performed by annual transvaginal ultrasound and serum CA125 measurement

64 epithelial ovarian malignancies (59 invasive and 5 borderline), developed in the cohort. 26 tumours were detected at prevalent round, there were 27 incident detected cancers and 11 interval. Sixty-five percent of cancers were stage 3 or 4, however, stage and survival were little different for prevalent versus post prevalent cancers. Five year and 10-year survival in 49 BRCA1/2 mutation carriers was 58.6% (95% CI 50.9-66.3%) and 36% (95% CI 27-45%), which was significantly worse than for 15 non BRCA-carriers (91.8% (95% CI 84-99.6%) both 5 and 10-year survival $p=0.015$). Annual surveillance, by trans-vaginal ultrasound scanning and serum CA125 measurement in women at increased familial risk of ovarian cancer is ineffective in detecting tumours at a sufficiently early stage to substantially influence survival in BRCA1/2 carriers.

A collaborative study between Norway and the UK has shown that survival in prospectively detected breast cancers in BRCA1 carriers in an annual mammography screening programme is significantly worse than for BRCA2 and other familial groups. It appears this may be due to relatively poor survival for small node negative cancers. Some of this poor survival may be attributable to the failure to treat these small tumours with chemotherapy. This is particularly relevant when assessing the benefits of MRI which in combination with mammography has >90% sensitivity at detecting breast cancers in an annual programme. The benefits of the combined approach for BRCA2 appear robust with survival likely to exceed 90% for breast cancers identified in surveillance programmes.

S05.3

Managing genetic risk: some issues for BRCA1 and BRCA2 mutation carriers

N. Hallowell;

Public Health Sciences, University of Edinburgh, Edinburgh, United Kingdom.

Men and women who have a number of relatives with breast, ovarian and prostate cancer in close relatives may be at risk of developing these diseases because they carry a dominantly inherited (BRCA1/2) mutation. These individuals need to reach a decision about managing their cancer risks. There are a number of risk management strategies available - which can be divided into familial and individual strategies. The former entails DNA screening - determining whether individuals and, subsequently, their relatives carry a mutation. The latter include: bodily surveillance (breast, ovarian and prostate screening), chemoprevention (e.g. tamoxifen, oral contraception), risk-reducing pre-symptomatic surgery (e.g. mastectomy, oophorectomy), which are available to at-risk confirmed and unconfirmed mutation carriers.

This presentation will present an overview of some of the main issues emerging from research which investigates the psychosocial implications of cancer risk management. I will argue that both risk management decisions and the process of managing risk have both an individual and familial dimension. Some of the factors influencing risk management decisions such as: gender, cancer status and stage in the lifecycle will be discussed as will the repercussions for identity of adopting particular risk management practices. Finally, some of the

implications of this research for service delivery in cancer genetics will be considered.

S06.1

Common, low-penetrance breast cancer susceptibility alleles: the clinical relevance

P. Pharoah;

University of Cambridge Dept of Oncology, Strangeways Research Laboratory, Cambridge, United Kingdom.

Empirical, genome-wide association studies have discovered seven breast cancer susceptibility alleles that are common in the population. These findings have brought the promise of a "polygenic" approach to the prevention of breast cancer a step nearer. The risks conferred by individual loci are small, but risk alleles seem to act multiplicatively. As a result there is an approximately six-fold difference in risk of breast cancer between women carrying 14 risk alleles and those carrying no risk alleles at these loci. Overall, the distribution of relative risk in the population based on combinations of genotypes at these loci is approximately log-normal. The efficiency of population-based preventive programs, such as screening mammography, could be improved by targeting women at greatest risk based on genotype.

S06.2

What GWAS have taught us about the genetic architecture and pathogenesis of the inflammatory bowel diseases (IBD).

J. Rioux;

Université de Montréal and the Montreal Heart Institute Research Center, Montreal, QC, Canada.

Crohn's disease and ulcerative colitis are debilitating, inflammatory diseases of the gastrointestinal tract, collectively known as the inflammatory bowel diseases (IBDs). Genetic studies have been particularly successful in the identification of genes for Crohn's disease. In fact, in 2001 one of the first successful discoveries of a causal gene for a complex trait was the identification of three genetic variants in the NOD2 gene that are associated with Crohn's disease as well as the identification of an associated haplotype on chromosome 5q31, known as IBD5, containing five genes: IRF1, SLC22A5, SLC22A4, PDLIM4, and P4HA2.

Recent GWAS of CD has identified and confirmed an additional set of nine genetic risk factors. These studies have since led to an international collaboration to combine the data from over 3,000 patients with CD, examined in the individual screens, in order to identify the most significant associations for replication in an independent set of nearly 4,000 patients with CD. This collaborative work has identified a minimum of 20 additional risk factors for susceptibility to CD. It is estimated that the 31 loci identified to date explain about 10% of the overall variance in disease risk; providing some indications of the extent of the complexity in genetic architecture for this chronic immune-mediated disease. Some of the pathogenic pathways newly identified by these GWAS include autophagy, novel innate immunity mechanisms, and T_H17 mediated immune responses. Interestingly, a subset of the genes identified to date are also seen to influence other immune mediated diseases and thus provide a window into the disease-specific and shared pathogenic pathways. In this presentation we will discuss the results from these recent discoveries and some of conclusions that can currently be drawn from this data in terms of the genetic architecture and pathogenesis of IBD as a model for other complex human traits.

S07.1

Genomic encoding of positional identity

H. Y. Chang;

Program in Epithelial Biology, Stanford University School of Medicine, Stanford, CA, United States.

The problem of how genetic information gives rise to the spatial organization has long intrigued biologists. While cellular differentiation addresses the control of expression of specific genes within a cell, pattern formation addresses the spatial arrangement of distinct cell types. A major mechanism of pattern formation in the embryo is the

use of positional information. By linking differentiation programs to cell positions on a coordinate system, an assembly of cells can be programmed to develop into well-defined spatial patterns that are not easily perturbed by the removal or addition of cells. In contrast to embryonic development, the higher-order patterns of cellular specialization in adult animals and mechanisms of their maintenance are less well understood. Here I discuss progress in using genomic expression programs to understand the organization and mechanisms of pattern formation and maintenance in mammalian epithelia.

The major themes are the encoding positional identity in one class of cells and the transfer of this information by epithelial-mesenchymal interaction; the role of chromatin modifications in the fidelity of transcriptional memory, and the discovery of a class of long non-coding RNAs that regulate chromosomal domains of chromatin modification to enable position-specific gene expression.

The architecture of DNA in the cell nucleus is an emerging key contributor to genome function. To better understand how DNA is folded inside the cell nucleus, we recently developed 4C technology. 4C technology is a high-throughput technique that combines 3C (chromosome conformation capture) technology with tailored micro-arrays to uniquely allow for an unbiased genome-wide search for DNA loci that interact in the nuclear space (Simonis et al., *Nature Genetics* 2006). It is based on formaldehyde cross-linking and capturing of in vivo interacting DNA elements, which are subsequently ligated to each other and PCR amplified.

Here, we will show that 4C technology is also a powerful technique for the accurate identification of balanced and unbalanced genomic rearrangements. Balanced chromosomal rearrangements (inversions, translocations) frequently occur in the human population and can cause disease, but techniques for their rapid and accurate identification are missing. 4C technology accurately reconstructs at least 5-10 megabases of the one-dimensional chromosome sequence map around the selected genomic viewpoint. Changes in this physical map as a result of genomic rearrangements are therefore identified by 4C technology. We demonstrate that 4C detects balanced inversions and translocations, but also unbalanced rearrangements like deletions, at a resolution (~7kb) that allows immediate sequencing of the breakpoints. Breakpoints are identified even when they are 4 megabases away from the genomic viewpoint. We have applied 4C to samples from patients with congenital malformations and with T cell acute lymphoblastic leukemia (T-ALL). Using 4C, we have identified novel rearrangements underlying T-ALL. We will show that balanced rearrangements are identified also if they occur in a small subpopulation of cells. 4C technology therefore offers a novel high-resolution genomic approach that can efficiently identify balanced genomic rearrangements.

S07.3

Integrative genomic approaches for the identification of regulatory variation underlying disease risk

J. Blangero;

Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

S08.1

Deciphering Developmental Disorders

N. Carter;

Wellcome Trust Sanger Institute, Genome Campus, Cambridge, United Kingdom.

Genetically determined disorders of development result in malformations (e.g. congenital heart defects), a dysmorphic appearance (i.e. unusual craniofacial appearance) and/or neurodevelopmental disability. They have a profound effect on the life and health of the individual and of their family. Many developmental disorders are caused by gene

mutations or larger chromosome rearrangements affecting gene copy number or regulation. However, in spite of expert clinical assessment and conventional chromosome analysis, most children with developmental disorders remain undiagnosed and indeed are undiagnosable using this methodology.

Recently it has become possible to screen patients for submicroscopic chromosome imbalance (microdeletions and microduplications) and to identify mutations in genes on a genome-wide scale. The application of comparative genomic hybridisation to DNA microarrays (array-CGH) has revolutionised our ability to identify small chromosome imbalances down to a few Kb not only in patients but also as normal copy number variation in unaffected individuals. A number of clinical laboratory centres worldwide are now applying genomic microarray technology to investigate a small proportion of patients with developmental delay, learning disability and congenital malformation. However the sporadic nature and rarity of the majority of these cases limits the ability of the individual clinician, working in isolation, to interpret the molecular findings from genome-wide array analysis. There is a great need for international collaboration to report and catalogue genotype-phenotype correlations such that clusters of individuals sharing similar genomic rearrangements and phenotypes can be identified. To facilitate such international collaboration, we have developed the DECIPHER database with the general aim of providing a clinical and research tool to:

- Aid in the interpretation of data from genomic microarray analysis e.g. the differentiation between pathogenic and polymorphic copy number changes
- Utilise the human genome map via the Ensembl genome browser to define genes involved in a specific microdeletion, microduplication, translocation or inversion
- Facilitate collaboration between clinical geneticists and molecular cytogeneticists using the world-wide-web to accelerate progress in the delineation of new syndromes and of gene function

S08.2

Processes of allelic and ectopic recombination in the human genome

A. J. Jeffreys, I. L. Berg, M. C. Ergoren, K. G. Lam, V. E. Lawson, C. A. May, R. Neumann, L. Odenthal-Hesse, S. Sarbajna, A. Webb;

Department of Genetics, University of Leicester, Leicester, United Kingdom.

Single molecule typing of sperm DNA allows very high resolution analysis of meiotic recombination events in human DNA and has revealed narrow crossover hotspots dominating the allelic recombination landscape, at locations that in general correlate well with regions of breakdown of linkage disequilibrium. All 36 hotspots characterised to date by sperm typing show a very similar morphology but vary hugely in recombination activity. Polymorphism between men in activity at specific hotspots is common, consistent with rapid evolutionary turnover of hotspots, but curiously appears to be restricted to less active hotspots, at least half of which show either quantitative variation or complete on/off polymorphism. These polymorphisms help identify local DNA sequence determinants and other factors that appear to influence hotspot activity. Single DNA molecule methods have also been developed to explore ectopic recombination between locally repeated DNA sequences. Analysis of the α -globin gene cluster has revealed recombinational exchanges between the duplicated α - γ 10 β v γ evs leading to apparently reciprocal duplications and deletions, though with some evidence for an additional minor pathway of intramolecular deletion. These exchanges are surprisingly common, contrasting sharply with the rarity of rearranged chromosomes in most human populations and implying significant selection pressure against these rearrangements, despite the lack of obvious phenotypic effect in individuals carrying these copy number variants. Unlike recombination at allelic crossover hotspots, exchanges between α -globin genes are not restricted to meiosis but also arise mitotically to give various classes of rearrangement whose frequencies can be erratically inflated by mutational mosaicism, even in the germline. Similar analysis of Lepore-type deletions in the β -globin gene cluster has provided further support for distinct allelic and ectopic recombination pathways, with evidence that a very active allelic recombination hotspot within the cluster is not responsible for driving ectopic exchanges.

S08.3**Chromosome rearrangements and fusion genes in breast and other epithelial cancers****P. Edwards;***Department of Pathology, University of Cambridge, Hutchison-MRC Research Centre, Cambridge, United Kingdom.*

Chromosome translocations that form fusion transcripts or activate genes by promoter insertion are central to leukaemias, lymphomas, and sarcomas, but for various reasons have been neglected in the common epithelial cancers. It is now clear that at least some of the abundant chromosome rearrangements in the common cancers create fusion genes (reviewed by Mitelman et al, *Nature Reviews Cancer* 2007;7:233). Tomlins et al. (*Science* 2005;310:644) have shown that most prostate cancers have fusions of ETS transcription factors and Soda et al (*Nature* 2007;448:561) reported an EML4-ALK fusion present in around 7% of NSCLC lung cancers. We have undertaken a comprehensive analysis of chromosome rearrangements in breast cancer cell lines, mapping all rearrangements to 1Mb resolution or better (Howarth et al, *Oncogene* 2008, PMID18084325). We used 'array painting', in which chromosomes are isolated using a cell sorter (flow cytometer) and then hybridised to DNA microarrays to determine what parts of the genome are present in each chromosome. We found that many more translocations were balanced than expected: a total of nine reciprocal translocations in three cell lines completely analysed, with several other translocations balanced for at least one of the participating chromosomes. Many of the mapped breakpoints were in the kind of genes one would expect oncogenic translocations to target, and to date three in-frame fusion transcripts have been verified. It may be that gene fusions caused by chromosome rearrangement will prove to be as significant in common epithelial cancers as in leukaemias and sarcomas.

S09.1**Intracellular Trafficking and Neurodegeneration - The SCA1/ataxin-1 Story****H. T. Orr;***Institute of Human Genetics, The University of Minnesota, Minneapolis, MN, United States.*

Spinocerebellar Ataxia type 1 (SCA1) is one of nine inherited disorders caused by a polyglutamine expansion in the affected protein. In SCA1 this expansion is in the ataxin-1 (ATXN1) protein. Nuclear localization of ATXN1 is implicated in the pathology of SCA1. Previous work showed that toxicity of mutant ATXN1 is due to soluble protein and its interacting proteins. Thus, polyglutamine-expanded mutant ATXN1 is able to interact with several other nuclear proteins and incorporate into native complexes similar to wild type protein. We identified partners of ATXN1 that interact with it in a manner dependent on two criteria necessary for toxicity: polyglutamine expansion and phosphorylation at serine 776. Polyglutamine expansion as well as phosphorylation of serine 776 in ATXN1 favors the formation of a particular protein complex containing a putative regulator of RNA splicing RBM17. We further found that changing the serine at position 776 to an aspartic acid (a substitution that can mimic phosphorylation) renders a wild type allele of ataxin-1 with 30 glutamines pathogenic *in vivo*. Mice expressing ataxin-1 30Q-D776 have a phenotype very similar to that seen in mice expressing ataxin-1 82Q-S776. These findings demonstrate the glutamine expansion in ATXN1 enhance protein/protein interactions that are normally regulated by its phosphorylation at serine at position 776 and that polyglutamine-induced misregulation of S776 phosphorylation and subsequent alterations in nuclear trafficking underlie SCA1 pathogenesis.

S09.2**Polyneuropathies and axonal trafficking****K. A. Nave;***Department of Neurogenetics, Max Planck Institute of Experimental Medicine, Goettingen, GERMANY.***S09.3****'Neurotic Yeast' and the Molecular Basis of Parkinson's Disease****T. F. Outeiro;***Instituto de Medicina Molecular, Cell and Molecular Neuroscience Unit, Lisboa, Portugal.*

Aging is the major known risk factor for Alzheimer's disease (AD) and Parkinson's disease (PD), but genetic defects have been associated with familial cases. Huntington's disease (HD) is a purely genetic neurodegenerative disorder, where mutations in the *IT15* gene, encoding for the protein huntingtin, determine the development of the disease.

A common hallmark to many neurodegenerative diseases is the presence of proteinaceous inclusions inside neuronal populations, which are selectively affected in each disorder. Lewy bodies, made of α -synuclein in PD, and huntingtin inclusions, in HD, are but a few examples of protein aggregates deposited inside neurons. Whether inclusions are themselves toxic or actually cytoprotective is still under current debate, but it is widely accepted that protein misfolding and oligomerization are central molecular events in these diseases.

Molecular genetic approaches using different model organisms, from yeast to mammalian cell culture and mouse models, coupled with advanced microscopy techniques resulted in a detailed characterization of the pathways and events involved in cytotoxicity.

Using the budding yeast *Saccharomyces cerevisiae* as a 'living test tube' we were able to unveil fundamental aspects of α -synuclein biology. Powerful yeast genetic screens enabled us to identify several molecular pathways as playing central roles in the toxicity induced by α -synuclein. Genes involved in intracellular trafficking, lipid metabolism, and oxidative stress, were among the most highly represented categories. With this knowledge at hand, we are applying a variety of tools to unravel the molecular basis of neurological disorders associated with protein misfolding, with the goal of developing novel avenues for therapeutic intervention.

S10.1**In utero stem cell transplantation: where are we now?****T. H. Bui;***The Karolinska Institute, Department of Molecular Medicine, Clinical Genetics Unit, Karolinska University Hospital, Stockholm, Sweden.*

In the last 35 years, extensive progress has been made in the prenatal diagnosis of genetic disorders. In contrast, success in fetal therapeutic interventions has been more limited.

One of the basic tenets of immunology is *learned self tolerance*: the ability, at the cellular and molecular levels, to recognise "self" and to eliminate that which is "foreign" must be "learned" during fetal life. This paradigm has served to support the concept of *in utero* transplantation (IUT), a promising approach with the potential to effectively treat fetuses with a variety of genetic defects. The rationale is to take advantage of normal events during haematopoietic and immunological ontogeny to facilitate allogeneic stem cell engraftment at an early stage of pregnancy, before permanent damage has occurred to the fetus. Clinical success has been realised, so far, in only fetuses with severe combined immunodeficiency syndromes. More recently, research has focused on mesenchymal stem cells (MSCs). Like adult bone marrow-derived MSCs, fetal liver-derived MSCs appear to be non-immunogenic both *in vitro* and *in vivo*. Both adult and fetal MSCs retain multilineage potential to form e.g. cartilage, bone, adipose and muscular tissues on induction. The first cases of IUTs using fetal MSCs for fetuses with severe osteogenesis imperfecta have been performed in our Centre.

Lessons learned from animal studies and clinical cases have contributed in defining new strategies to possibly overcome barriers to engraftment or tolerance in the fetus. The experience gained in IUTs is likely to benefit also the new experimental field of intrauterine gene therapy. Clearly, ethical issues relating to these new frontiers of medicine need also to be addressed.

S10.2**Non-invasive prenatal diagnosis of Down syndrome: a challenging puzzle in circulating fetal nucleic acid research****R. Chiu;**

Li Ka Shing Institute of Health Sciences and Department of Chemical Pathology, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, New Territories, Hong Kong.

In 1997, our group discovered the existence of cell-free fetal DNA and subsequently fetal RNA in the plasma of pregnant women. Such circulating fetal nucleic acids represent a convenient source of genetic material from the unborn child that could be sampled non-invasively and simply through the collection of a maternal blood sample. This approach is thus a safe alternative to conventional methods which rely on fetal cell sampling through invasive procedures such as amniocentesis. We showed that the detection of circulating fetal nucleic acids could potentially be applied to the non-invasive assessment of fetal blood group status, sex-linked genetic diseases and beta-thalassaemia as well as the monitoring of pregnancy-related complications, such as preeclampsia. Among these applications, the non-invasive assessment of fetal rhesus D status has been adopted as a routine clinical test in a number of centres in Europe. However, Down syndrome is the main reason for couples opting for prenatal diagnosis. Due to the cell-free nature of fetal DNA/RNA in maternal plasma, development of non-invasive definitive diagnostic methods for Down syndrome had been a challenge. After tackling this puzzle for a decade, we have recently developed strategies to directly assess the dosage of chromosome 21 from maternal plasma allowing for direct non-invasive detection of fetal Down syndrome. One method, termed the RNA-SNP approach, is based on determining the ratio between polymorphic alleles of a placental expressed mRNA derived from chromosome 21 in maternal plasma. Another method, termed the relative chromosome dosage approach, is based on the detection of an excess of chromosome 21 DNA sequences with respect to a reference chromosome in maternal plasma. These approaches have brought us closer to realising the goal of non-invasive prenatal diagnosis of fetal Down syndrome.

S10.3**The regulation of prenatal and preimplantation genetic diagnosis in the UK****E. Jackson;**

Law Department, London School of Economics, London, United Kingdom.

This paper will explain how the Human Fertilisation and Embryology Authority (HFEA) regulates preimplantation genetic diagnosis (PGD) in the UK. Prenatal genetic diagnosis is not separately regulated in the UK, although abortion law provides a special ground for abortion on the grounds of abnormality, and this initially was used as a model for the regulation of PGD.

PGD is not specifically mentioned in the UK's legislation - the Human Fertilisation and Embryology Act 1990. Instead the HFEA has laid down the circumstances in which PGD may be used through its Code of Practice, currently in its 7th edition. In short, there has to be a significant risk of a serious condition being present in the embryo, and the Code fleshes out what this means.

Every centre that wants to carry out PGD needs a variation to its licence for each genetic condition it wishes to test for. There is a list of previously-approved conditions which can be authorized fairly speedily if an experienced centre wishes to add them to its licence. For new centres, and for late-onset or lower-penetrance conditions, each application must be separately approved by a licence committee.

The HFEA has also permitted preimplantation HLA-typing, provided certain criteria are met.

This paper will explore how the HFEA has made *policy* decisions about legitimate uses of PGD, and how, in practice, it *regulates* PGD. It will also consider whether the law which is currently before parliament will make any substantive changes to the regulatory framework in the UK.

S11.1**Peroxisomal disorders: biochemistry, molecular biology and genetics****H. R. Waterham;**

Academic Medical Center, Laboratory Genetic Metabolic Diseases, Amsterdam, Netherlands.

Peroxisomes are ubiquitous organelles that play an essential role in cellular metabolism as underscored by the recognition of a large number of often severe genetic disorders in which one or more peroxisomal functions are defective. These peroxisomal disorders can be classified into two main groups, including the Peroxisome Biogenesis Disorders (PBDs) and the single peroxisomal enzyme deficiencies.

The group of single peroxisomal enzyme deficiencies currently comprises 10 different defects, 5 of which involve enzymes involved in peroxisomal fatty acid beta-oxidation, including the most common peroxisomal disorder X-linked adrenoleukodystrophy (X-ALD). The distinction between the different disorders can be readily made on the basis of specific metabolite patterns in combination with selective enzyme diagnostics and followed by diagnostic DNA testing.

The PBDs comprise a group of severe, often lethal multi-systemic autosomal recessive disorders displaying considerable clinical, biochemical and genetic heterogeneity. Based on clinical and biochemical parameters, originally 3 different presentations had been defined, including Zellweger syndrome (ZS), neonatal adrenoleukodystrophy (NALD) and infantile Refsum disease (IRD), with decreasing clinical and biochemical severity. Recently, however, they have been assigned to the Zellweger Spectrum continuum based on the recognition that the different presentations can be caused by mutations in different genes, different mutations within the same gene and the fact that they show considerable clinical and biochemical overlap. A fourth entity assigned to the group of PBDs is Rhizomelic Chondrodysplasia Punctata (RCDP) type 1, the clinical presentation of which clearly differs from those observed in the Zellweger Spectrum disorders.

PBDs can be caused by mutations in any of at least 13 different *PEX* genes, which encode proteins (peroxins) involved in different stages of peroxisomal protein import and organelle biogenesis. To establish the overall mutational spectrum of PBDs with respect to the affected *PEX* gene as well as mutations therein and to allow rapid identification of the defective *PEX* gene for diagnostic purposes, we developed genetic complementation assays based on peroxisome restoration assessment following PEG-mediated fusion of patient cell lines with tester cell lines or transfection of patient cell lines with either of the known *PEX* cDNAs. Using these assays we have assigned skin fibroblasts from over 500 patients diagnosed with a PBD, to different genetic complementation groups representing defects in the various *PEX* genes. For all the genes we implemented diagnostic DNA testing involving gene sequencing.

S11.2**Diagnostic tools in mitochondrial respiratory chain defects****O. Elpeleg;**

Hadassah Hebrew University Medical Center, Jerusalem, Israel.

Congenital disorders of the mitochondrial respiratory chain are common inborn errors of metabolism with an incidence of 1:5,000-8,000 live births. The respiratory chain consists of 85 subunits which are assembled into five enzymatic complexes. Thirteen of the 85 subunits are encoded by the mitochondrial DNA (mtDNA) and a large number of proteins are required for the replication of the mtDNA molecule, its expression and for the assembly of each of the complexes. Most patients present with neurological symptoms accompanied by lactate elevation and the enzymatic diagnosis is established in muscle tissue. However, translation of the results of the enzymatic analysis into genetic counseling is hampered by the fact that the same defect is not present in fibroblasts and that many of the genes encoding the non-structural factors are presently unknown.

Because all our patients originate from small consanguineous families and since most of the proteins responsible for congenital disorders of the mitochondrial respiratory chain are encoded by the nuclear genome and the defects are transmitted in an autosomal recessive manner, we have used homozygosity mapping. This method, in combination with mtDNA and mtRNA quantification, resulted not only in a fast and economic diagnosis, but has also led to the identification of novel genes involved in the biogenesis of the mitochondrial respiratory chain.

S11.3

Glutaryl-CoA dehydrogenase deficiency: biochemical and molecular aspects

A. Ribes;

Department of Biochemistry and Molecular Genetics. Division of Inborn Errors of Metabolism (IBC). Hospital Clínic, Barcelona, Spain.

Glutaric aciduria type I (GA I; OMIM 231670) is an autosomal recessive disorder due to deficient or non-functional glutaryl-CoA dehydrogenase (GCDH). The metabolic block leads to the accumulation of glutaric, and 3-hydroxyglutaric acids as well as glutarylcarnitine in body fluids. The clinical picture is characterized by the sudden onset of a severe dystonic-dyskinetic disorder, hypotonia, irritability, macrocephaly and degeneration of the caudate and putamen, which generally appear between the 5th and 14th months of age, but mild symptoms such as motor delay and hypotonia can be observed at earlier ages.

The gene *GCDH* consists of 11 exons and codes for a precursor protein of 438 amino acids. The active enzyme is a homotetramer. Single prevalent mutations have been found in small isolated ethnic groups. However, mutations of the *GCDH* gene in general population are heterogeneous. To date, more than 150 disease-causing mutations have been identified.

More than half of the reported patients had completely absence of GCDH activity, while others had a residual activity between 5- 15% and very few patients had a residual activity up to 30%. Complete absence of activity was connected to certain mutations. The most frequent was p.R402W. Less but also frequent was the mutation p.A293T. This group of patients all excreted considerable amounts of both glutarate and β -hydroxyglutarate with significant higher amounts of the former. The most frequent mutations associated with residual activity, were p.V400M, p.R227P and p.A421V and most of these patients had low excretion of glutarate and β -hydroxyglutarate with highest excretion of the latter compound. Therefore, it seems clear that two distinct genetically and biochemically groups of patients exist, but the severity of the clinical phenotype seems to be closely linked to the development of encephalopathic crisis rather than to residual enzyme activity or to the genotype.

S12.1

Genetic genomics: a combination of genetic variation with genomic profiling to reconstruct molecular networks

R. Jansen^{1,2};

¹University of Groningen, Groningen Bioinformatics Centre (GBIC), Groningen Biomolecular Sciences and Biotechnology Institute, University of Groningen, Haren, Netherlands, ²Dept of Genetics, University Medical Centre Groningen,

University of Groningen, Groningen, Netherlands.

Genetically different individuals can exhibit large quantitative variation for disease susceptibility, physiology, and many other traits of interest. Such variation stems, at least partly, from variations in the DNA. Modern sequencing technologies can reveal the variations in the (epi)genome, and genome-wide linkage (GWL) analysis and genome-wide association (GWA) analysis can then link or associate them to variations in the trait of interest. These strategies are increasingly applied to a growing number of organisms, including human, mouse, rat, cattle, pigs, *A. thaliana*, tomato, corn, yeast, *C. elegans*, and *D. melanogaster*, and have pinpointed many quantitative trait loci (QTL) on the genome. To lift the veil that covers the genome-to-phenotype relation we may need to monitor the whole trajectory of intermediate biomolecular phenotypes. Today's molecular technologies, particular microarray and deep sequencing for transcriptome and high resolution mass spectrometry and nuclear magnetic resonance for proteomics and metabolomics, have reached a cost-efficiency level allowing for comprehensive molecular profiling of many samples at multiple biomolecular levels. We here discuss the results, promises and pitfalls for network reconstruction using system-wide data on gene expression (eQTLs), proteins (pQTLs) and metabolites (mQTLs) from studies on human, mouse and *A. thaliana*.

S12.2

Metabolic networks in biology and diseases

Z. Oltvai;

Department of Pathology, University of Pittsburgh, Pittsburgh, PA, United States.

Most diseases are the consequence of the breakdown of cellular processes, but the relationships among specific genetic/ epigenetic defects and variations (SNPs, CNVs, etc) and these disruptions, the molecular interaction networks underlying them, and the disease phenotypes remains poorly understood. To begin to gain insights into such relationships we have constructed a bipartite human disease association network in which nodes are diseases and two diseases are linked if mutated enzymes associated with them catalyze adjacent metabolic reactions. We will describe the characteristics of this network and show that the structure and modeled function of the human metabolic network can provide insights into disease comorbidity, with potentially important consequences for disease diagnosis and prevention.

S12.3

Reverse engineering the transcriptional networks

D. diBernardo;

Group Leader, Telethon Institute of Genetics and Medicine (TIGEM) & Research Associate - University of Naples Federico II, Naples, Italy.

One of the main challenges in the era of post-genomic research is to develop methods to extract information from the vast amount of data generated by high-throughput techniques. Tools such as microarrays probing expression of all known genes are now a standard technique worldwide, whereas new approaches based on sequencing are fast emerging.

This genome-wide data yields information not only at the single gene level, but also at the 'systems' level, i.e. how genes, proteins and metabolites interact with each other to perform a specific function. In order to 'read' such information new methods coming from quantitative sciences such as physics and engineering, have to be used.

We will introduce experimental protocols and computational algorithms to infer gene regulatory networks.

We have applied our reverse-engineering approach to elucidate the transcriptional network regulated by the transcription factor p63, whose mutations are causative of human malformation syndromes, in primary keratinocytes.

We have identified over 100 novel targets of p63 and shown that it transiently regulates members of the AP-1 protein complex.

S13.1**Dysregulated RAS signaling in Noonan syndrome and related disorders****M. Tartaglia;***Department of Cell Biology and Neurosciences, Istituto Superiore di Sanità, Rome, Italy.*

In the last few years, mutations in genes coding for transducers with role in the RAS-MAPK signaling pathway have been identified as the molecular cause underlying a group of clinically related developmental disorders with features including reduced postnatal growth, facial dysmorphism, cardiac defects, ectodermal anomalies, cognitive deficits and variable predisposition to certain malignancies. Noonan syndrome (NS), which is the most common condition among these Mendelian traits, is caused by heterozygous mutations in *PTPN11*, *SOS1*, *KRAS* and *RAF1* in approximately 65% of affected individuals. Missense *PTPN11* and *RAF1* mutations also account for the vast majority of LEOPARD syndrome (LS), while defects in *KRAS*, *BRAF*, *MEK1* and *MEK2*, and a bunch of missense changes in *HRAS* occur in 60-80% of cardiofaciocutaneous syndrome (CFCS) and in Costello syndrome (CS), respectively.

The RAS-MAPK signaling pathway controls cell proliferation, survival and differentiation, and represents the most common target for somatic activating mutations in cancer. NS-, LS-, CFCS- and CS-causing alleles encode for proteins with aberrant biochemical and functional properties, mostly resulting from impaired catalytic autoinhibition, that promote increased signal flow through the MAPK cascade.

The available structural, molecular and biochemical data support the view that, besides its crucial role in oncogenesis, dysregulation of RAS-MAPK signaling has profound consequences on development. These findings also provide evidence that germline transmitted mutations causing developmental disorders define a novel allele series that have distinctive perturbing role on signaling, and offer a model in which distinct gain-of-function thresholds of the activity of individual transducers are required to induce cell-, tissue- or developmental-specific phenotypes, each depending on the transduction network context involved in the phenotype.

S13.2**The molecular dissection of Joubert syndrome and allied ciliopathies***H. H. Arts¹, D. Doherty², S. E. C. van Beersum¹, S. J. F. Letteboer¹, T. A. Peters³, I. A. Glass², N. V. A. M. Knoers¹, R. Roepman¹;**¹Dept. of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, ²Dept. of Pediatrics, University of Washington School of Medicine, Seattle, WA, United States, ³Dept. of Otorhinolaryngology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.*

Joubert syndrome is a disorder that is primarily characterised by a typical hind brain malformation known as the “molar tooth sign”, as seen on CT and MRI images. Retinal degeneration, cystic kidneys, mental retardation and abnormal breathing patterns (episodic hypernea and apnea) are also common features. To date, four genes are known to be involved in Joubert syndrome, and three of the protein products localize to primary cilia.

We examined the function of the RPGRIP1-like protein (RPGRIP1L), encoded by *RPGRIP1L* on chromosome 16q12.2. This is the homologue of RPGRIP1 (RPGR interacting protein 1), a ciliary protein involved in congenital blindness (Leber congenital amaurosis). *RPGRIP1L* is ubiquitously expressed and its protein product localizes to basal bodies of cilia in brain, retina and kidney. We identified homozygous frameshift and splice site mutations in two families with typical Joubert syndrome and compound heterozygous nonsense and missense mutations in a third family. All mutations disrupt the interaction of the C2-domain of RPGRIP1L with nephrocystin-4, encoded by *NPHP4* which is mutated in Senior Løken syndrome patients (retinal dystrophy and cystic kidneys). Interestingly, one of the patients had post-axial polydactyly and encephalocele resembling the Meckel-Gruber syndrome phenotype, suggesting that *RPGRIP1L* could be involved in disorders that represent different spectra of the same underlying defect.

We and others have found that these disorders with overlapping phenotypes in the retina, the brain and the kidney, can result from perturbation of individual components of shared functional modules, regulating distinct processes that are based at (primary) cilia. Functional

dissection of these modules has yielded important information of the molecular pathogenesis of the associated disorders, the “ciliopathies” disease family. They point towards a role of the cilia in regulating a wide variety of basic cellular processes, such as vesicle transport, Wnt signalling and Hedgehog signalling. Furthermore, similar to the identification of *RPGRIP1L*, they have provided us with a valuable collection of novel “ciliopathy candidate genes”, that will even expand the ciliary factor in various disease processes.

S13.3**Alterations of FGF signalling in LADD syndrome****B. Wollnik;***Institute of Human Genetics, Cologne, Germany.*

Mutations in different components of the FGF signalling pathway cause the lacrimo-auriculo-dento-digital (LADD) syndrome, an autosomal dominant disorder mainly characterized by anomalies of the lacrimal system, ears and hearing, teeth, and distal limb development. Notably, all LADD mutations identified so far in FGFR2/3 are located within the tyrosine kinase (TK) domains of the receptors within loops that play an important regulatory function in the control of receptor activity. Our functional studies of FGFR2 LADD mutants indicated a reduced tyrosine kinase activity of the receptor itself as well as reduced FGFR2-mediated substrate phosphorylation and reduced downstream signalling. Moreover, the timely and precisely ordered dynamics and patterns of autophosphorylation are changed in FGFR2 mutants as shown by biochemical investigations and crystal structure analysis. While FGFR2 LADD mutants exert a putative dominant-negative effect on normal FGFR2 protein, FGF10 LADD mutations cause haploinsufficiency. Beside novel mutational mechanisms of known LADD genes, we found an autosomal recessive inheritance in a severely affected LADD patient caused by the homozygous p.R579W in the TK domain of FGFR2. Interestingly, we also observed molecular overlaps of LADD-like phenotypes with p63-related disorders. Our data shed light on pathophysiological mechanisms underlying LADD syndrome and expand the spectrum of disorders associated with altered FGF signalling.

S14.1**Molecular mechanisms of cellular senescence****F. Fagagna;***IFOM-IEO Campus, Milan, Italy.*

Early tumorigenesis is associated with the engagement of the DNA-damage checkpoint response (DDR). Cell proliferation and transformation induced by oncogene activation are restrained by cellular senescence. It is unclear whether DDR activation and oncogene-induced senescence (OIS) are causally linked. Here we show that the expression of an activated oncogene (H-RasV12) in normal human cells, results in a permanent cell cycle arrest caused by the activation of a robust DDR. Experimental inactivation of DDR abrogates OIS and promotes cell transformation. DDR and OIS are established after a hyper-replicative phase occurring immediately after oncogene expression. Senescent cells arrest with partly replicated DNA and with DNA replication origins having fired multiple times. In vivo DNA labelling and molecular DNA combing reveal that oncogene activation leads to augmented numbers of active replicons and to alterations in DNA replication fork progression. Therefore OIS results from the enforcement of a DDR triggered by oncogene-induced DNA hyper-replication. Senescence is also associated with a global heterochromatinization of nuclear DNA. These senescence associated heterochromatic foci (SAHFs) are enriched in histone H3 di-tri methylated on lysine 9 (H3K9m) and HP1 proteins and High mobility group A (HMGA) proteins are also known to be essential structural components of SAHFs. Our most recent results on the interplay between DDR activation and oncogene-induced heterochromatinization will be presented.

S14.2**Cornelia de Lange Syndrome and the Cohesinopathies: Developmental Repercussions of Cohesin Dysfunction****I. D. Krantz;***Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA, United States.*

The cohesin proteins compose an evolutionarily conserved complex whose fundamental role in chromosomal cohesion and coordinated

segregation of sister chromatids has been well characterized across species. Recently regulators and structural components of cohesin have been found to surprisingly cause specific human developmental disorders (collectively termed “cohesinopathies”) when mutated. Mutations in NIPBL, the vertebrate homolog of the yeast Sister chromatid cohesion 2 (Scc2) protein, a regulator of cohesin loading and unloading, are responsible for approximately 50% of cases of Cornelia de Lange syndrome (CdLS). Mutations in the cohesin structural components SMC1A and SMC3 were also found to result in CdLS. CdLS is a multisystem developmental disorder classically characterized by facial dysmorphism, upper extremity malformations, hirsutism, cardiac defects, growth and cognitive retardation, and gastrointestinal abnormalities. A mild form of CdLS has been consistently reported, however, it had not been clear if this is a distinct etiologic entity from classic CdLS or truly a mild manifestation, however molecular testing of cohesin genes has identified mutations in individuals with very subtle features of CdLS bordering on apparent isolated mental retardation. Mutations in another cohesin regulator, ESCO2, result in Roberts syndrome (RBS) and SC phocomelia. Roberts syndrome is a recessively inherited multisystem disorder with craniofacial, limb, cardiac, other systemic abnormalities and neurocognitive dysfunction. While there is some overlap between Roberts syndrome and CdLS they are clinically readily differentiated. Other developmental disorders have also recently been found to be associated with cohesin dysfunction. The recent implication of the cohesin complex and its regulators in transcriptional control has shed light on the mechanism by which alterations in this complex leads to the specific phenotypes seen in these disorders. A review of cohesin function, the disorders associated with disruption of this pathway and future clinical and bench-top research directions will be discussed.

S14.3

Nijmegen breakage syndrome: clinical manifestation of defective response to DNA double-strand breaks

M. Digweed;

Charité - Institut für Humangenetik, Berlin, Germany.

Patients with the human genetic disorder, Nijmegen Breakage Syndrome (NBS) display a characteristic facial appearance, microcephaly and a range of symptoms including immunodeficiency, growth retardation and chromosomal instability. NBS patients have an extremely high risk of developing lymphoma. Patients were found to be highly sensitive to ionising irradiation (IR) and this radiosensitivity had fatal consequences in some undiagnosed patients. The most dangerous DNA-lesion caused by IR is considered to be the double-strand break (DSB) and indeed, NBS patient cells are sensitive to all mutagens which produce DSBs directly or indirectly.

The underlying gene, *NBN*, codes for a protein, nibrin, involved on the one hand, as a “caretaker”, in the processing/repair of DNA double strand breaks and on the other hand, as a “gatekeeper”, in the regulation of cell cycle checkpoints. The majority of patients are homozygous for a founder mutation in *NBN*, a 5bp deletion in exon 6. This mutation leads to a truncated amino-terminal fragment containing FHA and BRCT domains, and a carboxy-terminal protein (p70-nibrin) which is produced by alternative initiation of translation from a cryptic upstream start. *NBN* is an essential gene and it is clear that the carboxyterminal p70-nibrin protein is sufficient to ensure patient survival.

We have been examining patient cells and conditional *Nbn* null mutant mouse cells in order to establish which functions of full length nibrin can be carried out by the carboxy terminal fragment and, more particularly, how this partial functioning explains aspects of the human disease. In this connection a further rare nibrin fragment, p80-nibrin, which is associated with a milder course of the disease has been of particular interest since it may define the basis of a potential anti-cancer prophylactic treatment for NBS patients.

Genomic Perspectives on Human Origins

S. Pääbo;

Max-Planck-Institute for Evolutionary Anthropology, Leipzig, Germany.

One approach to understanding what makes humans unique as a species is to perform structural and functional comparisons between the genomes of humans and our closest evolutionary relatives the great

apes. Recently, the draft sequences of the chimpanzee and rhesus macaque genomes have opened up new possibilities in this area. I will discuss work that compares functional and structural aspects of the human and ape genes, using FOXP2, a gene involved in speech and language, as an example. I will also discuss how a genome-wide analysis of the Neandertal genome will enhance our ability to identify genes that have been of importance during human evolution.

S15.2

Human genetic population structure: Patterns and underlying processes

G. Barbujani;

University of Ferrara, Department of Biology and Evolution, Ferrara, Italy.

Classical studies of genetic diversity in humans consistently showed that the largest proportion of human diversity occurs among members of the same population. On average, differences among different populations in the same continent represent 5% of the global human variance, and differences among continents another 10%. Genetic variation is largely discordant across the genome, meaning that different loci show different spatial patterns, and implying that a good description of population structure can only be based on the analysis of multiple loci. Studies of single loci are also unlikely to reasonably identify an individual's place of origin. A general decline of genetic diversity with distance from Africa, and a parallel increase in linkage disequilibrium, can be accounted for by the effects of a series of founder effects accompanying the spread of anatomically-modern humans from Africa. Recent DNA analyses at the global level show that most allelic variants are cosmopolitan and only a small percentage are continent-specific, whereas a clearer continental structure emerges when considering composite haplotypes. This suggests that, at the global level, gene flow has had a strong impact on genetic diversity, through both directional dispersal and successive short-range migratory exchanges. At the local level, several factors have contributed to genetic differentiation, and, in particular, language barriers have been shown to be associated with small but non-negligible increases of the genetic differences between neighboring populations.

Patients with a microscopically visible deletion of the distal part of the long arm of chromosome 1 have a recognisable phenotype, including mental retardation, microcephaly, growth retardation, a distinct facial appearance and various midline defects including corpus callosum abnormalities, cardiac, gastro-oesophageal and urogenital defects as well as various central nervous system anomalies.

So far, only 8 cases with a pure submicroscopic deletion of distal 1q have been clinically described. In general, patients with a submicroscopic deletion have a similar phenotype, suggesting that the main phenotype of these patients is caused by haploinsufficiency of genes in this region.

In the present study we describe the clinical presentation of 13 new patients with a submicroscopic deletion of chromosome 1q43q44, of which 9 were interstitial, and report on the molecular characterisation of the deletion size.

The clinical presentation of these patients has clear similarities with previously reported cases with a terminal 1q deletion. Corpus callosum abnormalities were present in ten of our patients. The *AKT3* gene has been reported as an important candidate gene causing this abnormality. However, through detailed molecular analysis of the deletion size in our patient cohort, we were able to delineate the critical region for corpus callosum abnormalities to a 360 kb genomic segment which contains four possible candidate genes, but excluding the *AKT3* gene.

C01.2

Submicroscopic duplications of the hydroxysteroid dehydrogenase *HSD17B10* and the E3 ubiquitin ligase *HUWE1* are associated with mental retardation

Submicroscopic copy number imbalances contribute significantly to the genetic etiology of human disease. We report on a novel microduplication hot spot at Xp11.22 identified in 6 unrelated families with predominantly nonsyndromic XLMR. All duplications are unique and segregate with the disease, including the large families MRX17 and MRX31. Our FISH data are strongly suggestive for tandem duplication events with their sizes ranging from 0.4 to 1.0 Mb with a minimal, commonly duplicated region that contains three genes: *RIBC1*, *HSD17B10* and *HUWE1*. *RIBC1* could be excluded based on its absence of ex-

pression in the brain and since it escapes X-inactivation in females. For the other genes, expression array and quantitative PCR analysis in patient cell lines compared to controls showed a significant up-regulation of *HSD17B10* and *HUWE1* as well as several important genes in their molecular pathways. Loss-of-function mutations of *HSD17B10* have previously been associated with progressive neurological disease and XLMR. The E3 ubiquitin ligase *HUWE1* has been implicated in TP53-associated regulation of the neuronal cell cycle. We also detected segregating sequence changes of highly conserved residues in *HUWE1* in three XLMR families, which are possibly associated with the phenotype. Mutations in *HSD17B10* have previously been reported to be associated with XLMR and a progressive neurological disorder. Our findings demonstrate that an increased gene dosage of *HSD17B10*, *HUWE1*, or both contribute to the etiology of XLMR, and suggest that point mutations in both genes are associated with this disease too.

C01.3

Clinical outcome and molecular investigation of Pitt-Hopkins syndrome: a series of 9 patients

L. de Pontual¹, Y. Mathieu¹, M. Rio¹, A. Munnich¹, S. Lyonnet¹, J. Amiel¹; INSERM U-781, Department of Genetics, Necker Hospital, Paris, France, Paris, France.

Pitt-Hopkins syndrome (PHS) is a syndromic encephalopathy characterised by severe psychomotor delay, epilepsy, daily bouts of diurnal hyperventilation starting in infancy, and distinctive facial features. A systematic 1Mb resolution genome wide BAC array identified a 1.8 Mb *de novo* microdeletion on chromosome 18q21.1 in 1 case. We subsequently identified *de novo* heterozygous mutations of *TCF4* gene in 8 additional PHS cases. These findings provide the first evidence of a human disorder related to class I basic helix-loop-helix transcription factor (also known as E-proteins) defects. Our data support that haploinsufficiency is the most likely disease-causing mechanism, while a dominant-negative effect is an alternative hypothesis currently being tested for missense mutations occurring in the basic domain. Expression analysis of the *TCF4* gene during human embryonic development will also be presented.

Bouts of hyperventilation and epilepsy, although distinctive, are not fully penetrant. Several clinical features will be underscored as possible diagnostic clues in particular the facial gestalt, dysautonomia and subtle immunoglobulin deficiency. EEG and brain MRI may also give valuable clues that will be discussed. Patients diagnosed with PHS display a broad spectrum of dysautonomic features that will be detailed. These data may also shed new light on the normal processes underlying autonomic nervous system development and maintenance of an appropriate ventilatory neuronal circuitry.

States, ⁷University of Texas at Austin, San Antonio, TX, United States, ⁸Wilford

Hall Medical Center, San Antonio, TX, United States, ⁹University of Texas

Health Science Center at San Antonio, San Antonio, TX, United States.

Background. Thus far, the phenotype of tetrasomy 18p has been primarily delineated by a series of published case series and case reports. Findings reported in more than 25% of these cases include neonatal feeding problems, growth retardation, microcephaly, strabismus, abnormalities in muscle tone, scoliosis/kyphosis, and variants on MRI. Developmental delays and mental retardation are also universally present. **Methods.** To further refine the phenotype and natural history of tetrasomy 18p, we reviewed the medical history and records of 34 individuals with tetrasomy 18p. In addition, 20 individuals with tetrasomy 18p were clinically evaluated at our center. These individuals had multiple evaluations, including endocrinology, ophthalmology, neuropsychology, orthopedics, ENT, and genetics. They also underwent an MRI as well as a hearing test. **Results.** As a result of these analyses,

we can expand the phenotypic description of tetrasomy 18p. Findings identified in more than 25% of our patient population included neonatal jaundice, recurrent otitis media, hearing loss, seizures, refractive errors, a history of constipation and gastroesophageal reflux, heart defects, pes planus, and attention problems. Dysmorphic features that were reported in more than 25% of the population included ptosis; posteriorly rotated ears; unraveled helices; small ears; abnormal columella; smooth philtrum; small mouth; thin upper lip; abnormal Cupid's bow; palatal abnormalities, and a prominent or pointed chin. **Conclusion.** These findings further our knowledge of the clinical manifestations of tetrasomy 18p and will enable physicians to better anticipate and manage complications as they arise.

C01.5 Congenital nephrotic syndrome, microcephaly, trigonocephaly, polydactyly, brain and eye anomalies: a distinct autosomal recessive disorder

M. Zenker¹, O. Gross², E. Mildenberger³, B. Albrecht⁴, V. Matejas¹, D. Wiczorek⁴;

¹Institute of Human Genetics, Erlangen, Germany, ²Dept. Nephrology&Rheumatology, University Hospital Goettingen, Goettingen, Germany, ³Dept. of Pediatrics, University Hospital Benjamin Franklin, Berlin, Germany, ⁴Institute of Human Genetics, University Hospital Essen, Essen, Germany.

Congenital nephrotic syndrome (CNS) is a heterogeneous disease. While genetic causes of isolated CNS are well established, the knowledge on the genetic basis of various syndromic forms is still fragmentary. One of them is characterized by the association of CNS with microcephaly / brain anomalies, also known as Galloway-Mowat syndrome (GMS). It is obvious that GMS itself is not a homogeneous entity.

We observed a strikingly similar form of syndromic CNS in four children originating from unrelated consanguineous families. All affected children had gross proteinuria from birth and rapid progress to end stage renal failure. Two had evidence of additional tubular involvement. Head circumference fell below the 3rd centile within the first months of life in all patients. Trigonocephalic head shape was present in three of them. All children had cerebral gyration anomalies, and Dandy-Walker malformation was present in two. Further constant findings were postaxial hexadactyly and eye anomalies including iris atrophy, non-reactive miosis, coloboma, and microphthalmia. Three children had an atrial septal defect.

One of these patients was reported previously (Mildenberger et al.: *Acta Paediatr* 1998), but no other similar reports exist to our knowledge. We propose that this is a distinct autosomal recessive disorder within the heterogeneous group of microcephaly-nephrosis syndromes. It may be considered a subtype of GMS or a separate entity (Mildenberger syndrome). There is an obvious overlap with Pierson syndrome (OMIM 609049), which is caused by LAMB2 mutations, but no mutations in this gene were found in the disorder presented here.

C01.6 An undescribed phenotype associated with cranio-fronto-facio-nasal malformations, total alopecia and genital abnormalities

N. A. Akarsu¹, H. Kayserilip², I. Vargel³, Y. Alanay⁴, S. Candar², G. Tuncbilek⁵, O. Uyguner², S. Balci⁶;

¹Hacettepe University, Pediatrics, Gene Mapping Laboratory, Ankara, Turkey, ²Istanbul University Medical Genetics, Istanbul, Turkey, ³Kirikkale University, Plastic and Reconstructive Surgery, Kirikkale, Turkey, ⁴Hacettepe University, Pediatrics, Clinical Genetics, Ankara, Turkey, ⁵Hacettepe University, Plastic and Reconstructive Surgery, Ankara, Turkey, ⁶Hacettepe University, Pediatrics, Clinical Genetics (Emeritus Member), Ankara, Turkey.

We report an unusual malformation in the craniofrontonasal region of four males from two distinct inbred families. Major characteristics are: 1-) total alopecia; 2-) brachycephaly due to coronal suture synostosis; 3-) frontonasal dysostosis providing hypertelorism, blepharophimosis, severely depressed nasal bridge with bifid tips; 4-) posterior cranial skull defects; 5-) small naevi on the posterior skull; 6-) rotatory nystagmus and 7-) corpus callosum agenesis. These malformations are also associated with bilateral cryptorchidism and hypogonadism. The first family contains three affected individuals with one premature death at the age of two months, the others, 13 and 45 years old respectively, belong to different branches of the same family. The second pedigree contains a three months old single affected male with similar symp-

toms. Since both families originated from nearby cities in the Blacksea region of Turkey, this suggested a possible role of a founder mutation. As a consequence of the highly inbred nature of these families an autosomal recessive mode of inheritance is likely. Alternatively, since all patients are males, X-linked inheritance challenged by inbreeding should also be considered. Some of these findings apparently overlap with cerebrofrontofacial (OMIM 6085789) and craniofrontonasal (OMIM 304110) syndromes. However, neither a total alopecia, nor hypogonadism has been associated with the aforementioned conditions previously. To the best of our knowledge, this is a new disorder with severe cranio-fronto-nasal malformations in association with alopecia and genital abnormalities. Clinical and molecular investigations of this new disorder are done within the CRANIRARE consortium supported by the European Research Area Network "E-RARE".

C02.1 Fas-associated factor-1, a protein involved in apoptosis, causes cleft lip and palate

M. Ghassibe¹, L. Desmyter², F. Claes^{3,4}, O. Boute⁵, B. Bayet⁶, P. Pellerin⁷, L. Backx⁸, K. Hermans^{3,4}, P. Brouillard¹, N. Revencu¹, R. Vanwijck⁶, J. R. Vermeesch⁸, H. A. Poirel^{1,9}, P. Carmeliet^{3,4}, M. Vikkula¹;

¹Laboratory of Human Genetics, de Duve Institute, Brussels, Belgium, ²Laboratory of Human Genetics, de Duve Institute, université catholique de Louvain, Brussels, Belgium, ³Department for Transgene Technology and Gene Therapy, VIB, Leuven, Belgium, ⁴Center for Transgene Technology and Gene Therapy (CTG), K.U.Leuven, Leuven, Belgium, ⁵Centre de Génétique, CHU de Lille, Lille, France, ⁶Centre Labiopalatin, Service de Chirurgie Plastique, Cliniques universitaires Saint-Luc, Brussels, Belgium, ⁷Service de Chirurgie Plastique et Reconstructive, CHU de Lille, Lille, France, ⁸Center for Human Genetics, Leuven University Hospital, Leuven, Belgium, ⁹Center for Human Genetics, Cliniques universitaires Saint-Luc, Université catholique de Louvain, Brussels, Belgium.

Cleft lip and palate is the most common craniofacial birth defect with complex etiology. We show that a reciprocal translocation, which cosegregates with cleft palate in a family, disrupts the Fas-Associated Factor-1 (FAF1) gene. The mutation results in lowered expression, and likely haploinsufficiency. Transmission disequilibrium analysis demonstrates that FAF1 associates with cleft lip and palate. In situ hybridization unravels high levels of mFaf1 along the lips and the medial edge epithelium (MEE) of the fusing palate in mice. Moreover, in zebrafish larvae, zFaf1 is mostly expressed in the pharyngeal cartilages, where its knock-down results in orofacial defects. As FAF1 is a member of the Fas death-inducing complex that initiates apoptosis, it likely causes cleft palate by preventing MEE degeneration. The data provides strong molecular evidence that "death", rather than epithelial mesenchymal transformation or anterior/posterior migration, is the major fate for MEE. These data also predict that other factors in the FAS-induced apoptosis pathway likely play a role in cleft pathogenesis.

C02.2 Sporadic venous malformation is caused by somatic mutations in TIE2

M. Uebelhoer¹, V. Wouters¹, N. Limaye¹, L. M. Boon^{1,2}, J. B. Mulliken³, M. Vikkula¹;

¹de Duve Institute, Université catholique de Louvain, Brussels, Belgium, ²Center for Vascular Anomalies, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium, ³Vascular Anomalies Center, Children's Hospital, Boston, MA, United States.

Venous malformations (VM) are the most frequent vascular malformations referred to vascular anomaly centers. An autosomal dominant familial form, termed cutaneomucosal venous malformation (VMCM), representing about 1% of venous lesions, is caused by gain-of-function mutations in the TIE2 gene. The aetiology of sporadic VM, which represents more than 95% of venous lesions, has however remained unknown. Here we show that sporadic VMs are caused by somatic mutations in TIE2. We identified seven missense mutations in VM tissue-derived DNA, which were however absent in blood DNA from these patients, and in tissue DNA from 90 controls. All of the mutations, predicted by bioinformatic analysis to have deleterious effects of varying severity on protein function, were found to result in a strong in vitro ligand-independent increase in phosphorylation of TIE2. In some patients, we observed two mutations acting in cis. Such combinations on the same allele induced even higher phosphorylation levels of the

receptor than the constituent single mutations. Additional mutations were identified in lesion-derived cDNA, suggesting that the number of cells carrying a mutation can be in the minority, making the reduction of tissue heterogeneity an important factor in mutation detection. These data provide molecular evidence that sporadic venous malformations are caused by somatic activating TIE2 mutations, which are often linked to additional somatic genetic events. They explain the localized, predominantly unifocal nature of these lesions, and furthermore, pinpoint the TIE2 signaling pathway as a target for the development of therapeutic interventions. (miikka.vikkula@uclouvain.be)

C02.3

LTBP2 mutation in autosomal recessive microspherophakia with some marfanoid features

J. Desir¹, Y. Sznajder², J. Laes³, F. Roulez⁴, M. J. Abramowicz¹;

¹Medical Genetics Department, Hopital Erasme-ULB, Brussels, Belgium, ²Medical Genetics Department, HUDERF-ULB, Brussels, Belgium, ³DNAvision, Gosselies, Belgium, ⁴Ophthalmologic Department, HUDERF-ULB, Brussels, Belgium.

Microspherophakia is a lens malformation encountered in Marfan (MFS) and Weill-Marchesani (WMS) syndromes. We observed a large consanguineous family with three children affected with microspherophakia. The proband had tall stature with an arm span larger than his height, long slender fingers, and a high-arched palate. He did not meet the diagnostic criteria for MFS, nor WMS. No mutation was found in the MFS-associated gene *FBN1* (CMG, University of Gent, Belgium). We mapped the locus by homozygosity to a 12.6 cM region of chromosome 14q2 using a 10K GeneChip SNP array in the affected siblings, followed by microsatellite analysis, with a multipoint LOD of 2.57. The linkage interval contained one conspicuous candidate gene, *LTBP2*, encoding a latent transforming growth factor-beta binding protein. LTBP2s are extracellular matrix proteins with multiple domain structures bearing strong homologies with fibrillins, and may play several roles, including finely controlling TGF- β activity in the matrix, a structural role in microfibrils, and a role in cell adhesion. We found a truncating mutation g.76339dupC (p.Pro599ProfsX4), homozygous in the affected siblings, heterozygous in the parents, and absent from 100 unrelated control subjects from the same ethnic group. Using a polyclonal antibody, we found *LTBP2* to be strongly expressed in the calf ciliary zonule. Fibroblast cultures and lymphoblast cell lines from the affected siblings are under study. We conclude that the *LTBP2* truncating mutation reported here is a rare cause of microspherophakia with marfanoid features.

C02.4

Novel ARVD5 gene causes autosomal dominant sudden cardiac death due to missense mutations in the TMEM43 gene

T. Young¹, N. D. Merner¹, K. Hodgkinson¹, A. F. Haywood¹, W. McKenna², S. Connors¹, V. French¹, L. Thierfelder³, P. Syrris², P. Parfrey¹;

¹Memorial University, St. John's, NL, Canada, ²The Heart Hospital, London, United Kingdom, ³Max-Delbrück Centrum für Molekulare Medizin, Berlin, Germany.

Autosomal dominant arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) causes sudden cardiac death and is characterized by clinical and genetic heterogeneity. Fifteen unrelated ARVC families from Newfoundland's founder population were identified wherein patients with ARVC shared an ancestral haplotype on chromosome 3p (*ARVD5*). Identification of key recombination events and sequencing of the 20 annotated genes mapping within the *ARVD5* critical region identified one rare variant that resulted in a missense mutation in all patients from all families in Transmembrane Protein 43 (*TMEM43* 1073 C>T, S358L). This variant was not found in population-matched controls. Interestingly, *TMEM43* is not predicted to be a desmosomal protein. Although little is known about the function of the *TMEM43* protein in the cardiac myocyte, the gene contains a response element for PPAR γ (an adipogenic factor) which may explain the fibrofatty replacement of the myocardium, a characteristic pathological finding in ARVC, and may act upstream of the desmosomal proteins that cause other forms of ARVC. Results from full gene sequencing of *TMEM43* in a series of 150 ARVC probands from the UK will also be presented.

C02.5

Knock-out models in mice and men suggest a proatherogenic role for USF1

P. P. Laurila¹, K. Merikanto¹, J. Perttälä¹, J. Saharinen¹, M. Gentile¹, J. Naukarinen¹, P. K. Laurila², A. Tuomainen³, C. Ehnholm¹, V. M. Olkkonen¹, M. Jauhiainen¹, L. Peltonen^{1,4,5};

¹National Public Health Institute, Finland, Helsinki, Finland, ²Department of Pathology, Helsinki University Central Hospital, Helsinki, Finland, ³Institute of Dentistry, University of Helsinki, Helsinki, Finland, ⁴The Wellcome Trust Sanger Institute, Cambridge, United Kingdom, ⁵The Broad Institute of MIT and Harvard, Boston, MA, United States.

Disturbances in body lipid homeostasis are tightly linked with cardiovascular disease (CVD). We recently established the association of USF1 transcription factor with high blood triglycerides and cholesterol (Pajukanta et al, 2004).

We have generated a strain of *Usf1* knockout (-/-) mice which along with their +/- and +/- littermates (n=12) were fed with 'Western' diet rich in triglycerides (TG) and cholesterol for 8 weeks. After the diet *Usf1* -/- mice had significantly lower blood (p<0.05) and VLDL (p<0.01) TG than their +/- littermates. By using Affymetrix expression arrays, we observed that lipoprotein lipase (Lpl) mRNA levels were elevated (p<0.01) in -/- mice liver and muscle as compared to controls, consistent with the TG phenotype. In -/- mice adipose tissue, the cholesterol biosynthetic pathway was significantly down-regulated when compared to their +/- littermates.

We also established a cellular model representing USF1 knock-down, employing treatment of human hepatoma cells (HuH7) with USF1 siRNAs. We labeled the cells for 30 min with [3H]acetic acid, followed by a chase, and quantified the [3H]cholesterol and TG synthesized. A decreased amount of both [3H]cholesterol and TG (p<0.05) was observed in siRNA treated cells as compared to controls. Again, with Affymetrix microarrays we observed that several cholesterol biosynthetic pathway enzymes were down-regulated in USF1 knockdown cells.

Since the loss-of-function of USF1 caused a decrease in plasma TG in vivo as well as cholesterol and TG biosynthesis in vitro, we hypothesize that USF1 could be proatherogenic and its knockdown in appropriate tissues actually has a favorable cardiovascular effect.

C02.6

Disruptions of highly conserved, very distant regulatory elements on either side of SOX9 are associated with Pierre Robin sequence

¹MRC Human Genetics Unit, Edinburgh, United Kingdom, ²INSERM U-781, Hôpital Necker-Enfants Malades, Paris, France, ³Oral Health Research Group, Musculoskeletal Disorders Theme, Murdoch Children's Research Institute, Royal Children's Hospital, Parkville, Australia, ⁴Université Paris 5 René Descartes, Paris, France, ⁵Fundación Jiménez Díaz, Genética, Madrid, Spain, ⁶CHRU de Lille, Hôpital Jeanne de Flandre, Lille, France, ⁷Assistance Publique-Hôpitaux de Paris, Service de Chirurgie Maxillo-Faciale, Hôpital d'Enfants Armand Trousseau, Paris, France.

Most evolutionarily conserved human DNA has no protein-coding function but may have regulatory function. The mechanism of action and size of the domains controlled by these highly conserved non-coding elements (HCNE) remains largely unknown. We show here that disruption of very distant cis-regulatory HCNE on either side of *SOX9* gene causes Pierre Robin sequence (PRS), a common and important orofacial cleft anomaly with hypoplastic jaw. Evidence for an autosomal dominant PRS locus on 17q24 comes from linkage in a large PRS family and a cluster of breakpoints in three independent familial translocations mapping to gene desert 1.06-1.23 Mb centromeric to *SOX9*. We identified potential regulatory mutations via comparative genomic hybridization across a 3.6Mb conserved region surrounding *SOX9*. Heterozygous microdeletions involving one or more HCNEs were identified in three of eleven PRS patients 1.38-1.58 Mb up- or downstream of the *SOX9* gene. In one family a single non-polymorphic nucleotide change in a HCNE was found that altered transcription factor binding and enhancer function in vitro. Interphase FISH analysis of the orthologous region in 13.5 dpc mouse embryos showed that this

normally condensed genomic region demonstrates dynamic expression-dependent chromatin decondensation in the developing mandible. Normal development of the mandible thus requires the action of very long-distance cis-acting elements operating on both sides of the SOX9 promoter, at transcriptional and chromatin levels. The domain of action of tissue-specific cis-regulation appears to be very large indeed and this has significant implications for mutation analysis in human disease and genome biology

C03.1

Mitochondrial complex 3 deficiency associated with homozygous mutation in *UQCRQ*, encoding ubiquinol-cytochrome c reductase, complex III subunit VII, 9.5kDa

O. Barel¹, Z. Shore², H. Flusser², R. Ofri¹, G. Narkis¹, G. Finer¹, H. Shalev², A. Nasasra¹, O. S. Birk^{1,2};

¹National Institute for Biotechnology in the Negev, Beer-sheva, Israel, ²Soroka Medical Center, Beer-sheva, Israel.

A consanguineous Israeli Bedouin kindred presented with an autosomal recessive phenotype of severe psychomotor retardation and extrapyramidal signs, dystonia, athetosis and ataxia, mild axial hypotonia, marked global dementia with defects in verbal and expressive communication skills. Metabolic workup was normal except for mildly elevated blood lactate levels. Brain MRI showed increased density in the putamen, with decreased density and size of the caudate and lentiform nuclei. Reduced activity specifically of mitochondrial complex 3 was evident in muscle biopsies. Homozygosity of affected individuals to *UQCRB* and to *BCSIL*, previously associated with isolated complex 3 deficiency, was ruled out. Genomewide linkage analysis identified a homozygosity locus of ~9cM on chromosome 5q31 that was further narrowed down to 2.14cM, harboring 30 genes (LOD score 8.82 at $\theta=0$). All 30 genes were sequenced, revealing a single missense (Ser45Phe) mutation in *UQCRQ* (ubiquinol-cytochrome c reductase, complex III subunit VII, 9.5kDa), one of the 10 nuclear genes encoding proteins of mitochondrial complex 3.

C03.2

Genetic defects underlying autosomal recessive nonsyndromic hearing impairment in Turkey; three novel and five known genes

Autosomal recessive nonsyndromic hearing impairment (ARNSHI) is genetically highly heterogeneous. To date, about 70 loci for ARNSHI have been mapped; for 26 of these loci the causative gene has been identified.

Ninety-four Turkish families with ARNSHI were evaluated. Screening of the *GJB2* gene revealed mutations in 29 of the families. In a number of *GJB2*-negative families genome-wide homozygosity mapping was performed and in twelve of these families causative mutations were found in *TMC1*, *TMPRSS3*, *DFNB59*, *MYO15A* and *LHFPL5* (*TMHS*). The latter was novel. Four families were found to have syndromic forms of hearing loss with mutations in *SLC26A4* or *USH1G*.

In family TR21 the linkage interval partially overlapped with the previously described *DFNB35* locus. Sequencing of candidate genes in the overlapping region revealed a mutation in *ESRRB*. Screening of *ESRRB* in the original *DFNB35* family and in three other Pakistani *DFNB35*-linked families revealed four additional mutations. RNA *in situ* hybridization and immunohistochemical analyses indicate that *ESRRB* is essential for inner ear development and ion homeostasis.

In family TR56 a novel locus (*DFNB63*) was found. Combination of results which we obtained with the separately described *DFNB63* families narrowed the critical interval. Sequencing of the genes from this interval revealed four mutations in the *DFNB63* gene. In situ hybridization and RT-PCR analyses show expression of the *DFNB63* gene in inner ear and some other tissues.

Our results indicate that in 43 (48%) of the 90 ARNSHL families causative mutations distributed in eight different genes, of which *LHFPL5*, *ESRRB* and *DFNB63* were novel.

C03.3

Thromboxane synthase mutations in an increased bone density disorder (Ghosal syndrome)

Ghosal hematodiaphyseal dysplasia syndrome (GHDD) is a rare autosomal recessive disorder characterized by increased bone density with diaphyseal involvement, abnormal long bone modeling and cortical hyperostosis associated with aregenerative corticosenes anemia and chronic inflammation. Studying four consanguineous GHDD families, we first localized the disease locus gene on chromosome 7q33-q34 and then identified four distinct homozygous mutations in the thromboxane synthase gene (*TBXAS1*) which codes for thromboxane synthase (TXAS). The mutations segregated with the disease and were not identified in 210 chromosome controls. TXAS is an enzyme of the arachidonic acid (AA) cascade and converts prostaglandins H₂ into Thromboxane A₂ (TXA₂), which is a powerful inducer of platelet aggregation. We therefore investigated primary haemostasis in our subjects. No history of spontaneous bleeding disorder was reported but platelet studies from GHDD patients revealed a specific deficit in AA aggregation and platelet exocytosis. In addition, ELISAs detecting TXB₂-the metabolite of TXA₂-and PGE₂ showed low TXB₂ and high PGE₂ levels in patients, which might be responsible for anemia and inflammation observed in GHDD.

Finally, in order to elucidate the mechanism of increase bone density in GHDD, we investigated the effect of TXAS and TXA₂ on *RANKL* and *OPG* expression in primary cultured osteoblasts and found that adding a stable analog of TXA₂ markedly increased *RANKL* and decreased *OPG* while the addition of a specific inhibitor of TXAS had an opposite effect. These findings suggest that thromboxane synthase acts as a local regulator of bone resorption with a key function in bone remodeling.

C03.4

Congenital arthrogyriposis: autosomal recessive lethal congenital contractural syndrome caused by mutations in *PIP5K1C* and in *ERBB3*

G. Narkis¹, E. Manor², D. Landau², M. Volokita¹, K. Elbadour², O. S. Birk^{1,2};

¹National Institute for Biotechnology in the Negev, Beer-Sheva, Israel, ²Soroka Medical Center, Beer-sheva, Israel.

We demonstrate that mutations in genes associated with the phosphatidylinositol pathway cause lethal congenital contractural syndrome (LCCS), a neurogenic form of arthrogyriposis. We previously mapped

an autosomal recessive form of the disease (LCCS2, MIM 607598) in Israeli Bedouin kindred to chromosome 12q13. We now mapped a similar phenotype (LCCS3) in another Bedouin kindred to 3.4Mb on chromosome 19p13, demonstrating a homozygous mutation in *PIP5K1C*, encoding phosphatidylinositol-4-phosphate 5-kinase, type I, gamma (PIP1 γ), an enzyme that phosphorylates phosphatidylinositol 4-phosphate (PI4P) to generate phosphatidylinositol-4,5-bisphosphate (PIP2). The mutation abolishes the kinase activity of PIP5K1C. Based on this finding, we sequenced genes in the LCCS2 locus that encode proteins in pathways interacting with the phosphatidylinositol pathway. We demonstrate that LCCS2 is caused by a mutation in *ERBB3* (*Her3*) which is known to modulate PI3K, an enzyme that phosphorylates PIP2 to produce phosphatidylinositol-3,4,5-triphosphate (PIP3). Thus, a defect in the phosphatidylinositol pathway leading to decrease in synthesis of PIP2, a molecule active in endocytosis of synaptic vesicle proteins, culminates in lethal congenital arthrogryposis.

C03.5

Drastic reduction in the life span of cystatin C L68Q gene carriers due to life-style changes in the last two centuries

A. Palsdottir¹, A. Helgason^{2,3}, S. Palsson^{4,5}, H. T. Bjornsson⁶, B. T. Bragason¹, S. Gretarsdottir², U. Thorsteinsdottir^{2,7}, E. Olafsson^{8,7}, K. Stefansson^{2,7};

¹Institute for Experimental Pathology, Keldur, University of Iceland, Reykjavik, Iceland, ²DeCODE Genetics, Reykjavik, Iceland, ³Department of Anthropology, University of Iceland, Reykjavik, Iceland, ⁴Institute of Biology, University of Iceland, Reykjavik, Iceland, ⁵DeCODE Genetics, Reykjavik, Iceland, ⁶Johns Hopkins University School of Medicine, Baltimore, MD, United States, ⁷Faculty of Medicine, University of Iceland, Reykjavik, Iceland, ⁸Department of Neurology, LSH University Hospital, Reykjavik, Iceland.

Hereditary cystatin C amyloid angiopathy (HCCAA) is an autosomal dominant disease with high penetrance, manifest by brain hemorrhages in young normotensive adults. In Iceland, this condition is caused by the L68Q mutation in the cystatin C gene, leading to amyloid deposition in cerebral arterioles, ending in the death of contemporary carriers at an average age of only 30 years. Here, we report, based both on linkage disequilibrium and genealogical evidence, that all known copies of this mutation derive from a common ancestor born roughly 18 generations ago. Intriguingly, the genealogies reveal that obligate L68Q carriers, in all families, born 1825 to 1900 experienced a drastic reduction in life span, from 65 years to the present day average. At the same time, a parent-of-origin effect emerged, whereby maternal inheritance of the mutation was associated with a 9 year reduction in life span relative to paternal inheritance. As these trends can be observed in several different extended families, three centuries after the mutational event, it seems likely that some environmental factor is responsible, perhaps linked to radical changes in the life-style of Icelanders during this period. A mutation with such radically different phenotypic effects in reaction to normal variation in human life-style not only opens the possibility of preventive strategies for HCCAA, it may also provide novel insights into the complex relationship between genotype and environment in human disease.

C03.6

Greater than 1% of Contemporary West Africans are Carriers of a Founder Mutation for Severe Recessive Type VIII OI, Which Was Presumably Brought to America with the Colonial Slave Trade and Also Occurs in African-Americans

W. A. Cabral¹, A. M. Barnes¹, C. N. Rotim², L. Brody³, J. E. Bailey-Wilson⁴, F. D. Porter⁵, J. C. Marini¹;

¹Bone & Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD, United States, ²National Human Genome Center, Howard University, Washington, DC, United States, ³Molecular Pathogenesis Section, Genome Technology Branch, NHGRI, NIH, Bethesda, MD, United States, ⁴Statistical Genetics Section, Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD, United States, ⁵Heritable Disorders Branch, NICHD, NIH, Bethesda, MD, United States.

Classical Osteogenesis imperfecta (OI) is caused by a wide variety of dominant mutations, many de novo, in type I collagen and has an incidence of 1/20,000 births. Two recessive OI types, caused by defects in cartilage-associated protein (CRTAP) or prolyl 3-hydroxylase 1 (LEPRE1), account for approximately 5% of OI cases in North America. We identified a recurring mutation in LEPRE1, IVS5+1G>T (Nat Genet (2007) 39:359-365) in 6 probands (9/12 alleles) with severe/lethal recessive type VIII OI (OMIM #610915). All probands had carrier

parents who were African-Americans or contemporary West-African immigrants to USA, suggesting the existence of a mutant allele which had been transported to America with the colonial slave trade. To estimate the carrier frequency of IVS5+1G>T in African-Americans, we extracted genomic DNA from 1429 random African-American newborn metabolic screening cards from Pennsylvania. We identified 1/286 carriers (0.35%), predicting a possible incidence of lethal type VIII OI due to IVS5+1G>T homozygosity of 1/330,000 African-American births. Furthermore, genomic DNA from contemporary West Africans was screened by SNP assay, followed by PCR confirmation of positive samples. Fifteen of 1097 independent individuals (1.37%) from Nigeria and Ghana were heterozygous for IVS5+1G>T. This high carrier frequency suggests that the incidence of type VIII OI in West Africa from this mutation alone is equivalent to the incidence of dominant OI. Haplotype data on probands, carriers and unaffected sibs supports the occurrence of a common founder mutation over 300 years ago, consistent with our hypothesis on the transportation of this West African allele to the Americas.

C04.1

Copy number variations in patients with overgrowth syndromes detected by array-CGH

V. Malan^{1,2}, V. Cormier-Daire^{1,2}, S. Chevallier¹, C. Coubes³, D. Lacombe⁴, L. Pasquier⁵, J. Soulier⁶, N. Morichon-Delvallez^{1,2}, M. Vekemans^{1,2}, A. Munnich^{1,2}, L. Colleaux^{1,2};

¹Departement de Génétique et INSERM U781, Paris, France, ²Université Paris Descartes, Paris, France, ³CHU Hôpital Saint-Eloi, Montpellier, France, ⁴Service de Génétique Médicale, Centre Hospitalier Universitaire Pellegrin, Bordeaux, France, ⁵Unité de Génétique Clinique, Hôpital Sud, Rennes, France, ⁶Laboratoire d'Hématologie, Hôpital Saint-Louis, Paris, France.

Overgrowth syndromes are a heterogeneous group of conditions including endocrine hormone disorders, several genetic syndromes and many situations with thus far unexplained mechanisms. Interestingly, chromosomal deletions and duplications have been identified in patients with overgrowth such as dup(4)(p16.3), dup(15)(q26-qter) and del(9)(q22.32-q22.33). Thus, we hypothesized that the sensitivity of array-CGH could improve the genetic diagnosis of overgrowth conditions.

Sixty-five patients with unexplained overgrowth syndrome were analyzed using a 1 Mb resolution array-CGH. The patients were classified into two groups: group I (32 cases) includes patients with a clinically known syndrome (i.e Sotos syndrome or Simpson-Golabi-Behmel syndrome) whereas group II (32 cases) includes patients with unclassified overgrowth syndrome.

We detected eight possibly pathogenic imbalances (12,3%) among 2 patients belonging to group I and 6 patients belonging to group II. Two are deletions and 6 are duplications. No recurrent abnormality was identified. FISH analyses confirmed the chromosomal abnormalities in 5 cases while the remaining cases are still under investigation.

Firstly, these results demonstrate that array-CGH is able to provide a high diagnostic yield in patients with overgrowth syndrome. Secondly, while chromosomal deletions are most often associated with growth retardation, we found that the majority of the imbalances detected in our patients are duplications. Thirdly, careful re-examination of patients may allow the delineation of novel clinically recognizable overgrowth syndromes. Finally, besides their importance for diagnosis and genetic counseling, these data may pave the way to the search of genes involved in the pathogenesis of overgrowth.

C04.2

Design, implementation and results using diagnostic oligo array-cgh

J. A. Crolla^{1,2}, S. Huang², S. J. Beaf¹, V. Maloney², J. C. K. Barber²;

¹University of Southampton, Salisbury, United Kingdom, ²National Genetics Reference Laboratory (Wessex), Salisbury, United Kingdom.

Array-cgh is an essential tool for the detection, quantification and interpretation of cryptic copy number changes throughout the genome. Using Agilent Technology's eARRAY we have designed and customised a 60mer oligo array printed in 4x44K format (i.e. four 44,000 oligo arrays per slide). This constitutional array provides maximum even coverage of the genome and targets known microdeletion/duplication syndrome regions, is semi-automatable and provides a high-throughput platform for array-cgh. To date we have reported 350 diagnostic oligo arrays

(a) 85% ascertained following normal karyotypes but with idiopathic mental retardation, dysmorphism and/or congenital abnormalities; (b) 15% for further characterisation of visible chromosome abnormalities including apparently balanced translocations (ABCR), complex rearrangements (CCR) and supernumerary marker chromosomes (SMC). We have detected copy number changes (ranging in size from 88 Kb - 5 Mb) in 25% of ascertainment group (a), including a number of previously unreported de novo abnormalities. The majority of group (b) cases were found to have deletions or duplications not detected by light microscopy (ABCR and CCR), or arrays resolved their chromosomal origin and composition (SMC). Interpretation of array-cgh results remains challenging and the increasing use and resolution of this technology suggests that it may soon replace karyotyping for some primary ascertainment groups.

C04.3
The challenge of interpreting microduplications detected by arrayCGH

C. M. A. van Ravenswaaij-Arts, B. Leegte, T. Dijkhuizen, R. Hordijk, I. Stolte-Dijkstra, M. de Jong, M. Kerstjens-Frederikse, K. Kok, B. Sikkema-Raddatz;
 Department of Genetics, University Medical Center, Groningen, The Netherlands.

The decision whether arrayCGH copy number alterations are causative for the phenotype comprises a number of steps: exclusion of known polymorphisms, confirmation by MLPA/FISH, analyzing parental samples, and a literature/database search to compare the phenotype with cases with similar genotypes. The interpretation of microduplications is difficult. FISH confirmation is technically not always possible and specific MLPA primers have to be constructed. The phenotype is usually variable and thus inheritance from a (near) normal parent does not always exclude a causal relationship. The scarcity of published cases is also a well known problem.

We analysed 300 karyotypically normal MR/MCA patients with an in house 6500k BACarray. We detected, besides polymorphic CNV's, 38 microduplications (0.3-7.3Mb) in 35 patients. In 28 cases FISH resulted in 18 confirmed (1.4-7.3Mb) and ten non-confirmed (0.3-3.4Mb) duplications. In eight of the ten non-confirmed cases the duplication was shown to be inherited by arrayCGH, demonstrating that FISH is not always suitable for confirming duplications. Three FISH non-confirmed duplications were tested and confirmed by MLPA. For 26 duplications the parents were tested: 19 were inherited (0.5-4.14Mb) and seven were *de novo* (0.3-7.3Mb). Upon re-evaluation one mother appeared to have a similar phenotype as her affected son. Of the 38 microduplications six still need confirmation, seven need parental testing, 18 are inherited from a phenotypically normal parent and three could not be confirmed. So far four seem to be clinically relevant; the *de novo* duplications 9p24.3, 17p13.3, and 19q13.31q13.32, and a maternally inherited duplication 22q13.3. Clinical information will be presented.

C04.4
Array-CGH analysis of MCA/MR patients: identification of 5 novel microdeletion syndromes

F. T. Papa, E. Katzaki, M. A. Mencarelli, R. Caselli, V. Uliana, M. Pollazzon, K. Sampieri, I. Longo, F. Ariani, I. Meloni, F. Mari, A. Renieri;
 Medical Genetics, Siena, Italy.

We have investigated 84 patients with mild to severe mental retardation associated to facial dysmorphisms and/or congenital anomalies. All patients had a normal karyotype and have been evaluated by clinical geneticists (AR and FM) who excluded a recognizable syndrome on a clinical ground. Using 105K oligo Array-CGH a mean of 5 CNVs/patient were identified. These ranged in size from 62Kb to 1Mb and they are reported in the databases as benign polymorphisms. Private imbalances were detected in 24 out of 84 patients. In 10 cases (12%) a private rearrangement was inherited from one healthy parent. In 14 cases (16.5%) the rearrangement was de novo: 5 were novel deletions (Tab.1, cases 1-5) and 9 were known syndromes in atypical cases (Tab.1, cases 6-14). The last group included three cases of 22q11 deletions, the shortest 4p- known in the literature, and one case of Potocki-Lupski. The five novel de novo deletions ranged between 2.6 and 13.9Mb and they overlapped with polymorphic regions for an extent of 5-48%. Only two (6q24.3-q25.1 and 7q36.1-q36.2) are flanked by LCRs. An accurate search of the literature allowed to identify additional patients with overlapping deletions. Comparative analysis of the

phenotype of these patients with our patients suggested that a specific phenotype of these syndrome may be defined. These characteristics should be taken into account in order to identify additional patients.

C04.5
Towards an improved genetic diagnosis of individuals with a congenital heart defects

B. Thienpont¹, L. Tranchevenet², P. Van Loo^{1,2}, J. Breckpot¹, M. Gewillig³, Y. Moureaux², K. Devriendt¹;

¹Center for Human Genetics, Leuven, Belgium, ²Department of Electrical Engineering, ESAT-SCD, Leuven, Belgium, ³Pediatric Cardiology Unit, Leuven, Belgium.

Detection of submicroscopic chromosomal imbalances by array-CGH opens opportunities in diagnostics as well as in the identification of novel loci involved in the patients phenotype. We analysed 130 patients with idiopathic 'syndromic' congenital heart defects (CHDs) by array-CGH with a 1Mb resolution. Causal chromosomal abnormalities were detected in 22/130 patients (17%).

In some of the regions, genes known to cause CHDs upon mutation are found: TBX1, NKX2.5, GATA4, NSD1, EHM1, NOTCH1, ATRX and CBP. In the remaining regions no genes are known to cause CHDs, and they thus represent novel loci linked to CHDs. To identify the causal genes, the genes in imbalanced regions were first scored for their potential involvement in cardiogenesis using a tailored modular prioritisation algorithm based on ENDEAVOUR (Aerts et al, Nat Biotech 24 p 537). We first added expression microarray data of murine cardiogenesis to the ENDEAVOUR framework. We next constructed 6 different training sets related to different aspects of CHDs or cardiogenesis. Leave-one-out cross-validations determined which data sources contain relevant information for prioritization of genes related to that process. Next we fused these different prioritizations (of one candidate gene set, using different training sets) into one overall prioritization. We validated the prioritisation of ENDEAVOUR by expression analysis in zebrafish. 45 of the highest-ranking genes were analysed. As a positive control we analysed expression of some of the identified genes known to cause CHDs. Two strong candidate genes for CHDs emerge from these analyses: BMP4 and HAND2.

C04.6
Information management for constitutional cytogenetics: tools for ArrayCGH in a clinical diagnostic context

S. W. L. A. Van Vooren¹, B. Coessens¹, J. R. Vermeesch², Y. Moreau¹;

¹K.U.Leuven, ESAT/SCD (SISTA), Heverlee, Belgium, ²Center for Human Genetics, Leuven University Hospital, Leuven, Belgium.

As Microarray-CGH is introduced into clinical practice for identification of submicroscopic genomic aberrations, tools to handle related data become essential for clinical geneticists and biomedical researchers alike. We have developed Bench, a web application that combines a constitutional cytogenetics database and tools for search, visualisation, genome annotation, automated genotype-phenotype linkage,

reporting, and literature mining.

Array-CGH technology is currently on its way to replace classical karyotyping as primary diagnostic tool in copy number screening. Its vast importance in clinical diagnosis and research are underlined by large number of genes in human development and disease still unknown. A data storage and mining tool aimed specifically at leveraging the power of Array-CGH in a clinical context will aid aetiology of rare and complex genetic diseases by characterising genomic rearrangements, annotating and analysing clinical features, and providing advanced data mining and integration. For example, through an automated analysis of PUBMED abstracts, Bench allows to prioritize candidate genes in genomic deletions and duplications by phenotype characteristics annotated to the patient. Also, known Copy Number Variations, genes and their functions, and other genome annotations, when integrated with patient related data, aid in diagnosis and aetiology of new submicroscopic chromosomal imbalance syndromes.

Bench provides a collaborative Array-CGH LIMS system that allows to maintain records of phenotype and chromosome rearrangements in patients, augmented with data mining, reporting and visualisation facilitating research, diagnostics, research and genetic counseling by involving relevant information from a variety of sources. Bench can be used free of charge in a research collaboration. <http://www.esat.kuleuven.be/cghgate/>.

C05.1

Functional interactions of conserved non-coding (CNC) sequences with other CNC using circular chromosome conformation capture (4C)

D. Robyr, G. Duriaux-Sail, S. E. Antonarakis;

University of Geneva Medical School, Geneva, Switzerland.

The comparison of human chromosome 21 (Hsa21) sequences with the mouse syntenic regions led to the identification of roughly 3500 regions displaying an identity of >70% over a length of a least 100 nucleotides of ungapped alignment. About 65% (~ 2300) of these are conserved non-coding sequences (CNCs). Very little is known about the function of most CNCs. We speculated that a functional CNC may interact with its genomic target (i.e. an enhancer would bind to its cognate gene promoter). Thus, the identification of any part of the genome that interacts directly with a CNC could provide clues on the function of the latter. We have generated libraries of CNC-interacting DpnII fragments by chromosome conformation capture (4C) whose identity is determined by subsequent high-throughput sequencing.

We are currently screening for the interactions of 18 CNCs located in the two ENCODE regions of HSA21 in different cell lines. Preliminary results for two CNCs in K562 cells indicate that these may interact near regions of the genome that show conservation among vertebrates. Indeed, the median distances from the sequenced DpnII fragments to the nearest conserved region are 381.5 bp ($P = 0.0583$) and 764bp ($P = 0.023$) respectively for the 2 CNCs analysed. These results provide initial evidence that the function of CNCs is mediated by their interactions with other conserved regions. Interestingly, these CNCs are capable of interactions with loci not only in cis and over several Mb, but also in trans with loci located on other chromosomes.

C05.2

A high-resolution structural variation map of a human genome by next-generation, high-throughput paired-end sequencing

F. M. De La Vega¹, H. E. Peckham², S. S. Ranade², S. F. McLaughlin², C. C. Lee², Y. Fu², Z. Zhang¹, F. C. L. Hyland¹, C. L. Clouser², A. A. Antipova², J. M. Manning², C. L. Hendrickson², L. Zhang², E. T. Dimalanta², T. D. Sokolsky², M. W. Laptewicz², B. E. Coleman², J. K. Ichikawa², J. B. Warner², B. Li¹, J. M. Kidd¹, J. A. Malek⁴, G. L. Costa², E. E. Eichler³, K. J. McKernan²;

¹Applied Biosystems, Foster City, CA, United States, ²Applied Biosystems, Beverly, MA, United States, ³HHMI, University of Washington, Seattle, WA, United States, ⁴Weill Cornell Medical College in Qatar, Doha, Qatar.

The human genome and HapMap projects have considerably increased our understanding of the role of sequence variation in evolution and disease. Hybridization microarrays and fosmid-end sequencing reveal that structural variants (SVs) including insertions, deletions, duplications, inversions and translocations are common and extensive. Microarray methods, however, lack resolution and are blind to unbalanced events, while clone-based end-sequencing is time consuming and expensive. Here, we present a high-resolution survey of SVs of a

human genome, a HapMap Yoruba sample (NA18507), by ultra-high throughput sequencing of paired-end libraries with the AB SOLiD(TM) System. We sequenced a variety of 2x25-bp paired-end libraries (>15Gb) with insert sizes ranging from 600bp to 6kb (SD 10-23%). Each library provides over 10x physical (clone) coverage, with a total combined physical coverage >60x for 90% of the genome. The high physical coverage and diverse insert sizes allowed detecting small indels within tags (1-10 bp), and approximately 70,000 indels of length 20 bp to >100 kb. Additionally, we sequenced 7Gb of 50-bp fragment libraries, which combined with the paired libraries provided over 12x sequence coverage, allowing us to discover millions of SNPs of which 75% are found in dbSNP. Inferred SVs were compared to a database of end-sequence pairs of 10x physical coverage obtained by di-deoxy sequencing of 40kb fosmid ends. A subset of novel SVs were validated by PCR and Sanger sequencing. Our results serves as a model for further high-resolution exploration of genetic variation in human populations and cancer with next-generation sequencing.

C05.3

Expression analysis using deep Solexa sequencing shows major advances in robustness, resolution and inter-lab portability over microarray platforms

J. T. den Dunnen^{1,2}, Y. Ariyurek², H. H. Thygesen¹, E. Vreugdenhil³, J. M. Boer¹, G. B. van Ommen¹, P. A. C. 't Hoen¹;

¹Human and Clinical Genetics, Leiden, The Netherlands, ²Leiden Genome Technology Center, Leiden, The Netherlands, ³Medical Pharmacology, Leiden / Amsterdam Center for Drug Research, Leiden, The Netherlands.

The hippocampal transcriptomes of wild-type mice and mice transgenic for δ C-doublecortin-like kinase were analyzed with the Solexa deep sequencing technology. We determined around 2 million sequence tags per sample and compared these data with results of the same samples analysed using five different microarray platforms. Seventy percent of the sequence tags were mapped to approximately 30,000 unique, high-confidence transcripts, their abundance spanning four orders of magnitude. Antisense transcription, undetectable by microarrays, was found in 51% of all genes, and alternative poly-adenylation in 47%. With a dedicated Bayesian model and false discovery rate of 8.5%, we measured statistically significant differential expression for 3179 transcripts; many more and with higher fold-changes than observed using microarrays. The deep sequencing technology demonstrates superb reproducibility, not only between biological replicates but even across laboratories. The described major advance in robustness, comparability and richness of sequence-based transcriptomics data is expected to boost in-depth collaborative, comparative and integrative genomics studies.

C05.4

Studying gene dosage imbalance in embryonic stem cells

G. Cobellis^{1,2}, A. Romito¹, R. De Cegli¹, S. Iacobacci¹, A. Fedele¹, D. di Bernardo¹, A. Ballabio¹;

¹TIGEM, Napoli, Italy, ²Second University of Naples, Naples, Italy.

To gain insight into the alterations of the transcriptional pathways underlying the pathogenesis of Down syndrome, we decided to use an integrated strategy combining the systematic overexpression of chromosome 21 genes in ES cells, transcriptome analysis and systems biology approaches.

We generated an ES cell clone bearing an inducible/exchangeable cassette in the ROSA26 locus to be used to insert, one by one, every murine orthologs of human chromosome 21 genes. Using this flexible system, we developed a library of ES cells over-expressing, in an inducible manner, murine orthologs of human transcription factors, kinases and miRNAs mapping on HSA21 in order to perturb the physiological genetic network at the cellular level. The biological pathways affected by the over-expression of each coding and non-coding gene and their regulators and regulated genes have been inferred using system biology approach. We already mapped the regulatory gene networks specifically altered by each transcription factors and kinases, opening new hypothesis toward the understanding of pathogenesis of Down syndrome.

Finally, the above-described ES cell lines have been used to study the gene dosage imbalance effects on ES cell differentiation to cardiomyocytes, myeloid and neuronal lineages, tissues affected by the DS.

This project represent the first to involve a systematic overexpression

of all individual genes from a single human chromosome (HSA21) in mouse ES cells to identify the effects of gene dosage imbalance on the global transcriptome and on the ability of pluripotent ES cells to differentiate into lineages relevant to human aneuploidy phenotypes.

C05.5

A large human miRNA library screen reveals a potential role of miRNAs in the fine tuning of fibrinogen levels

A. Fort¹, C. Borel¹, R. J. Fish¹, S. E. Antonarakis¹, M. Neerman-Arbez^{1,2};

¹University Medical Center, Geneva, Switzerland, ²Division of Angiology and Haemostasis, University Hospital, Geneva, Switzerland.

In humans, plasma fibrinogen levels are maintained between 2-4 g/L with a wide variability in the population. Here, we addressed the role of microRNAs in the regulation of fibrinogen gene expression by screening the regulatory potential of 471 human microRNAs (from the ~1'000 annotated miRNAs in the human genome) on all five fibrinogen transcript 3'UTRs (FGA, FGA α -E, FGB, FGG and FGG'). For this purpose, we cloned each fibrinogen 3'UTR behind a firefly luciferase reporter gene. Co-transfections in HEK-293 cells included one of the firefly luciferase reporter gene constructs, a microRNA precursor and a transfection efficiency control (expressing renilla luciferase). The regulatory effects of microRNAs on each fibrinogen 3'UTR was calculated by dividing the ratio of luciferase intensities (firefly/renilla) of each transfection with a microRNA by the ratio from a reaction without microRNA. We also screened human liver RNA for expression of 362 microRNAs, by qPCR. 57% of the tested microRNAs are expressed in the liver. With these experiments, we identified 8 microRNAs, expressed in the liver, showing -13% to -40% down-regulating potential; 4 of these acting specifically on FGA, 2 on FGB, 1 acting on FGA and FGG and 1 down-regulating all fibrinogen 3'UTRs. None of these microRNAs showed an effect on the control firefly luciferase vector lacking a 3'UTR, demonstrating fibrinogen 3'UTR-specific down-regulation potential. We also detected 16 liver-expressed microRNAs with up-regulating potential of + 16% to + 176%. Ongoing experiments are assessing the effects of these candidate microRNAs on endogenous fibrinogen synthesis in HepG2 cells.

C05.6

Visualization of molecular interactions *in situ*, with single-molecule resolution

O. Söderberg;

Uppsala University, Uppsala, Sweden.

New, powerful techniques are required to observe individual protein molecules and their interactions *in situ*, in order to analyze, with high precision, in which cells the interacting proteins are located, and in what sub-cellular compartments.

We therefore developed a method called *in situ* proximity-ligation assay (*in situ* PLA) that requires multiple recognition events, by a pair of antibodies, for detection. By conjugating DNA-strands to the antibodies we convert the binding of the antibodies to a protein or a protein complex into an amplifiable DNA molecule, thus increasing both the selectivity and sensitivity of the assay. Rolling-circle amplification generates a concatemeric product for localized detection by fluorescently labeled probes. Using the *in situ* PLA, we could detect interactions between two (c-Myc/Max) and three (c-Myc/Max/RNA pol II) endogenous proteins, visualizing the active fraction of c-Myc as it exert its function in promoting gene transcription (Söderberg *et al.* *Nature Methods*, 2006), as well as post-translational modifications, i.e. phosphorylation of PDGFR β , in cultured cells and fresh frozen tissues sections *in situ* (Jarvius *et al.* *Molecular & Cellular Proteomics*, 2007). *In situ* PLA is applicable for detection of all types of biomolecules (e.g. proteins, DNA and RNA) and interactions thereof, allowing detection and enumeration of biomolecules within cells and tissue, at a single-molecule resolution. As the read-out of the method is based upon DNA amplifications, *in situ* PLA can easily be multiplexed for simultaneously detection of multiple analytes. *In situ* PLA provides a unique opportunity to monitor interaction patterns for diagnostic purposes.

C06.1

Mutations in the Cyclin family member FAM58A cause a novel X-linked dominant disorder characterized by syndactyly, telecanthus, anogenital and renal malformations (STAR syndrome)

J. Kohlhas¹, D. Boehm¹, F. J. Kaiser², S. Kaulfuss³, W. Borozdin¹, K. Buiting⁴, P. Burfeind⁵, J. Boehm⁵, F. Barrionuevo⁵, A. Craig⁶, K. Borowski⁶, K. Keppler-Noreuil⁷, T. Schmitt-Mechelke⁷, B. Steiner⁸, D. Barthold⁹, G. Mortier⁹, R. Sandford¹⁰, B. Zabel¹¹, A. Superti-Furga¹¹, S. Unger^{6,11};

¹Center for Human Genetics Freiburg, Freiburg, Germany, ²University Clinic Schleswig-Holstein, Campus Luebeck, Luebeck, Germany, ³Human Genetics, University of Goettingen, Goettingen, Germany, ⁴University Clinic Essen, Essen, Germany, ⁵Human Genetics, University of Freiburg, Freiburg, Germany, ⁶Medical Genetics, University of Iowa, Iowa City, IA, United States, ⁷Neuropediatrics, Kinderspital Luzern, Luzern, Switzerland, ⁸Medical Genetics, University of Zurich, Schwerzenbach, Switzerland, ⁹Medical Genetics, University of Ghent, Ghent, Belgium, ¹⁰Medical Genetics, University of Cambridge, Cambridge, United Kingdom, ¹¹Pediatrics, University Clinic Freiburg, Freiburg, Germany.

We recently identified four girls with a consistent constellation of toe Syndactyly, Telecanthus, Anogenital and Renal malformations, and we propose the name STAR syndrome for this condition. A single mother-daughter pair had previously been reported by Green *et al.* with a similar combination of malformations. The authors noted that this condition was autosomal dominantly inherited and overlapping with but distinct from Townes-Brocks syndrome (OMIM #601446). Array CGH performed with DNA of one of our patients revealed a de novo heterozygous deletion of 37.9-50.7 kb including exons 1 and 2 of the gene FAM58A on Xq28, and qPCR detected a de novo deletion of FAM58A exon 5 in a second case. Point mutation analysis revealed one truncating and two splice mutations in FAM58A in three further cases including the family reported by Green thus confirming this disorder as a distinct recognizable X-linked dominant condition. FAM58A encodes a Cyclin box fold domain, and in accordance with that siRNA mediated knockdown in cultured cells revealed a proliferation defect. FAM58A interacts with SALL1 but not SALL4 as determined by co-immunoprecipitation, corresponding to the close phenotypic overlap with Townes-Brocks syndrome.

C06.2

KCNQ2 mutations and implications for counselling and perinatal care in Benign Familial Neonatal Convulsions

N. Verbeek¹, M. Poot¹, W. Arts², K. Flipsen-ten Berg¹, B. Gunning³, D. Lindhout¹, M. van Kempen¹;

¹Division of Biomedical Genetics, Utrecht, The Netherlands, ²Erasmus MC, Rotterdam, The Netherlands, ³Epilepsy Centre Kempenhaeghe, Heeze, The Netherlands.

Background: Benign familial neonatal convulsions (BFNC) is an autosomal dominantly inherited form of epilepsy characterized by seizure onset around the third day of life, spontaneously resolving within a few months. In general, psychomotor development is normal, but 10-15% of patients develop epilepsy later in life. BFNC is caused by mutations in the voltage-gated potassium channel subunit gene KCNQ2 (20q13.3) or, less frequently, KCNQ3 (8q24). Purpose of this study is to determine the frequency of KCNQ2-mutations in BFNC families and sporadic cases.

Methods: MLPA- and sequence analysis of the KCNQ2 gene was performed in 28 probands/families with neonatal seizures. Larger deletions were analysed with Infinium humanhap300 SNP-array. Phenotypic details were provided by the referring physician.

Results: In eleven families and three sporadic cases, three missense, eight frameshift or nonsense mutations, and three large deletions were detected. All large deletions (ranging from 49 to 479 kbp) contained one to fourteen annotated genes, including the frontal lobe epilepsy gene, CHRNA4, in two families. Associated mental retardation (without active epilepsy), autism or (febrile) seizures later in life, occurred in multiple families. Perinatal mutation analysis was performed in two families.

Conclusions: Mutations were found in 50% of probands with (benign) neonatal convulsions. Large deletions comprise a substantial portion (21%) of KCNQ2-mutations. Mutation detection in neonates with benign convulsions can prevent superfluous diagnostic procedures. Furthermore, perinatal mutation analysis in sibs with 50% risk to BFNC could significantly improve perinatal management.

C06.3

Clinical features of maternal uniparental disomy 14 are also present in patients with an epimutation and a deletion of the imprinted *DLK/GTL2* gene cluster

G. Gillissen-Kaesbach¹, D. Kamber², J. I. Martin-Subero³, W. Lieb⁴, P. Terhaf⁵, B. Albrecht⁶, E. Rossier⁶, D. Rita⁶, S. Das⁷, S. Purmann¹, S. Groß⁸, C. Licht⁹, R. Sieber⁶, B. Horsthemke², K. Buiting²;

¹Institut für Humangenetik, Universität zu Lübeck, Lübeck, Germany, ²Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany, ³Institut für Humangenetik, Christian Albrecht Universität Kiel, Kiel, Germany, ⁴Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands, ⁵Institut für Humangenetik, Universitätsklinikum Tübingen, Tübingen, Germany, ⁶The Park Site Center, Park Ridge, Illinois, IL, United States, ⁷Department Of Human Genetics, University of Chicago, Chicago, IL, United States, ⁸Institut für Humangenetik, Christian Albrecht Universität Kiel, Kiel, Germany. Maternal uniparental disomy 14 [upd(14)mat] is associated with a recognizable phenotype that includes pre- and postnatal growth retardation, neonatal hypotonia, feeding problems and precocious puberty. Chromosome 14 contains an imprinted gene cluster, which is regulated by a differentially methylated region (IG-DMR) between *DLK1* and *GTL2*. Here we report on six patients with clinical features of maternal upd(14)mat who show a typical methylation pattern at the IG-DMR and the *GTL2* promoter region, but biparental inheritance for chromosome 14. In five of the patients loss of paternal methylation appears to be a primary epimutation, whereas the other patient has a paternally derived deletion of ~1 Mb that includes the imprinted *DLK-GTL2* gene cluster. These findings demonstrate that the upd(14)mat phenotype is caused by altered expression of genes within this cluster.

C06.4

Capillary Malformation - Arteriovenous Malformation: clinical and molecular aspects

N. Revencu^{1,2}, L. M. Boon^{1,3}, J. B. Mulliken⁴, O. Enjolras⁵, M. Cordisco⁶, P. E. Burrows⁴, P. Clapuyt⁷, F. Hammer⁸, J. Dubois⁹, E. Baselga⁹, D. Chitayat¹⁰, M. Vikkula¹;

¹de Duve Institute, Brussels, Belgium, ²Center for Human Genetics, Cliniques universitaires Saint Luc, Brussels, Belgium, ³Vascular Anomalies Centre, Division of Plastic Surgery, Cliniques universitaires Saint Luc, Brussels, Belgium, ⁴Vascular Anomalies Center, Children's Hospital, Boston, MA, United States, ⁵Centre Multidisciplinaire des Angiomes de l'enfant, Hôpital d'enfants Armand-Trousseau, Paris, France, ⁶Department of Pediatric Dermatology, Hospital de Pediatría Dr. J.P. Garrahan, Buenos Aires, Argentina, ⁷Department of Radiology, Cliniques universitaires Saint Luc, Brussels, Belgium, ⁸Department of Medical Imaging, Sainte-Justine Mother-Child University Hospital, Montreal, QC, Canada, ⁹Hospital de la Santa Creu I Sant Pau, Barcelona, Spain, ¹⁰Medical Genetics Program Mount Sinai Hospital, Toronto, ON, Canada.

Background: Mutations in *RASA1* were documented in 6 families (39 individuals) with autosomal dominant multifocal capillary malformations (CMs). Nine individuals had an associated arteriovenous malformation/fistula (AVM/AVF). One patient had Parkes Weber syndrome (PKWS), a disorder considered to be sporadic and non-genetic.

Methods: We collected clinical information and DNA samples for 61 probands (from 21 centers) and their families with a phenotype similar to that observed in the original study: 56 had multifocal CMs, and 35 also a fast-flow vascular anomaly: 19 AVM/AVF and 16 PKWS; 5 had PKWS without multifocal CMs. *RASA1* was screened by DHPLC followed by sequencing.

Results: We identified 42 distinct mutations in 44/61 probands: 16/19 with AVM/AVF, 13/16 with PKWS, 15/21 with multifocal CMs only, and 0/5 with PKWS without multifocal CMs. *RASA1* mutation was also found in 57 relatives. Overall, 17 individuals with a *RASA1* mutation had an AVM/AVF: 8 were intracranial, 2 of which were vein of Galen aneurysmal malformations. Moreover, 7 patients had either a benign or a malignant tumor, 3 of which are known to occur in neurofibromatosis type 1 or 2. Penetrance of *RASA1* mutations was 98% and de novo occurrence was 32%.

Conclusions: Multifocal CM is the hallmark of *RASA1* mutation. These patients often have extra- or intracranial AVM/AVF. This study confirms the original association designated capillary malformation-arteriovenous malformation (CM-AVM). In addition, PKWS, as well as vein of Galen aneurysmal malformation are genetic diseases, part of the CM-AVM spectrum. Specific neural tumors also may be linked to *RASA1*.

C06.5

A novel, autosomal dominant, Pseudoxanthoma Elasticum-like phenotype in a five-generation family

P. D. Turnpenny¹, O. M. Vanakke², L. Costrop², A. de Paepe², L. Schurgers³, R. Florijn⁴, F. M. Pope⁵, M. James⁶, S. Tomkins⁶, P. Newman⁷, S. Ellard⁸, E. Young⁸, M. L. P. Robert¹;

¹Peninsula Clinical Genetic Service, Exeter, United Kingdom, ²Center for Medical Genetics, Ghent University, Ghent, Belgium, ³VitaK & CARIM, University of Maastricht, Maastricht, The Netherlands, ⁴The Netherlands Ophthalmic Research Institute, Amsterdam, The Netherlands, ⁵Northwick Park Health Institute, London, United Kingdom, ⁶South Western Regional Genetics Service, Bristol, United Kingdom, ⁷Dept Histology, Royal Devon & Exeter Hospital, Exeter, United Kingdom, ⁸Molecular Genetics, Royal Devon & Exeter Hospital, Exeter, United Kingdom.

Pseudoxanthoma elasticum (PXE) is an autosomal recessive (AR) progressive disorder of elastic fibres characterised by dermal, ocular and vascular lesions, due to mutations in *ABCC6*, an ATP-binding cassette transporter, in ~80% of cases. Autosomal dominant (AD) inheritance is very rare and usually due to pseudodominance (Plomp et al. 2004). We studied 17 individuals from a 5-generation family with PXE-like skin manifestations. Many subjects also suffer premature claudication pain and ischaemic heart disease but they do not have typical PXE ophthalmic signs. Electron microscopy analysis of skin was normal except in one patient who had fragmentation and clumping of elastic fibres with no evidence of calcification. Sequencing of *ABCC6* was negative and linkage to this locus excluded. Vanakker et al (2007) reported *GGCX* mutations in 3 families with an AR PXE-like phenotype and vitamin K-dependent coagulopathy. Our family has no history of abnormal bleeding, clotting assays were normal in one affected individual, and sequencing of *GGCX* and *VKORC1* was normal. Immunohistochemistry of lesional skin tissue showed disturbance in the gamma-carboxylation of vitamin K-dependent mineralization inhibitors, particularly matrix gla protein (MGP). This suggests involvement of a related pathway as in the PXE-like phenotype of Vanakker et al (2007). Genome-wide linkage results, and candidate gene sequencing, are awaited. This 5-generation family with a PXE-like phenotype demonstrates unequivocal AD inheritance. We believe this is a previously unreported clinical and genetic entity, the pathogenesis of which may provide new information on the molecular pathways involved in PXE and related disorders.

C06.6

Clinical phenotypes and outcome of 101 LMNA gene mutation carriers

N. Marziliano¹, M. Pasotti¹, M. Grasso¹, A. Pilotto¹, E. Serafini¹, B. De Giorgio¹, M. Diegoli², A. Brega³, E. Arbustini¹;

¹Fondazione IRCCS Policlinico San Matteo, PAVIA, Italy, ²University of Pavia, PAVIA, Italy, ³University of Milan, MILANO, Italy.

Background. Lamin A/C (LMNA) gene mutations cause a variety of phenotypes. In the cardiologic setting, patients diagnosed with idiopathic dilated cardiomyopathy (DCM) plus atrio-ventricular block (AVB) constitute the majority of reported cases.

Methods. This was a longitudinal retrospective study conducted in 32 consecutive families in which LMNA gene defects were identified in the probands, sharing DCM (n=31) and ARVD (n=1) phenotype.

Results. Of the 171 family members, 101 were carriers of LMNA gene mutations. 65 of 101 (64.5%) were phenotypically affected while 36 were only genotypically affected, including 5 with preclinical signs. The 65 patients had DCM with AVB (n=44), DCM with Ventricular Tachycardia/Fibrillation (VT/VF) (n=12), DCM with AVB and Emery-Dreifuss Muscle Dystrophy type 2 (EDMD2) (n=6), AVB plus EDMD2 (n=2) and ARVD (n=1). The disease was proven to be familial autosomal dominant (AD) in 23 of the 32 families; likely familial AD in 6 and associated with a de novo mutation in 3. During a median follow-up of 57.4 months (interquartile range 26-115 months) we observed 54 events in 47 DCM patients (7 had a later event excluded from the analysis) whereas no event was observed among the 36 non-affected carriers. The events were related to heart failure.

Conclusions. DCMs caused by LMNA gene defects are highly penetrant, adult-onset, malignant diseases characterized by high rate of HF and life-threatening arrhythmias predicted by NYHA class, competitive sport activity and type of mutation. We also found a LMNA gene defect associated with an ARVD clinical phenotype.

C07.1**Oligosaccharyltransferase subunits mutations in non-syndromic mental retardation**

F. Molinari¹, F. Foulquier², P. S. Tarpey³, W. Morelle², J. Teague³, S. Edkins³, P. A. Futreal³, M. R. Stratton³, G. Turner⁴, G. Matthijs⁵, J. Gecz⁶, A. Munnich¹, L. Colleaux¹;

¹INSERM U781 and Université Paris Descartes, Paris, France, ²UMR CNRS/USTL 8570, Lille, France, ³Wellcome Trust Sanger Institute, Cambridge, United Kingdom, ⁴The Gold Service, Adelaide, Australia, ⁵Laboratory for Molecular Diagnostics, Center for Human Genetics, Leuven, Belgium, ⁶Department of Pediatrics and School of Molecular & Biomedical Science, University of Adelaide, Adelaide, Australia.

Mental Retardation (MR) is the most frequent handicap among children and young adults. While a large proportion of X-linked MR genes have been identified, only four genes of autosomal recessive non-syndromic MR (AR-NSMR) have been described so far.

Here, we report on two new genes involved in autosomal and X-linked NSMR. First, autozygosity mapping in two sibs born to first cousin French family led to the identification of a region on 8p23.1-p22. This interval encompasses the gene *N33/TUSC3* encoding one subunit of the oligosaccharyltransferase (OTase) complex which catalyses the transfer of an oligosaccharide chain on nascent proteins, the key step of N-Glycosylation. Sequencing *N33/TUSC3* identified a one base-pair insertion, c.787_788insC, resulting in a premature stop codon, p.N263fsX300, and leading to mRNA decay. Surprisingly, glycosylation analyses of patient fibroblasts showed normal N-glycan synthesis and transfer. Subsequently, screening the X-linked *N33/TUSC3* paralog, the *IAP* gene, identified a missense mutation (c.932T>G, p.V311G) in two brothers with X-linked NSMR. Interestingly, quantitative RT-PCR analyses showed increased *IAP* expression in *N33/TUSC3* mutated cells, suggesting that normal N-glycosylation observed in patient fibroblasts may be due to functional compensation.

Recent studies of fucosylation and polysialic acid modification of neuronal cell adhesion glycoproteins have shown the critical role of glycosylation in synaptic plasticity. However, our data provide the first demonstration that a defect in N-Glycosylation can result in NSMR. Altogether, our results demonstrate that fine regulation of OTase activity is essential for normal cognitive function development, providing therefore new insights to understand the pathophysiological bases of MR.

C07.2**Influence of Friedreich ataxia GAA non-coding repeats expansions on pre-mRNA processing**

F. Pagani;

ICGEB, Trieste, Italy.

The intronic GAA repeat expansion in the frataxin gene causes the hereditary neurodegenerative disorder Friedreich's ataxia. While it is generally believed that GAA repeats block transcription elongation, a direct proof in eukaryotic system is lacking. We tested in hybrid minigenes the effect of GAA and TTC repeats on nascent transcription and pre mRNA processing. Unexpectedly, disease-causing GAA repeats (n=100) did not affect transcriptional elongation in nuclear HeLa RUN ON assay nor pre mRNA transcript abundance but resulted in a complex defect on pre mRNA processing. GAA but not TTC repeats insertion downstream of reporter exons resulted in their partial or complete exclusion from the mature mRNAs and in the generation of a variety of aberrant splicing products. Interestingly, the GAA expansion induced the accumulation of an upstream pre mRNA splicing intermediate, which is not turned over into mature mRNA. This effect of GAA repeats was observed to be position and context-dependent, as their insertion at different distance from the reporter exons had a variable effect on splice site selection. Reduction of GAA triplets partially restored normal splicing consistent with a repeat length dependent phenotypic variability.

This data indicates, for the first time, an association between GAA non-coding repeats and aberrant pre-mRNA processing and suggests an alteration of the coordination between transcription and pre-mRNA processing in this disease. Transcribed GAA repeats might create a "decoy" exon that binding to trans acting splicing factors may interfere with normal turnover of non-coding intronic RNA leading to degradation and lower transcript levels.

C07.3**Mechanisms of MECP2 function underlying Rett syndrome as revealed from overexpression and knock-down systems in vitro**

M. Vecsler^{1,2}, A. J. Simon^{1,3}, G. Rechavi^{1,3}, N. Amariglio^{1,3}, E. Gak^{1,2};

¹Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel, ²Genetics Institute, Sheba Medical Center, Tel Hashomer, Israel, ³Cancer Research Center, Institute of Hematology, Sheba Medical Center, Tel Hashomer, Israel.

Rett syndrome is a severe X-linked neurodevelopmental disorder mainly affecting girls and is the second common cause of mental retardation in girls after the Down syndrome. The methyl CpG-binding protein 2 (MeCP2), a ubiquitous transcriptional repressor interacting with the chromatin remodeling machinery, is considered a single causative factor of Rett syndrome and related phenotypes, and some autistic cases. Our present study is focusing on interaction between MeCP2 and chromatin proteins leading to changes in chromatin architecture and silencing of gene expression. Using confocal microscopy, we demonstrate that MeCP2 protein is localized at the nuclear heterochromatin compartment together with the heterochromatin protein 1 alpha (HP1α). In addition, we have developed in-vitro systems overexpressing the normal MeCP2 and MeCP2 containing Rett related mutations, as well as a knock-down system of the endogenous MECP2 using specific siRNA. Studying these systems with a comprehensive gene regulation antibody array, we demonstrate that the expression of a specific set of nuclear proteins, including hBRM/hSNF2a component of SWI/SNF, HMGB1 high mobility group protein, G9a histone methyltransferase, PRMT1 protein arginine methyltransferase and HDAC2 histone deacetylase, is synchronized with MeCP2 overexpression and knock-down. Moreover using co-immunoprecipitation analyses, we demonstrate a direct interaction between MeCP2 and hBRM/hSNF2a component of ATPase-dependent SWI/SNF complex involved in global chromatin remodeling mechanism. Our findings suggest that MeCP2 acts through parallel mechanism of chromatin remodeling involving HDACs and SWI/SNF complex, thereby inducing local as well as large scale changes in chromatin architecture and compaction.

C07.4**Mutations in *UBE1* are associated with X-linked infantile spinal muscular atrophy (XL-SMA) and cause decreased gene expression in patients and carrier females**

A. Meindl¹, J. Ramser¹, C. Lenski¹, M. von Rhein², B. Wirth³, K. O. Yariz⁴, M. E. Ahearn⁴, L. Baumbach-Reardon⁴;

³Institute of Human Genetics, University of Cologne, Cologne, Germany, ⁴Miller School of Medicine, University of Miami, Miami, FL, United States.

X-linked infantile spinal-muscular atrophy (XL-SMA; MIM301830) is a rare X-linked disorder that presents with the clinical features of hypotonia, areflexia and multiple congenital contractures (arthrogryposis) associated with anterior horn cell loss and infantile death. Large scale mutation analysis in the linkage interval (*DXS8080-DXS7132*) resulted in the detection of three rare novel variants in exon 15 of the gene coding for the Ubiquitin-Activating Enzyme E1 (UBE1): two missense mutations (c.1617 G>T, p.Met539Ile, c.1639 A>G, p.Ser547Gly) present each in one XL-SMA family and one synonymous C>T substitution (c.1731 C>T, p.Asn577Asn) identified in additional four unrelated families. Each of these variants was demonstrated to segregate with the disease. Absence of the missense mutations was demonstrated for 3550, absence of the silent mutation was shown in 7914 control X-chromosomes. These results yielded statistical significant evidence for the association of the silent substitution and the two missense mutations with XL-SMA ($P = 2.416 \times 10^{-10}$, $P = 0.001815$). We have also demonstrated that the silent C>T substitution leads to significant reduction of UBE1-expression in patients and interestingly to a lesser extent also in carrier females and alters the methylation pattern of exon 15, implying a plausible role of this DNA element in developmental UBE1-expression in humans. UBE1 catalyzes in the ubiquitin-proteasome system (UPS) the first step in ubiquitin conjugation to mark cellular proteins for degradation. Our observations indicate that XL-SMA is part of a growing list of neurodegenerative disorders associated with defects in the ubiquitin-proteasome pathway.

C07.5

VLDLR (very low density lipoprotein receptor) is the first gene implicated in cerebellar hypoplasia and quadrupedal locomotion in humans

T. H. Ozelik¹, N. Akarsu², E. Uz¹, S. Caglayan¹, S. Gulsuner¹, O. E. Onat¹, M. Tan³, U. Tar⁴;

¹Bilkent University, Ankara, Turkey, ²Hacettepe University, Ankara, Turkey,

³Baskent University, Ankara, Turkey, ⁴Cukurova University, Adana, Turkey.

Quadrupedal gait in humans is a rare phenotype. We studied four consanguineous families, reported as Unertan syndrome, all exhibiting quadrupedal gait, dysarthric speech, mental retardation, and varying degrees of cerebro-cerebellar hypoplasia. Homozygosity mapping linked the locus for this unique autosomal-recessive trait to chromosome 9p24 in families A & D and 17p13 in family B. Family C excluded linkage to both loci. These results suggest that hereditary disorders associated with quadrupedal gait are genetically heterogeneous. The 9p24 region includes the gene VLDLR, which is a component of the reelin signaling pathway. Sequence analysis of VLDLR revealed two distinct mutations, R257X in family A, and I780TfsX3 in family D. Both of these mutations presumably truncate the protein, apparently leaving behind a non-functional product. Unlike chromosome 9p24, the chromosome 17p interval is large and contains at least 157 genes. We adopted a bioinformatics approach to screen the 17p interval for tri nucleotide repeats GAA, CAG, CGG and CTG, and neuronal expression. This analysis revealed several genes including lissencephaly-1 (LIS1, alternative symbol PAFAH1B1). LIS1 interacts with VLDLR, and heterozygous LIS1 mutations in humans cause lissencephaly I. Neither LIS1 nor four additional genes (WDR81, RUTBC1, MNT, TRPV1) showed an expansion of their repeat sequences. The search for the chromosome 17p13 gene in Family B continues. Our data suggest that mutations in VLDLR impair cerebro-cerebellar function and confer a dramatic influence on gait in humans.

The utilization of T3/T4 screening of males with MR of unknown etiology to identify patients with Allan-Herndon-Dudley syndrome

T. Wood¹, D. Hobson², B. Browning¹, C. Rogers¹, C. Skinner¹, H. H. Ardinger³, F. Collins⁴, A. Aronsky⁶, M. J. Friez¹, C. E. Schwartz¹;

¹Greenwood Genetic Center, Greenwood, SC, United States, ²Wake Forest University, Winston-Salem, NC, United States, ³Children's Mercy Hospitals and Clinics, Kansas City, MO, United States, ⁴Western Sydney Genetic Program, Sydney, Australia, ⁵Newark New Jersey, Newark, NJ, United States.

Allan-Herndon-Dudley syndrome (AHD; OMIM 309600) is an X-linked recessive disorder presenting with hypotonia progressing to spasticity, delay in developmental milestones, and severe mental retardation. Mutations in the *MCT8/SLC16A2* gene have shown to be causative in clinically diagnosed AHD patients. MCT8 functions as a thyroid hormone transporter with an essential function in the transport of triiodothyronine (T3) into neurons. An imbalance of certain plasma thyroid hormones has been identified in AHD patients. To investigate the clinical utility of thyroid screening in patients with MR, we measured free T3 and free T4 in a cohort of 137 males with MR of unknown etiology. Twenty males were identified to have elevated T3 and molecular analysis of *MCT8* in these patients identified two (10%) with pathogenic changes. One mutation was an insertion of 2 amino acids, p.G41_S42 dup, in exon 1. The 40 year old male had profound MR, was ambulatory and non-verbal. He also had a seizure disorder and a right spastic hemiparetic arm. The second mutation (p.G282C) was in a 5 year old boy with truncal hypotonia and hypertonia of his extremities with spasticity, dystonia and hyperreflexia - all consistent with AHD. Additionally, 28 males enrolled in our XLMR study, with clinical or biochemical evaluations suggestive of AHD, were analyzed for *MCT8* mutations and seven (25%) had pathogenic changes. Based on our results, testing the T3 level may serve as a general screen for the AHD syndrome and should certainly be considered in males with significant mental retardation and hypotonia.

C08.1

The role of the interferon regulatory factor 5 gene in autoimmune diseases

G. Kristjansdottir¹, S. Sigurdsson¹, J. Sandling¹, V. Dideberg^{1,2}, H. Göring³, L. Milani¹, V. Bours², F. Matesanz⁴, L. Rönnblom⁵, A. C. Syvänen¹;

IRF5 is a transcription factor involved both in the type I interferon and toll-like receptor signalling pathways. We have found polymorphisms in the IRF5 gene to be associated with several autoimmune diseases; systemic lupus erythematosus¹, rheumatoid arthritis², multiple sclerosis³ and inflammatory bowel disease⁴. By statistical methods two variants in the IRF5 gene have been shown to be independently associated with SLE. The variants are a CGGGG insertion-deletion (indel) polymorphism located in the promoter region of the IRF5 gene and a SNP rs10488631 located at the 3' end. The indel contains 3 or 4 repeats of the sequence CGGGG and the longer allele confers risk to all of the autoimmune diseases tested. The risk allele contains an additional binding site for the transcription factor SP1. Using electrophoretic mobility shift assays (EMSA) we observed allele-specific differences in protein binding to the indel and by proximity ligation assay (PLA) we demonstrated increased binding of the transcription factor SP1 to the risk allele.

Our study adds to the evidence that there might be genes or pathways that are common in multiple autoimmune diseases and that the type I interferon system is likely to be involved in the development of these diseases.

C08.2

Elevated expression of serotonin receptor type 3 genes may contribute to irritable bowel syndrome with diarrhea

J. Kapeller¹, L. Houghton², J. Walstab³, D. Möller¹, H. Bönnisch³, F. Autschbach⁴, N. Gassler⁵, C. Fischer¹, P. Whorwell¹, W. Atkinson², C. Fell⁶, G. Rappold⁴, B. Niesler¹;

¹Institute of Human Genetics, Heidelberg, Germany, ²University of Manchester, Manchester, United Kingdom, ³Institute of Pharmacology and Toxicology, Bonn, Germany, ⁴Institute of Pathology, Heidelberg, Germany, ⁵Institute of Pathology, Aachen, Germany.

Serotonin type 3 (5-HT₃) receptor antagonists are beneficial in some but not all patients with irritable bowel syndrome and diarrhea (IBS-D). As cis-regulatory variants can play a role in the etiology of complex conditions by affecting efficiency of translation, we investigated the 5' and 3' untranslated region (UTR) of the 5-HT_{3A} and 5-HT_{3E} subunit genes. Mutation analysis was carried out in 200 patients with irritable bowel syndrome and 100 healthy controls. We found a *HTR3A* 5' UTR variant and a novel *HTR3E* 3' UTR variant associated with the IBS-D subtype. Functional studies showed that both variants lead to significant upregulation of subunit expression. In HEK293 cells, the *HTR3A* variant results in a higher density of 5-HT_{3A} receptors at the cell surface compared to the wild-type control. The *HTR3E* variant affects a microRNA binding site and leads to a higher luciferase reporter gene expression. Both *HTR3E* and the miRNA co-localize in enterocytes of the mucosal cell layer of the gut epithelium as shown by *in situ* hybridization. We suggest that the increased expression of 5-HT_{3A} and 5-HT_{3E} subunits might result in a change in 5-HT₃ receptor composition and/or density of 5-HT₃ receptors in the epithelial cell layer of the mucosa and neurons of the enteric and central nervous system and could therefore contribute to the pathophysiology of IBS-D.

C08.3

Genome-wide association scan for serum TSH levels in 2375 Sardinians

Loi¹, A. Prinzis⁶, S. Mariotti⁶, L. Ferrucci⁵, G. R. Abecasis⁷, A. R. Shuldiner⁸, D. Schlessinger⁹, M. Uda¹, R. Nagaraja², S. Naitza¹;

¹Istituto di Neurogenetica e Neurofarmacologia, CNR, Monserrato, Italy, ²Laboratory of Genetics, National Institute on Aging, Baltimore, MD, United States, ³Riabilitazione Geriatrica, Azienda Sanitaria Firenze, Firenze, Italy, ⁴Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD, United States, ⁵Clinical Research Branch, National Institute on Aging, Baltimore, MD, United States, ⁶Endocrinologia, Dipartimento di Medicina "M. Aresu", Università di Cagliari, Cagliari, Italy, ⁷Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI, United States.

Thyroid stimulating hormone (TSH), the key regulator of thyroid function, regulates the growth of the thyroid gland and the secretion of the thyroid hormones T4 and T3. Thus, serum TSH concentrations are a sensitive indicator of thyroid function, with increased levels indicative of primary thyroid failure (hypothyroidism) and decreased level indicative of thyroid hormone overproduction (hyperthyroidism); however specific gene variants that influence levels are not known. To identify genetic factors associated with variation in TSH levels, we conducted a genome-wide association scan in 2375 Sardinians volunteers from 564 families participating to the ProgeNIA project, genotyped using the Affymetrix 500K and Affymetrix 10K Mapping Array. We evaluated the additive effect of 362,129 SNPs that passed quality controls, adjusting the model for familiarity and covariates. To control inflation of type I error due to outliers and departure from normality, quantile normalization was applied prior the analysis. The GWA scan revealed several loci putatively associated with serum TSH level and thus we followed up all the markers reaching the genome-wide significance threshold of 1.3×10^{-7} in an internal independent Sardinian cohort of 1903 volunteers, 1164 Tuscans samples from the InCHIANTI study, and 987 Amish samples from the HAPI study. Replication is ongoing, but preliminary results support the finding for the top associated chromosome 5 SNP (overall pvalue $<10^{-14}$), with the same allele responsible for an increase in TSH levels in all studies. Further detailed SNP analysis of the gene is necessary to define the causal variant and verify its direct implication on thyroid related pathologies.

C08.4

BCL11A is associated with persistent HbF and ameliorates the β -thalassemia phenotype

M. Uda¹, R. Galanello², S. Sanna¹, G. Lettre^{3,4}, V. G. Sankaran^{3,5}, G. Usala¹, F. Busonero¹, A. Maschio¹, S. Lai¹, L. Crisponi¹, S. Naitza¹, I. Asunis¹, M. Deiana¹, M. Marongiu¹, L. Porcu¹, M. ¹Istituto di Neurogenetica e Neurofarmacologia, INN, Consiglio Nazionale delle Ricerche, CNR, Monserrato, Cagliari, Italy, ²Clinica Pediatrica, Ospedale Microcitemico, Dipartimento di Scienze Biomediche e Biotecnologie, Università degli Studi di Cagliari, Cagliari, Italy, ³Children's Hospital of Boston, Boston, MA, United States, ⁴Broad Institute of Harvard and MIT, 7 Cambridge Center, Cambridge, MA, United States, ⁵Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, United States, ⁶Gerontology Research Center, National Institute on Aging, Baltimore, MD, United States, ⁷Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI, United States.

β -thalassemia and sickle cell anemia are among the most common inherited disorders worldwide, with a marked phenotypic heterogeneity related to environmental and/or genetic factors. The reasons for this are not well understood, although the level of fetal hemoglobin (HbF) is one well characterized ameliorating factor in both of these conditions. To dissect the genetic basis of this heterogeneity we conducted genome wide scans with 362,129 common SNPs on 4,305 Sardinians to look for genetic linkage and association with fetal hemoglobin levels. Our approach allowed us to identify genetic variants at the BCL11A locus strongly associated with this trait ($p < 10^{-35}$). Importantly, we have further shown that this BCL11A variant, by influencing the HbF levels, may moderate the phenotype of homozygous β -thalassemia. The fre-

quency of the C allele of SNP rs11886868, in the BCL11A gene, was significantly higher in Sardinian individuals with elevated HbF levels and patients with attenuated forms of β -thalassemia versus those with thalassemia major, detected by screening for β -thalassemia. We also showed that the same BCL11A variant is strongly associated with fetal hemoglobin levels in a large cohort of sickle cell patients.

These results indicate that BCL11A variants, by modulating HbF levels, act as an important ameliorating factor of the β -thalassemia phenotype, and it is likely they could help in moderating other hemoglobin disorders. Further genetic and functional studies are in progress to characterize the molecular mechanisms of fetal globin regulation, and could eventually lead to the development of new therapeutic approaches for β -thalassemia and sickle cell anemia.

C08.5

Genome-wide association study and follow up: identification of novel coeliac disease determinants related to the immune response

A. Zernakova¹, K. A. Hun², G. Turner³, L. Franke¹, G. Heap², J. Romanos⁴, F. Takeuchi⁵, G. Trynka⁴, C. J. J. Mulder⁶, M. C. Wapenaar⁴, P. Deloukas⁵, R. McGinnis⁵, R. McManus³, D. A. van Heef⁴, C. Wijmenga⁴;

¹Complex Genetics Section, DBG-Dept Biomedical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands, ²Institute of Cell and Molecular Science, Queen Mary University of London, London, United Kingdom, ³Departments of Clinical Medicine, Institute of Molecular Medicine, Trinity College Dublin, Dublin, Ireland, ⁴Genetics Department, University Medical Center and Groningen University, Groningen, The Netherlands, ⁵Wellcome Trust Sanger Institute, Hinxton, United Kingdom, ⁶Department of Gastroenterology and Department of Pediatric Gastroenterology, VU Medical Center, Amsterdam, The Netherlands.

Coeliac disease (CD) is a common inflammatory intestinal disease, caused by an immune response to wheat, rye and barley. HLA-DQ2/8 is necessary, but not sufficient for disease development.

To search for additional genetic factors predisposing to CD we have performed genome-wide associations (GWA) study in 778 coeliac cases and 1422 controls from the UK using the Illumina HumanHap300 BeadChip. Above the strong and extended association to the HLA region, the 4q27 genomic locus, including two immune related genes *IL2* and *IL21*, was associated at the genome-wide significance level ($p = 2.0 \times 10^{-7}$). Association with *IL2/IL21* gene locus was confirmed in three independent coeliac populations. Moreover, we observed similar association of *IL2/IL21* gene region in other autoimmune diseases (type 1 diabetes, rheumatoid arthritis), suggesting it as the common autoimmune locus. In a more extensive follow up we investigated 1,020 top genome-wide associated SNPs in multiple independent cohorts from three populations (5,049 samples). We identified seven new loci ($p < 5.0 \times 10^{-7}$), six of which contain genes controlling adaptive immune responses, including: *CCR3*, *IL12A*, *IL18RAP*, *RGS1*, *SH2B3* and *TAGAP*. Three novel CD loci (*IL2/IL21*, *CCR3* and *SH2B3*) overlap with genomic regions that show association to type 1 diabetes (HLA-mediated autoimmune disorder), whereas association in the *IL18RAP* loci overlap with another intestinal inflammatory condition - Crohn's disease. In the GWA study and the follow up we have identified new biological mechanisms for coeliac disease. This study shows the power of GWA studies with proper replication to uncover the genetics of complex traits.

C08.6

Genome-wide association and functional studies identify SLC2A9 (GLUT 9) as a novel uric acid transporter influencing serum urate concentration, urate excretion and gout disease

V. Vitart¹, I. Rudan², C. Hayward¹, N. Gray¹, C. Palmer³, I. Kolcic⁴, J. Wilson², J. Floy⁵, O. Polasek⁴, Z. Biloglav⁴, L. Zgaga⁴, A. Vorko-Jovic⁴, J. Graessler⁶, N. Hastie¹, H. Campbell⁶, A. Wright¹;

¹MRC Human Genetics Unit, Edinburgh, United Kingdom, ²Faculty of Medicine, Edinburgh, United Kingdom, ³Medical School, Dundee, United Kingdom, ⁴Faculty of Medicine, Zagreb, Croatia, ⁵University of Edinburgh, Edinburgh, United Kingdom, ⁶University of Technology, Dresden, Germany.

Aim. Uric acid is the end product of purine metabolism. Humans have lost hepatic uricase activity, leading to uniquely high serum uric acid concentrations compared with other mammals. We aimed to study genetic regulation of serum concentration of uric acid (SUA).

Materials and methods. A genome-wide association scan using

317,503 single nucleotide polymorphisms (SNPs) was carried out in a sample of 986 individuals from Vis island, Croatia, in which about 100 quantitative traits were (QT) measured. Pedigree-based genome-wide QT locus association method was used.

Results. SUA was strongly associated with three SNPs ($P \leq 10^{-7}$ after Bonaferroni correction), implicating the role of the major facilitator superfamily member *SLC2A9* and explaining 1.7-5.3% of the variance in SUA concentrations. We then confirmed the association between *SLC2A9* variants, low fractional excretion of uric acid and gout disease in several other population samples from United Kingdom, Croatia and Germany. In all samples the effects were substantially greater in females. A meta-analysis showed odds ratio for gout between 1.34 and 1.38 for the three implicated SNPs: rs1014290 T allele, rs6449213 T allele and rs737267 C allele. As *SLC2A9* was a known fructose transporter, we conducted several functional experiments in *Xenopus* oocytes and showed strong uric acid transport activity of *SLC2A9*. The uptake of uric acid was 7-fold greater than of the known urate transporter *URAT1* and 31-fold than in the control oocytes.

Conclusion. *SLC2A9* (*GLUT 9*) is a novel uric acid transporter influencing serum urate concentration, urate excretion and gout disease.

C09.1

QF-PCR as a stand-alone prenatal test for targeted referral groups; results from the first year of a new UK diagnostic service

K. Mann¹, R. Ellis², J. Burbridge², M. Holloway³, S. Edwards³, D. Morrogh³, J. Waters³, C. Mackie Ogilvie¹;

¹Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom, ²NWT Regional Genetics Service (KGC), London, United Kingdom, ³NEL Regional Cytogenetics Laboratory (Gt Ormond St Hospital), London, United Kingdom.

QF-PCR is widely used in European genetic laboratories as a rapid, robust and accurate test for the prenatal diagnosis of trisomy of chromosomes 13, 18 and 21. To date, our laboratory has tested more than 25,000 samples using both QF-PCR and karyotype analysis. Recent audits have found a low incidence of clinically significant non-trisomy chromosome abnormalities in prenatal samples referred for increased trisomy risk, which has led to debate in the UK over the clinical need for karyotyping such samples. In May 2007, the SE England Genetics Consortium therefore instigated a QF-PCR stand-alone service for a sub-set of prenatal samples, with the aim of minimising the identification of chromosome abnormalities of unknown clinical significance and reducing double testing. All prenatal samples are tested for trisomies 13, 18 and 21 using QF-PCR. Karyotype analysis is carried out only for referrals with NT >3mm before 14 weeks or >6mm thereafter, ultrasound abnormalities (excluding single soft markers), from families with a previous chromosome abnormality (excluding common trisomies) and to follow up abnormal QF-PCR results. During the first eight months of service, 1502 AF and 628 CVS were received. 26% of AF and 44.9% of CVS were karyotyped. 8% of AF and 22% of CVS were abnormal. In the groups targeted for karyotyping, 3.6% of AF and 7.1% of CVS had non-trisomy abnormalities. There was one discrepant QF-PCR (trisomy 13)/karyotype (normal) case due to mosaicism (possibly confined to the placenta). The first year of this innovative approach to prenatal diagnosis will be discussed.

C09.2

Chromosomal abnormalities detectable by prenatal screenings cover only half of the significant fetal chromosomopathy: an evaluation based on 115'576 invasive prenatal diagnoses

F. Maggi¹, **F. R. Grati¹**, A. Barlocco¹, M. Di Lemia², B. Grimi¹, S. De Toffol¹, G. Frascoli¹, A. M. Di Meco¹, R. Liuti¹, S. Milani¹, A. Trotta¹, S. Babucci³, F. Dulcetti¹, A. M. Ruggeri¹, G. Simoni¹;

¹Research and Development, Cytogenetics and Molecular Biology, TOMA Laboratory, Busto Arsizio, Italy, ²Clinical Chemistry and Toxicology, TOMA Laboratory, Busto Arsizio, Italy, ³Clinical Chemistry and Toxicology, Cytogenetics and Molecular Biology, TOMA Laboratory, Busto Arsizio, Italy.

A homogeneous survey of 115'576 prenatal diagnoses have been collected from our laboratory during the last 14 years: 84'847 on amniotic fluid (AF) and 30'729 on chorionic villi (CV). This experience could be a source to draw practical and useful information since it includes a great number of women <35 years that performed invasive prenatal diagnosis without a pathologic indication (22'414 on AF and 5401 on CV). As expected, in both first and second trimester they demonstrate

an incidence of unbalanced karyotypes (+21,+18,+13, X/Y aneuploidies other than XXX and XYY, true fetal mosaicism, supernumerary markers, and *de novo* rearrangements such as deletions, duplications, reciprocal translocations, inversions) halved compared with the group with the indication "advanced maternal age" (≥ 35). First and second trimester antenatal screenings evaluate the risk mainly for trisomy 21 and also for trisomy 13, 18, monosomy X and triploids with different detection rates (d.r.) ranging from 65% to 93%, depending on the applied test and on the chromosomal alteration. In our survey these abnormalities represent only a portion of the total fetal chromosomal pathology varying from 38.9% in women <35 in II trimester to 75.8% in those ≥ 35 in I trimester. Combining these data with the different reported d.r. it emerges that antenatal screenings are able to detect less than half (30.9-43.8%) of the possible fetal chromosomopathy in women <35 and, interestingly, 50.8-62.9% in those ≥ 35 . These findings provide the need to inform the couples about the actual limits of antenatal screenings.

C09.3

Ten years clinical application of preimplantation genetic diagnosis (PGD) for β -haemoglobinopathies, cystic fibrosis, X-linked and rare monogenic diseases: a Greek experience

J. Traeger-Synodinos¹, C. Vrettou¹, M. Tzetzis¹, A. Destouni¹, G. Kokkali^{1,2}, S. Davies³, M. Mastrominas³, G. Palmer⁴, D. Stavrou², K. Pantos², E. Kanavakis¹;

¹Medical Genetics, Athens University, Athens, Greece, ²Centre for Human Reproduction, Genesis Hospital, Athens, Greece, ³Embryogenesis Centre for Reproduction & Fertility Studies, Athens, Greece, ⁴Mitera IVF Unit, Mitera Maternity Hospital, Athens, Greece.

In Greece, PGD is now an established alternative to prenatal diagnosis (PND) for couples with unsuccessful reproductive history at risk of transmitting common (CF, β -thalassaemia/sickle syndromes) or rare monogenic diseases. During the past 10 years we have developed several single-cell genotyping methods for detecting a wide range of genotypes associated with β -haemoglobinopathies, CF, Congenital Lipoid Adrenal Hyperplasia (CLAH), Glycogen Storage Disease (GSD), Leber's Congenital Amaurosis (LCA), X-linked disorders and SMA. Protocols involved denaturing gradient gel electrophoresis and more recently real-time PCR, multiplex fluorescent RLFP and/or microsatellite haplotyping. Over 10 years, requests for PGD have steadily increased, presently reaching >60 cycles annually. To date 349 PGD cycles (335 for β -haemoglobinopathies, 12 for CF, 1 for CLAH and 1 for GSD) have been initiated in 250 couples, with 284 cycles to oocyte-retrieval. Genotyping was performed either on blastomeres from cleavage-stage embryos (267 cycles) or trophectoderm cells from 5-day blastocysts (17 cycles). Genotypes were achieved in >80% of embryos biopsied, identifying at least one unaffected embryo for transfer in 280 cycles. One hundred and nineteen pregnancies were HCG positive, although 40 were subsequently lost spontaneously. Currently, 79 pregnancies have resulted in 102 unaffected live-births, with 10 on-going (confirmed unaffected). This cohort represents a pregnancy rate of 26.6% per oocyte retrieval or 36.25% per embryo transferred, and an embryo implantation rate of 20%. Our 10 years of experience demonstrates that PGD can be reliably incorporated within the reproductive choices for couples with unsuccessful reproductive histories at risk for transmitting serious genetic disorders.

C09.4

Evaluation and validation of Preimplantation Genetic Diagnosis (PGD) by PCR analysis: comparison of the blastomere and corresponding embryo genotype

J. Herbergs^{1,2}, M. Drusedau¹, H. Smeets^{1,2}, C. De Die-Smulders¹, J. Dumoulin¹, J. Evers¹, J. Dreesen^{1,2}, J. Geraedts^{1,2};

¹Academic Hospital Maastricht, Maastricht, The Netherlands, ²Maastricht University, Maastricht, The Netherlands.

PGD can be an alternative for prenatal diagnosis for couples at high risk of a monogenic disorder. The aim of the present study is to validate the PGD-PCR procedure, and determine the diagnostic value. According to embryo morphology quality scores, embryos on day 4 post fertilization were divided into class 1-4, with class 4 being the lowest embryo morphology score. The genotype from the biopsied blastomere and the corresponding embryo were compared. To establish the validity of PGD-PCR procedure, sensitivity(Se), specificity(Sp), and Likelihood Ratio(LR) were calculated for the total, class 4 excluded

and class 4 embryo group. For the diagnostic value, Positive- (PPV) and Negative Predictive Value (NPV) were calculated.

In our centre 80 women underwent PGD-PCR, resulting in 793 embryo genotypes, 241 unaffected embryos were used for ET. PGD-PCR blastomere outcome, scored as affected or aberrant in 234/241 positive embryos (Se: 97,1%), and scored unaffected in 181/206 negative embryos (Sp: 87,9%). Out of the 7 false negative embryos, 6 were graded as class 4. The Se in the class 4 embryo group was 90,2% and Sp 93,2%. Exclusion of class 4 embryos resulted in Se of 99,4%, Sp of 86,4% and LR positive test of 7.3 and LR negative test of 0.006. The PPV of an abnormal PGD-PCR is 89.1%, the NPV of a normal PGD-PCR is 99.3% in this group.

PGD-PCR procedure is validated as a diagnostically reliable method for selecting unaffected embryos for ET. Accuracy of PGD-PCR analysis improves by rejecting class 4 embryos for ET.

C09.5

Multiple displacement amplification (MDA) in preimplantation genetic diagnosis (PGD)

M. De Rycke^{1,2}, C. Spits³, W. Verpoest³, K. Sermor², J. Vanderelst³, I. Liebaers^{1,2};

¹Centre for Medical Genetics UZ Brussel, Brussels, Belgium, ²Department of embryology and genetics Vrije Universiteit Brussel, Brussels, Belgium, ³Centre for Reproductive Medicine, UZ Brussel, Brussels, Belgium.

Introduction

PGD is an alternative to prenatal diagnosis, performed on single blastomeres from in vitro cultured embryos. Since many of the PGD requests for single-gene disorders involve new developments and the workup of single-cell multiplex-PCR is technically demanding and requires time and manpower, we evaluated a different approach relying on single-cell whole genome amplification (WGA) using MDA as a universal first step, followed by regular PCRs for specific loci.

Materials and Methods

During pre-clinical workup, MDA products from single lymphoblasts were used to assess the amplification efficiency, preferential amplification (PA), allele drop out (ADO) and contamination rates of loci (specific mutations and linked STR markers) involved in cystic fibrosis, Marfan syndrome, Huntington's disease, spinal cerebral ataxia 7 and neurofibromatosis type 1.

Nine couples underwent 18 clinical PGD cycles, in which 100 embryos were biopsied.

Results

The pre-clinical results showed an amplification efficiency of 96%; no contamination was detected. This is similar to PCR-based protocols. The PA and ADO rates varied for the different loci and the average rate of 25% was five fold higher than with PCR. Still, the diagnostic efficiency in the clinical cycles was 93 %. Twenty embryos were transferred in 13 cycles, resulting in two biochemical pregnancies, one singleton baby, one twin and one pregnancy ongoing.

Conclusions

The relatively high ADO and PA rates associated with single-cell MDA in PGD was overcome by analysis of at least four loci. The diagnostic efficiency is similar to PCR-based protocols. These results prove the applicability of single-cell MDA in PGD.

C09.6

Fluorescence In-Situ Hybridisation using Oligonucleotide probes (Oligo-FISH): a new strategy for Preimplantation Genetic Screening (PGS).

L. Robertson¹, S. Doubravska¹, M. Grigorova¹, D. K. Griffin², A. H. Handyside¹, A. R. Thornhill¹;

¹Bridge Genoma, London, United Kingdom, ²University of Kent, Canterbury, United Kingdom.

The principle of preimplantation genetic screening (PGS) is to biopsy 1 cell from a 6-10-cell embryo and determine chromosomal copy number within a 24 hr time frame before transferring chromosomally 'normal' embryos to the patient. Current PGS consists of sequential multicolour FISH using two or more probe sets derived from BACs. Our current clinical method consists of two rounds of FISH as follows: (1) chromosomes 13, 16, 18, 21 and 22 with a 2.5hr hybridisation time and 2) X, Y, 15 with a 16-18 hr hybridisation time allowing results to be reported in 24hr facilitating Day 4 embryo transfer. Recently FISH probes using labelled 30-mer oligonucleotides (ODNs) have been developed which

specifically hybridise to repetitive sequences on a range of different chromosomes. Based on the manufacturer's protocol, with a hybridisation step of 5 minutes, PGS for 8 chromosomes (2 x 4 chromosome probe sets) was performed in 1 hour. Four different ODNs probe sets for chromosomes (1) X, Y, 15,17 (2) X, Y, 16 (3) X, Y, 16q and (4) X, Y, 18 were validated using known normal donor lymphocytes. Validation of ODNs probe sets for chromosomes X, Y, 15,17; X, Y, 16; X, Y, 16q and X, Y, 18 scored >80% for probe efficiency using a short hybridisation time of 5 minutes. With modifications, we expect to reach > 95% efficiency for each probe set. The short length of ODN probes permits rapid hybridisation, a significant advantage for time critical procedures such as PGS.

C10.1

BRCA1 mutations and prostate cancer in Poland

J. Lubinski¹, C. Cybulski¹, B. Gorski¹, J. Gronwald¹, T. Huzarski¹, T. Byrski¹, T. Debniak¹, A. Jakubowska¹, D. Wokolorczyk¹, B. Gliniewicz¹, A. Sikorski¹, M. Stawicka², D. Godlewski², Z. Kwias³, A. Antczak⁴, K. Krajka⁵, W. Lauer⁶, M. Sosnowski⁷, P. Sikorska-Radek⁸, K. Bar⁹, R. Klijer¹⁰, Z. Romuald¹, B. Malkiewicz¹¹, A. Borkowski¹, T. Borkowski¹;

¹Pomeranian Medical University, Szczecin, Poland, ²Prophylactic and Epidemiology Center, Poznan, Poland, ³Medical University in Poznan, Poznan, Poland, ⁴Medical University of Lodz, Lodz, Poland, ⁵Medical University of Gdansk, Gdansk, Poland, ⁶Institut für Biomedizinische Technologien, Aachen, Germany, ⁷Medical University, Warsaw, Poland, ⁸Medical University, Poznan, Poland, ⁹Medical University, Lublin, Poland, ¹⁰University Hospital of Lublin, Lublin, Poland, ¹¹Medical University, Wrocław, Poland.

Evidence to date that BRCA1 mutation carriers are at an increased risk of prostate cancer is mixed - both positive and negative studies have been published. To establish whether inherited variation in BRCA1 influences prostate cancer risk we genotyped 1793 men with prostate cancer in Poland and 4570 controls for three founder mutations (C61G, 4153delA, 5382insC). BRCA1 mutation was present in 0.45% of cases and 0.48% of controls (OR=0.9; P=1.0). The odds ratios varied substantially by mutation. The 5382insC mutation is the most common of the three founder mutations. It was detected only in one case (0.06%), whereas it was seen in 0.37% of controls (P=0.06). In contrast, the 4153delA was more common in prostate cancer cases (0.22%) than in controls (0.04%) (OR=5.1; 95% confidence interval: 0.9-27.9; P=0.1). The C61G mutation was also found in excess in cases (0.17%) compared with controls (0.07%) (odds ratio=2.6; 95% confidence interval: 0.5-12.7; P=0.5). Eight men with prostate cancer carried a mutation. Only one of these carried the 5382insC mutation, compared with 17 of 22 individuals with mutations in the control population (P=0.003). These data suggest that 5382insC mutation is unlikely to be pathogenic for prostate cancer in Polish population. The presence of one of the other alleles was associated with an increased risk for prostate cancer (OR=3.6; 95% confidence interval: 1.1-11.3; P=0.045); in particular for familial prostate cancer (OR=12; 95% confidence interval: 2.9-51; P=0.0004). We consider that the risk of prostate cancer in BRCA1 carriers varies with the position of the mutation.

C10.2

Genomic differences between retinoma and retinoblastoma

M. Amenduni¹, K. Sampieri¹, F. Ariani¹, M. Bruttini¹, M. A. Mencarelli¹, M. C. Epistolato², P. Tot², S. Lazz², A. Marozza¹, F. Mari¹, T. Hadjistilianou³, S. De Francesco³, A. Acquaviva⁴, A. Renieri¹;

¹Medical Genetics, Siena, Italy, ²Department of human pathology and oncology, Siena, Italy, ³Retinoblastoma referral center, Department of ophthalmology, Siena, Italy, ⁴Department of pediatrics, obstetrics and reproductive medicine, Italian retinoblastoma registry, Siena, Italy.

Genomic copy number changes are involved in the multi-step process transforming normal retina in retinoblastoma (RB) after *RB1* mutational events. Previous studies on tumor samples led to a multi-step model in which after two successive *RB1* mutations, the following genomic changes accompany malignancy: 1q32.1, 6p22 and 2p24.1 gains and 16q22 losses. Recent data have demonstrated that retinoma, a rare benign retinal lesion, represents an early stage in the pathway to RB. In order to catch somatic events that determine retinoma-RB transition, we investigated genomic copy number changes in DNA isolated by laser capture from retinoma and retinoblastoma tissues of two different patients. We employed both genome wide array-CGH technique and Real-Time qPCR at four genes involved in RB pathogenesis (*MDM4*,

MYCN, *E2F3* and *CDH11*). Our results showed that some genomic rearrangements thought to belong only to RB (Dup6p including *E2F3*, gains of *MDM4* and *MYCN*) are already present in retinoma. Tumor tissues show a higher level of genomic instability, with additional rearrangements and progressive amplification of *E2F3* and *MYCN*. Interestingly, in one of the two RB cases, we found a deletion in 16q12.1-16q12, absent in retinoma. This region includes *RBL2* (p130), an efficient inducer of cellular senescence when the major arrest pathway determined by pRb/p16INK4a is abolished. In conclusion, these data confirm the pre-malignant nature of retinoma and indicate interesting candidate genes that could have a key role in the progression to malignancy.

C10.3

High resolution analysis of chromosomal changes in colorectal tumors matched with normal tissues from the same patients using 500,000 SNPs

G. Brown^{1,2}, D. L. Worthley^{3,4}, G. P. Young³, D. Brookes^{1,2}, J. Ross^{1,2}, G. N. Hannan^{1,2};

¹CSIRO Preventative Health Flagship, North Ryde, NSW, Australia, ²CSIRO Molecular and Health Technologies, North Ryde, NSW, Australia, ³Flinders Medical Centre, Bedford Park, SA, Australia, ⁴Queensland Institute of Medical Research, Herston, Qld, Australia.

Previous studies have identified many chromosomal abnormalities which occur amongst common colorectal cancers (CRCs). Until now these have been observed using fairly low resolution screening technologies so that it has been difficult to match changes to specific genes or to specific pathways. Another confounding issue has been the use of composite reference sets of "normal" DNAs to identify changes in tumor DNAs, leading to greater background noise in the estimations of copy number (CN) and loss of heterozygosity (LOH). We have used microarrays containing probes for 500,000 single nucleotide polymorphisms (SNPs) in genome wide scans to provide very high resolution estimations of CN change and LOH for each of five pairs of common colorectal tumors, pair-wise matched with normal tissues from the same patients. We show that pair-wise matching gave better definition of CN changes and regions of LOH than by comparing the tumor genome profiles against a composite genome profile derived from a reference set of 40 normal individuals. Our high resolution data allowed precise identification of many chromosomal changes in CRC tumors. We also report improved definition of some changes that have been observed previously using lower resolution methods. We show the importance of having LOH data as well as CN data to better understand the mechanisms involved in chromosomal rearrangements in CRC. These include likely instances of hemizygous deletions, gene conversions and uniparental disomy. We also present our analysis of regions gained, lost or showing LOH, that contain genes potentially involved in CRC.

C10.4

Leukemia biochip analysis of chromosomal translocations in childhood leukemia in Russia using hybridization and on-chip PCR approaches.

N. A. Guseva, O. S. Nurutdinova, A. V. Chudinov, E. N. Timofeev, S. V. Pankov, A. S. Zasedatelev, T. V. Nasedkina;

Engelhardt Institute of Molecular Biology RAS, Moscow, Russian Federation.

Leukemia is a clinically and genetically heterogeneous disease that requires accurate molecular diagnostic approaches to generate treatment strategies and to minimize toxicity of therapies.

Here we present biochip diagnostic tool to detect 14 most significant translocations of childhood leukemia together with quantitative approach to evaluate minimal residual disease (MRD). Biochips are three-dimensional oligonucleotide microchips consisting of gel pads attached to a hydrophobic plastic surface. For diagnostics of primary leukemia, the multiplex RT-PCR was used in combination with hybridization on biochips. The quantitative method was based on real-time on-chip PCR, which allowed identification of chimeric transcript copies, as measured by PCR-synchronized fluorescent microscope. The data obtained by on-chip PCR method for t(8;21) patients was validated by conventional real-time PCR. Leukemia biochip was used to screen 753 children from newborn up to 17 years. In total of 501 primary ALL children we found translocations in 23% of cases (69 children with t(12;21) TEL/AML, 23 with t(9;22) BCR/ABL p190, 12 with t(1;19) E2A/PBX,

12 with (4;11) MLL/AF4, 4 with t(10;11) MLL/AF10, 1 with t(11;19) MLL/ELL and 1 with t(11;19) MLL/ENL); in total of 201 AML patients there were 33% with translocations (21 with t(9;11) MLL/AF9, 19 with t(8;21) AML/ETO, 16 with t(15;17) PML/RARA, 8 with inv16 and 4 with t(6;11) MLL/AF6); 24 children with CML had t(9;22) BCR/ABL p210 and of 27 with non-Hodgkin lymphomas 4 (15%) had t(2;5) NPM/ALK. In conclusion, we developed a biochip platform to diagnose primary leukemia and to monitor MRD that is fast, accurate, convenient and cost-effective.

C10.5

Disruption of Ikaros function by the CALM/AF10 fusion protein might be responsible for abortive lymphoid development in CALM/AF10 positive leukemia

P. A. Greif, B. Tizazu, A. Krause, E. Kremmer, S. K. Bohlander; Helmholtz Zentrum München, München, Germany.

The t(10;11)(p13;q14) translocation leads to the fusion of the CALM and AF10 genes. This translocation can be found as the sole cytogenetic abnormality in acute lymphoblastic leukemia, acute myeloid leukemia and in malignant lymphomas. The expression of CALM/AF10 in primary murine bone marrow cells results in the development of an aggressive myeloid leukemia that is propagated by cells with lymphoid traits (Deshpande et al, Cancer Cell, 2006). Using a yeast two-hybrid screen, we identified the lymphoid regulator Ikaros as an AF10 interacting protein. Interestingly, Ikaros is required for normal development of lymphocytes, and aberrant expression of Ikaros has been found in leukemia. In a murine model, the expression of a dominant negative isoform of Ikaros causes leukemias and lymphomas. The Ikaros interaction domain of AF10 was mapped to the leucine zipper domain of AF10, which is required for malignant transformation both by the CALM/AF10 and the MLL/AF10 fusion proteins. The interaction between AF10 and Ikaros was confirmed by GST pull down and co-immunoprecipitation. Coexpression of CALM/AF10 but not of AF10 alters the subcellular localization of Ikaros in murine fibroblasts (Greif et al, Oncogene, in Press). The transcriptional repressor activity of Ikaros is reduced by AF10. These results suggest that CALM/AF10 might interfere with normal Ikaros function, and thereby block lymphoid differentiation in CALM/AF10 positive leukemias.

C10.6

Assessment of X Chromosome Inactivation Pattern in BRCA Mutation Carriers: Evidence for an Effect of Chemotherapy

M. Miozzo¹, C. Allemani², F. R. Grati^{3,4}, S. M. Tabano¹, B. Peisse⁵, P. Antonazzo⁶, V. Pensotti⁶, S. M. Sirchia¹, P. Radice^{6,7}, S. Manoukian⁴;

¹Medical Genetics, Department of Medicine, Surgery and Dentistry, University of Milan, Milan, Italy, ²Analytical Epidemiology Unit, Department of Preventive and Predictive Medicine, Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy, ³Units of Research and Development, Cytogenetics and Molecular Biology, TOMA Laboratory, Busto Arsizio, Italy, ⁴Medical Genetics Unit, Department of Experimental Oncology, Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy, ⁵Institute of Obstetrics and Gynecology I "L. Mangiagalli", University of Milan, Fondazione IRCCS Policlinico, Mangiagalli and Regina Elena, Milan, Italy, ⁶Fondazione Istituto FIRC di Oncologia Molecolare, Milan, Italy, ⁷Genetic Susceptibility to Cancer Unit, Department of Experimental Oncology, Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy.

BRCA1, a major breast/ovarian cancer predisposing gene, has been suggested to play a role in the mechanisms leading to X chromosome inactivation (XCI) in female cells. In addition, a high frequency of non-random (skewed) XCI was reported in carriers of *BRCA1* mutations affected with ovarian cancer. To verify whether constitutional alterations of the gene may influence XCI status, we analyzed the occurrence of skewed XCI in blood cells from 224 female *BRCA1* mutation carriers, both with and without cancer, and 177 healthy controls. Significant reduced odds of skewed XCI respect to controls were found in younger carriers (<55 years) (OR=0.35; 0.13-0.92), but not in elderly individuals (≥55 years). Using a multivariable logistic regression model, we observed that, when adjusted for age, the odds of skewed XCI in *BRCA1* mutation carriers without cancer and in carriers with cancer untreated with chemotherapy, cumulatively considered, were significantly lower than in controls (OR=0.39; 0.16-1.18). Conversely, no statistically significant difference was observed in carriers with cancer who received chemotherapy (OR=1.17; 0.61-2.26). Taken together, our findings are consistent with: i) a possible selection against X skewed embryos car-

rying *BRCA1* mutation, leading to a low frequency of females with a skewed XCI respect to the general population; ii) an effect of chemotherapy on XCI status that should be taken into account when analyzing XCI in cancer patients.

C11.1

Identification of causative mutations, including a ZRS sonic hedgehog regulatory variant, in an unselected cohort of 203 patients with congenital limb malformations

D. Furniss^{1,2}, S. Kan¹, P. S. Critchley², H. Giele², A. O. M. Wilkie¹;

¹Weatherall Institute of Molecular Medicine, Oxford, United Kingdom, ²Department of Plastic and Reconstructive Surgery, Oxford, United Kingdom.

Congenital limb malformations (CLMs) are common: major aetiological factors are genetic mutations and intrauterine disruptions. We have characterised the causative mutations in an unselected cohort of patients with CLMs requiring reconstructive surgery. At operation, blood was taken for DNA extraction and karyotype analysis. Candidate genes were screened for point mutations using DHPLC and sequencing, and for deletions by MLPA.

From a cohort of 203 patients, causative genetic changes were identified in 22 (11%). In addition to 4 chromosome abnormalities, these comprised mutations in *GLI3* (5), *HOXD13* (5), the ZRS of *SHH* (3), *SALL1* (2) and *SALL4*, *TBX5* and *ESCO2* (1 each). Factors that predicted the discovery of a genetic cause included bilateral malformation, positive family history, and increasing numbers of limbs affected (all $p < 0.01$). Furthermore, 39 patients had a family history of consistent limb malformations, and 5 patients had identified syndromes, strongly suggesting a genetic basis. Therefore, at least 32% of CLMs have a genetic aetiology.

This study is the first to systematically screen for genetic mutations in an unselected cohort of patients with CLMs. Specific clinical features predict a genetic aetiology, and help to refine the selection of patients for referral to a Clinical Geneticist. Mutations of *GLI3* and *HOXD13* are particularly common causes of CLM and genetic testing is now offered by the clinical molecular diagnostic service in Oxford. In addition, we have defined a new and frequent cause of triphalangeal thumb, caused by a regulatory mutation affecting the *SHH* gene.

C11.2

Genotype and phenotype of Stickler syndrome caused by mutations in the COL2A1 gene

K. P. Hoornaert, C. Dewinter, I. Vereecke, P. J. Coucke, G. R. Mortier; Center for Medical Genetics, Gent, Belgium.

Background: Stickler syndrome is an autosomal dominant connective tissue disorder caused by mutations in different collagen genes. Characteristic clinical features include severe myopia, spontaneous retinal detachment, Pierre-Robin sequence, midface hypoplasia, sensorineural hearing loss and early-onset osteoarthritis. The aim of this study was to investigate and correlate the allelic heterogeneity and phenotypic variability in Stickler syndrome patients with a COL2A1 mutation.

Materials & Methods: In 188 probands with the referring diagnosis of Stickler syndrome, the 54 exons and intronic boundaries of COL2A1 were amplified by PCR and analysed by either a mutation scanning technique or bidirectional fluorescent DNA sequencing. The effect of splice site alterations was investigated by analysing RNA.

Results: We identified 100 heterozygous COL2A1 mutations, including 1 entire gene deletion, 27 nonsense mutations, 35 frameshift mutations, 25 splice site alterations, 1 synonymous mutation altering splicing, 5 arginine-to-cysteine substitutions and 5 glycine alterations. Each of the 13 investigated splice site mutations was shown to result in a premature stop codon. A binary logistic regression analysis of the clinical features, revealed 7 major indicators for a type 2 collagenopathy in Stickler syndrome: vitreous abnormalities, retinal detachment, retinal abnormalities, low nasal bridge, cleft palate, micrognathia and positive family history.

Conclusions: We confirmed that Stickler syndrome type 1 is predominantly caused by loss-of-function mutations in the COL2A1 gene and we developed a phenotypic scoring system that facilitates distinction between patients with and without a COL2A1 mutation.

C11.3

Comprehensive clinical and molecular assessment of 32 probands with congenital contractural arachnodactyly: report of 14 novel mutations and review of the literature

Background: Beals-Hecht syndrome or congenital contractural arachnodactyly (CCA) is a rare, autosomal dominant connective tissue disease characterized by crumpled ears, arachnodactyly, contractures and scoliosis. Recent reports also mention aortic root dilatation, a finding previously thought to differentiate the condition from Marfan syndrome (MFS). In many cases, the disorder is caused by mutations in the fibrillin 2 gene (*FBN2*) with 26 mutations reported so far, all located in the middle region of the gene (exons 23-34).

Methods: We directly sequenced the entire *FBN2* gene in 32 probands clinically diagnosed with CCA. We reviewed the literature and compared the phenotypic findings of all patients harboring a *FBN2* mutation with the clinical characteristics of patients in whom no *FBN2* mutation was found.

Results and conclusions: In 14 probands, we found 13 new and one previously described *FBN2* mutation including a mutation in exon 17, expanding the region in which *FBN2* mutations occur in CCA.

The phenotype in *FBN2* positive patients was comparable to all previously published *FBN2* positive patients. Cardiovascular involvement included mitral valve prolapse in 2 adult patients and aortic root enlargement in 3 patients. Whereas the dilatation regressed in one proband, it remained marked in a child proband (z-score 4,09) and his father (z-score 2,94), warranting echocardiographic follow-up. We confirm paradoxical patellar laxity and report keratoconus, shoulder muscle hypoplasia and pyelo-ureteral junction stenosis as new features. In addition, we illustrate large intrafamilial variability. *FBN2* negative patients were clinically indistinguishable from patients harboring a *FBN2* mutation, suggesting locus heterogeneity.

C11.4

Phenotypic Characterization of Poland Syndrome Based on a Series of 122 Patients

A. Baban¹, A. Buluggiu², M. T. Divizia¹, S. Bianca³, M. Torre², S. Gimelli⁴, M. Valle⁵, M. G. Calevo⁶, G. Gimelli⁴, F. M. Sénès⁷, R. Ravazzolo^{1,8}, V. Jasonni⁹, M. Lerone¹;

¹Laboratory of Molecular Genetics and Cytogenetics, Gaslini Children Hospital, Genova, Italy, ²Department of Pediatric Surgery, Gaslini Children Hospital, Genova, Italy, ³Center of Genetic and Teratologic Counselling, Fetomaternal Department, ARNAS Garibaldi-Nesima, Catania, Italy, ⁴Department of Genetic Medicine and Development, University of Geneva Medical School, and University Hospitals, Geneva, Switzerland, ⁵Department of Radiology, Gaslini Children Hospital, Genova, Italy, ⁶Epidemiology and Biostatistics Section of Scientific Direction, Gaslini Children Hospital, Genova, Italy, ⁷Department of Orthopedic and Traumatology, Gaslini Children Hospital, Genova, Italy, ⁸Department of Pediatrics and CEBR, University of, Genova, Italy.

Poland syndrome (PS) was first described by Alfred Poland in 1841 and classically consists of unilateral hypoplasia/aplasia of the pectoralis muscles in isolated entity or in association with ipsilateral upper

limb or thoracic anomalies (ULA or TA).

Clinical characterization of PS has not been described in literature on a wide patient series. We have considered the following parameters:

- Describe the disease phenotype in a wide range of patients.
 - Verify the current data present in literature
 - Classify disease severity according to clinical features and identify risk factors according to gender, affected side and other phenotypic characteristics.
 - Definition of associated malformations or syndromes.
 - Obtain best methods in management of patients from diagnostic, therapeutic and prognostic points of view
 - Possibility to identify new etiopathogenetic hypotheses (genetic versus environmental factors) and validate those present in literature
- We have studied 122 Poland patients (64 M, 48 F) in the period 2003-2007.

The management of these patients was based on multidisciplinary approach. At the first phase of the study all included patients had undergone Specialistic Counselling (Genetic, Psychologic, Surgical, and Orthopedic).

The second phase was based on medical indication and included high resolution karyotyping or array-CGH. Moreover, the standardization of pectoral muscle and tendon components by ultrasound is ongoing. Other investigations included chest X-ray, Echocardiography, Abdominal ultrasound, and thoracic CT scan.

In collaboration with AISP (Italian Association of Poland Syndrome) A Spoken presentation on this topic was awarded young researcher prize at the Italian Society of Human Genetics Conference 2007

C11.5

Distal limb deficiency, micrognathia syndrome (OMIM 246560) and syndromic forms of split hand foot malformation (SHFM) are caused by chromosome 10q genomic rearrangements

B. I. Dimitrov¹, T. d. Ravel¹, C. d. Die-Smulders², A. Toutain³, J. R. Vermeesch¹, J. Fryns¹, K. Devriendt¹, P. Debeer¹;

¹Centre for Human Genetics, University Hospital Leuven, Leuven, Belgium,

²Department of Clinical Genetics, University Hospital of Maastricht, University of Maastricht, Maastricht, The Netherlands, ³Genetic Service, University Hospital Bretonneau, University of Tours, Tours, France.

As a part of screening for genomic rearrangements in patients with unexplained syndromic limb defects, arrayCGH was performed in a cohort of patients with various syndromic limb defects. A 10q24-microduplication was detected in 6 individuals with distal limb deficiency, associated with micrognathia, hearing problems and renal hypoplasia. In addition, in a family with two affected siblings, somatic mosaicism for the 10q24-microduplication was detected in the apparently healthy mother.

This chromosomal region has previously been implicated in SHFM. SHFM3 was mapped to a large interval on chromosome 10q24. The corresponding Dactylaplasia mouse model was linked to the syntenic locus on chromosome 19. When it was shown that the two existing *Dac* alleles result from MusD-insertions upstream of or within *Dactyllyn* (*Fbxw4*), this gene seemed a plausible candidate causing SHFM3. However, all efforts to identify mutations in this gene failed. Likewise, no mutations were found in other genes within the linkage area including *FGF8*, despite the fact that the observed limb defects resemble those detected in conditional *Fgf8*-knockout mice.

However, recently, a 10q24-microduplication was detected in a total of 15 familial and 4 sporadic SHFM3 cases. In contrast to the present patients, the previously reported individuals had an isolated form of SHFM. This difference cannot be explained by a difference in size of the duplication, since a similar size was present in all individuals.

These findings extend the clinical spectrum of SHFM3. Genetic counseling should consider the observed somatic mosaicism.

C11.6

Biallelic loss of function of the promyelocytic leukaemia zinc finger (PLZF) gene causes severe skeletal defects and genital hypoplasia

B. Horsthemke¹, S. Fischer¹, J. Kohlhas², D. Böhm², B. Schweiger¹, M. Heitmann¹, D. Wieczorek¹;

¹Universitätsklinikum Essen, Essen, Germany, ²Praxis für Humangenetik, Frei-

burg, Germany.

Deletions of 11q23 are associated with mental retardation, craniofacial dysmorphism, microcephaly and short stature. We present a patient with similar clinical findings plus absence of thumbs, hypoplasia of radii and ulnae, additional vertebrae and ribs, retarded bone age and genital hypoplasia. Using microarray based comparative genomic hybridization and microsatellite analysis, we identified an ~8 Mbp *de novo* deletion on the paternal chromosome 11, which includes the promyelocytic leukaemia zinc finger (*PLZF*) gene. In humans *PLZF* is one of five partners fused to the retinoic acid receptor alpha in acute promyelocytic leukaemia. *Plzf*-deficient mice show severe malformations of the vertebral and appendicular skeleton and male genital hypoplasia. Since patients with a deletion of 11q23 do not normally present with skeletal malformations and genital hypoplasia, we sequenced the maternal *PLZF* allele in our patient and identified a missense mutation (c.1849 A>G), which leads to the substitution of a highly conserved methionine to valine within the eighth zinc finger motive. The mutation was inherited from the mother, who does not have skeletal defects. *In vitro* reporter gene assays show that the mutation impairs the repressive function of PLZF. In summary, this is the first report on a germline mutation of *PLZF*. Our findings as well as observations in *Plzf*-deficient mice demonstrate that PLZF is a key regulator of skeletal and male germline development. Furthermore, our case highlights the importance to search for a recessive mutation on the non-deleted allele in patients with a microdeletion and atypical clinical findings.

C12.1

Mutations in Pericentrin cause microcephalic dwarfism (Seckel syndrome) with defective ATR-dependent DNA damage signalling

A. P. Jackson¹, E. Griffith¹, S. Walker², C. Martin¹, P. Vagnarelli³, T. Stiff⁴, B. Vernay¹, N. Al Sanna⁴, A. Saggar⁶, B. Hamel⁶, W. C. Earnshaw³, P. A. Jeggo², M. O'Driscoll⁵;

¹MRC Human Genetics Unit, Edinburgh, United Kingdom, ²Genome Damage and Stability Centre, University of Sussex, Brighton, United Kingdom, ³Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom, ⁴Pediatric Services Division, Dhahran Health Center, Dhahran, Saudi Arabia, ⁵Southwest Thames Regional Genetics Service, St. George's Hospital Medical School, London, United Kingdom, ⁶Radboud University Nijmegen Medical Center, Department of Human Genetics, Nijmegen, Netherlands.

Expansion of the brain is one of the defining characteristics of modern humans. In microcephalic dwarfism, brain and body size are markedly reduced to a similar degree to that seen in the recently discovered Indonesian hominid, *Homo Floresiensis*. Previously, only a single hypomorphic mutation in the ATR gene has been found as a cause of this genetically heterogeneous group of disorders.

Here, we report that homozygous truncating mutations in pericentrin (*PCNT*) cause microcephalic dwarfism, resulting in its loss from the centrosome, where it has key functions anchoring both structural and regulatory proteins. Furthermore, we find that *PCNT*-mutated patient cells have defects in ATR-dependent checkpoint signalling, providing the first evidence linking a structural centrosomal protein with DNA damage signalling. These findings also suggest that other known microcephaly genes implicated in either DNA repair responses or centrosomal function, may act in common developmental pathways determining brain and body size, pathways potentially important in human evolution.

C12.2

Polycomb complex shapes the higher order of D4Z4 chromatin structure during differentiation of normal and FSHD muscle stem cells

B. Bodega¹, S. Brunelli^{2,3}, F. Grasser⁴, N. Locatelli¹, R. Menever², A. Marozzi¹, S. Mueller², E. Battaglioli¹, E. Ginelli¹;

¹Dept. of Biology and Genetics for Medical Sciences, University of Milan, Milan, Italy, ²Dept. of Experimental Medicine, University of Milan-Bicocca, Monza, Italy, ³Stem Cell Research Institute (SCRI), DIBIT H San Raffaele, Milan, Italy, ⁴Dept. of Biology II – Anthropology and Human Genetics, Ludwig Maximilians University, Munich, Germany.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant neuromuscular disorder. FSHD involves a complex cascade of epigenetic events following contraction of a D4Z4 repeat located on chromosome 4q35.2 (FSHD locus). Previous work has indicated that

transgenic mice overexpressing FRG1, a gene proximal to the deletion, showed a phenotype resembling the FSHD disease. However, increased expression of FRG1 in FSHD patients has not been a uniform finding, and up to now several studies have failed in identifying the molecular mechanism affecting the FSHD locus functionality. We took advantage of ChIP/MeDIP and 3D immuno-FISH assays as complementary approaches to depict the higher order of chromatin organization of 4q35.2 region during myogenic differentiation of healthy and FSHD myoblast and mesoangioblast stem cells. We found that FRG1 undergoes to muscle specific regulation through a two-step activation mechanism, whereby removal of H3-K27 methylation and Polycomb complex components precedes MyoD recruitment on the FRG1 promoter; intriguingly, the same chromatin structure and PcG recruitment were contemporaneously found on D4Z4 array, rendering the Polycomb complex the first molecular player that links FSHD locus to myogenic differentiation. Moreover, D4Z4 H3-mK27 signals were strongly reduced in FSHD myoblasts in respect to controls, suggesting the severe impairment of the PcG complex recruitment. Nevertheless, molecular alterations of the D4Z4 array do not have in FSHD myoblasts an effect in cis on FRG1 gene expression. These observations evidence a role of 4q35 D4Z4 in muscle differentiation, probably through inter-chromosomal interactions.

C12.3

Active transport of the ubiquitin ligase MID1 along the microtubules is regulated by protein phosphatase 2A

B. Aranda Orgilles¹, J. Aigner¹, R. Schneider^{1,2}, S. Schweiger^{1,3};

¹Max Planck Institute for Molecular Genetics, Berlin, Germany, ²Institute of Biochemistry, Innsbruck, Austria, ³Division of Pathology and Neuroscience, Ninewells Hospital, Dundee, United Kingdom.

Mutations in the MID1 protein have been found in patients with Opitz BBB/G syndrome (OS), which is characterised by multiple malformations of the ventral midline. MID1 is a microtubule-associated protein that stabilizes microtubules and, in association with the regulatory subunit of protein phosphatase 2A (PP2A), $\alpha 4$, provides ubiquitin ligase activity for the ubiquitin-specific modification of PP2A. Using Fluorescence Recovery After Photobleaching (FRAP) technology, we show here that MID1 is actively and bi-directionally transported along the microtubules, and that this movement is directly linked to its MAP kinase and PP2A-mediated phosphorylation status. Intact transport depends on both kinesins and dyneins and is inhibited upon taxol and colcemid treatments. MID1 proteins carrying missense mutations in the $\alpha 4$ binding domain still bind the microtubules but can not be actively transported. Likewise, knock-down of the $\alpha 4$ protein, inhibition of PP2A activity by okadaic acid and fostriecin or the simulation of permanent phosphorylation at Ser96 in MID1 stop the migration of MID1-GFP, while preserving its microtubule-association. In summary, our data uncover an unexpected and novel function for PP2A, its regulatory subunit $\alpha 4$ and PP2A / $\alpha 4$ / mTOR signalling in the active transport of the MID1 ubiquitin ligase complex along the cytoskeleton. Furthermore, a failure in the microtubule directed transport of this protein complex would be an attractive mechanism underlying the pathogenesis of OS in patients with B-box1 mutations.

C12.4

A centrosomal protein molecularly links Usher syndrome to Leber congenital amaurosis and Bardet-Biedl syndrome in the retina

H. Kremer^{1,2}, E. van Wijk^{1,3}, F. Kersten^{3,4}, N. Zaghoul⁴, T. Peters¹, A. Kartono^{3,2}, S. Letteboer^{3,2}, U. Wolfrum⁵, N. Katsanis⁴, R. Roepman^{3,2};

¹Department of Otorhinolaryngology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, ²Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen, Nijmegen, Netherlands, ³Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, ⁴Departments of Ophthalmology and Molecular Biology and Genetics, McKusick Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States, ⁵Department of Cell and Matrix Biology, Institute of Zoology, Johannes Gutenberg University of Mainz, Mainz, Germany.

Usher syndrome (USH) is the most common cause of hereditary deaf-blindness in man. Ten loci are known for Usher syndrome, and we and others provided evidence for the existence of a protein network of the USH proteins at different subcellular sites in the retina and inner ear.

Disruption of one of the members of the USH network can lead to malfunction and degeneration of both photoreceptor cells and hair cells.

To elucidate the pathogenic mechanisms of Usher syndrome, we searched for novel interacting partners for the intracellular region of USH2A isoform B. This revealed the interaction with a centrosomal protein. Interestingly, simultaneous screens for interactors of the recently identified lebercilin (*LCA5*, and associated with Leber congenital amaurosis, LCA), identified the same centrosomal protein. In order to clarify the role of this protein *in vivo*, knockdown studies in zebrafish were performed. This gave rise to a classical planar cell polarity phenotype, similar to the defects observed after knockdown of the genes involved in Bardet-Biedl syndrome (BBS). Yeast two-hybrid interaction analysis subsequently revealed a specific physical interaction between the centrosomal protein and BBS6.

Our data indicate that the same centrosomal protein interacts physically with USH2A, lebercilin and BBS6, thereby linking the retinal ciliopathies Usher syndrome, Leber congenital amaurosis and Bardet-Biedl syndrome at the molecular level. The physical and genetic interactions between proteins/genes involved in Usher syndrome and Bardet-Biedl syndrome suggest a putative role for the Usher interactome in the establishment of planar cell polarity, with a central role of the cilia.

C12.5

Study of the role of the *Odf1* transcript in limb patterning and endochondral bone development

S. Bimonte¹, L. Quagliata¹, R. Tammaro¹, M. Ascenz², B. Franco^{1,3};

¹Telethon Institute of Genetics and Medicine-TIGEM, Naples, Italy, ²Department of Orthopaedic Surgery, Biomechanics Research Division, University of California, Los Angeles, CA, United States, ³Department of Pediatrics, University Federico II, Naples, Italy.

Oral-facial-digital type I (OFDI) syndrome is an X-linked dominant male lethal developmental disorder characterized by oral, facial and digital abnormalities. Recent data ascribed OFDI to the growing number of diseases due to dysfunction of primary cilia. *Odf1* null mutants recapitulate the phenotype observed in OFDI patients and displayed skeletal defects. To overcome the embryonic male and perinatal female lethality observed in *Odf1* null mutants we have generated a conditional model with *Odf1* limb mesenchyme specific inactivation. These mice displayed a severe polydactyly with loss of antero-posterior digit patterning, aberrant cilia formation, and shortened long bones. Defective digit patterning was found to be associated to progressive loss of Shh signaling and impairment of Gli3 processing. Shortening of long bones was found to be associated to misregulation of *Ihh* expression and activity during endochondral bone formation as revealed by RNA in situ studies. Immunohistochemical analyses to assess the proliferative state of chondrocytes revealed an increase in the number of proliferating pre- and hypertrophic chondrocytes in male mutants. This data suggest that the shortening of long bones observed in *Odf1*Prx1Cre mice is likely due to an increase in the number of proliferating chondrocytes associated to a delay in terminal chondrocytes differentiation. Finally Von kossa staining and RNA in situ studies demonstrated defective bone mineralization accompanied by loss/reduction of bone collar development suggesting a defect in osteoblast differentiation. Altogether our data demonstrate that *Odf1* is a patterning factor that plays multiple roles in limb and endochondral bone development.

C12.6

Integration into molecular diagnostic procedures of systematic screening for sequence variants of unknown significance using a splicing reporter minigene

M. Vezain¹, I. Tournier¹, A. Martins¹, C. Bonnet¹, S. Krieger², S. Baert-Desurmont¹, A. Killian¹, A. Hardouin², T. Frébourg^{1,3}, M. Tosi¹;

¹Inserm U614, Faculty of Medicine, Rouen, France, ²Laboratory of Clinical and Oncological Biology, Centre François Baclesse, Caen, France, ³Department of Genetics, University Hospital, Institute for Biomedical Research, Rouen, France.

Unclassified variants (UVs) found in genes involved in genetic diseases may have an effect on pre-mRNA splicing. In clinical practice, the interpretation of UVs is limited because patient blood samples are often not suitable for RNA analysis. We have recently developed a screening strategy based on genomic DNA from patients, using a splicing reporter minigene. We have now applied this screening protocol to more than 150 UVs from many genes including *MSH2*, *MLH1*,

APC, BRCA1 and BRCA2. The protocol steps have been streamlined for routine application as follows: 1) PCR amplification of the relevant exon, including flanking intronic sequences, 2) cloning into a two-exon splicing reporter minigene, 3) selection of wild-type- and variant-carrying plasmids, 4) transfection into HeLa cells, 5) RNA extraction and RT-PCR using primers targeting minigene sequences, and 6) sequence analysis of all RT-PCR products. Variants associated with total absence of correct exon inclusion in this monoallelic assay are considered as most likely pathogenic but UVs inducing partial alterations of normal mRNA sequences are also considered as biologically significant. In spite of our initial concern that exons are tested in a heterologous context, extensive comparisons with *in vivo* RNA data have shown that this minigene-based approach is sensitive and specific. Comparisons with results from *in silico* analysis indicate that current bioinformatic predictions are sensitive and rather specific concerning changes in splice site strength, activation of cryptic sites or generation of new splice sites, but are still inadequate for predicting the presence of relevant exonic splicing regulatory elements.

C13.1

A genome-wide scan of adult human stature and skeletal size

N. Soranzo¹, F. Rivadeneira², U. Chinappan³, M. Inouye¹, B. J. Richards³, S. Potter⁴, R. Williams¹, K. Papadakis⁴, E. Wheeler¹, I. Barroso¹, D. Hart⁵, G. Livshits⁶, R. J. F. Loos⁷, D. Strachan⁴, N. J. Wareham⁷, T. D. Spector³, A. Uitterlinden², P. Deloukas¹;

¹The Wellcome Trust Sanger Institute, Hinxton, United Kingdom, ²Erasmus MC, Rotterdam, The Netherlands, ³School of Medicine, King's College London, London, United Kingdom, ⁴St George's, University of London, London, United Kingdom, ⁵St. Thomas' Hospital, London, United Kingdom, ⁶Tel Aviv University, Tel Aviv, Israel, ⁷Institute of Metabolic Science, Cambridge, United Kingdom.

Human adult stature is a classical quantitative trait and a paradigm for genetic association studies of quantitative trait variation. We have carried out a meta-analysis of four genome-wide association scans of stature produced using the Illumina HumanHap300 SNP panel in 10,050 adults from four population-based cohorts (TwinsUK, EPIC Norfolk and 1958 Birth Cohort from the UK and the Rotterdam Study from the Netherlands). We have identified eighteen loci showing association with height with P-values of less than 10^{-5} , which we have brought forward for replication in an independent sample of 9,000 individuals.

The signals identified provide strong evidence for replication in genomic regions previously implicated in height, including HMGA2 (rs8756, P-value = 5×10^{-13}) and GDF5-UQCC (rs4911494, P-value = 1.5×10^{-10}). In addition, we have identified novel candidate genetic loci for human height, some of which are in or near genes implicated in cellular growth and development (HHIP, ADAMTSL3 and DLEU7). In an attempt to dissect the mechanisms underlying human growth, we have tested the association of these novel candidate height loci with different measurements of skeletal growth. Our results provide both novel and confirmatory evidence for the implication of genes and pathways in human growth, thus contributing to the understanding of the biological processes underlying many common and severe human diseases.

C13.2

Super-hotspots for Meiotic Recombination in the Human Genome

I. L. Berg, A. J. Webb, A. J. Jeffreys;

Department of Genetics, University of Leicester, Leicester LE1 7RH, United Kingdom.

Homologous recombination is a vital process for ensuring proper chromosome segregation during meiosis, as well as increasing diversity by reshuffling haplotypes between generations. In this study, we analysed Phase II HapMap data to identify autosomal regions showing extreme breakdown of linkage disequilibrium (LD). Sixteen of these regions were selected for crossover analysis directly in sperm. All contained active sperm hotspots, with similar characteristics as at previously studied hotspots, i.e. normally-distributed crossover breakpoints within regions 1-2 kb wide. These new hotspots were on average 10 fold more active than previously characterised autosomal hotspots and include the most active crossover hotspots yet discovered in the human genome. Their activity is however poorly predicted from LD data. Most crossovers in these hotspots were simple, exchanging haplotypes within a single interval between markers. However, 0.3% of exchanges were more

complex, switching haplotypes at several intervals during an exchange event. Most of these occurred within the boundaries of the hotspot while 22% occurred beyond the hotspot, implying a broader region involved during intermediate stages of recombination. Several hotspots showed crossover frequency variation between men, including two cases of complete presence/absence polymorphism. Instances of extreme or subtle biased gene conversion accompanying crossover were observed within some hotspots, in some cases correlating with crossover frequency variation between men. Curiously none of the most active hotspots showed polymorphism or strongly biased conversion, in contrast to the prediction that these hotspots should be the most vulnerable to attenuation/extinction by meiotic drive in favour of recombination suppressors.

C13.3

A full survey of common copy number variation in the human genome

R. Redon¹, D. F. Conrad¹, L. Feuk², C. Lee³, S. W. Scherer², M. E. Hurles¹, N. P. Carter¹;

¹Wellcome Trust Sanger Institute, Cambridge, United Kingdom, ²The Hospital for Sick Children, Toronto, ON, Canada, ³Brigham and Women's Hospital, Boston, MA, United States.

Copy number variation (CNV) in the genome is extensive and yet is grossly under-ascertained. As smaller CNVs are expected to be far more numerous than larger CNVs, improved CNV detection resolution will dramatically increase the numbers of known CNVs. The Genome Structural Variation Consortium has performed comparative genome hybridisation on a genome-wide set of tiling oligonucleotide arrays to discover the majority of common copy number variants >500bp in size in two populations with African and European ancestry. This set covers the assayable portion of the human genome with 42,000,000 probes with a median spacing of ~50bp. In addition we have generated data on a single chimpanzee to provide information on the ancestral state of observed variants. The results reveal, as expected, that previous surveys captured only 5-10% of the CNVs within a single genome. Because the boundaries of thousands of CNVs are defined precisely by this probe set, we can identify accurately functional sequences included in copy number variable regions. This provides new insights into the mechanisms generating chromosomal rearrangements and the biological functions of common CNVs.

C13.4

Gene expression variation from peripheral blood in the general population - the KORA study

D. Mehta¹, K. Heim¹, T. Illig², H. Wichmann^{2,3}, T. Meitinger^{1,4}, H. Prokisch^{1,4};

¹Helmholtz Zentrum München - Institute of Human Genetics, Munich, Germany,

²Helmholtz Zentrum München - Institute of Epidemiology, Munich, Germany,

³Institute of Medical Informatics, Biometry and Epidemiology, LMU, Munich, Germany,

⁴Institute of Human Genetics, Klinikum rechts der Isar, Technical University Munich, Munich, Germany.

Interrogation of gene expression variation in humans will provide better understanding of functional genetic variation and help identify disease variants. At present, the nature and extent of variation in transcript levels across the entire genome is largely unknown.

We assessed normal variation in gene expression from 350 KORA individuals, using the Illumina Human Ref-6 v2 whole genome microarray. Special features of inter individual variation in peripheral blood expression could be traced to gender and age differences. Several significant age-related genes and distinct gender-specific gene signatures were identified. Using the PAM algorithm, it was possible to predict the gender with an accuracy of 98%.

Using available KORA Affymetrix 500k genotypes, we performed a genome-wide association study to compare peripheral blood eQTLs (Expression Quantitative trait loci) to published lymphocyte cell culture eQTLs.

Expression data can be used to prioritize candidate genes with expression levels significantly correlated to the trait. In this context, a recent genome wide association study using the KORA population found the most significant SNPs associated with urate levels mapped within an uncharacterized carrier gene SLC2A9. Our analysis revealed a significant association between SLC2A9 expression and urate levels (Doering et al, Nature Genetics in print).

Analysis of further candidate genes where genome-wide association signals have been obtained is currently underway.

C13.5

The genetic control of microRNA expression variation in Humans

C. Borel, S. Deutsch, H. Attar, M. Gagnebin, C. Gehrig, E. Falconnet, Y. Dupré, S. E. Antonarakis;

Department of Genetic Medicine and Development, University of Geneva Medical School, CH, Geneva, Switzerland.

C.B. and S.D. contributed equally to this work.

MicroRNAs (miRNAs) are small non-coding RNA molecules that regulate the expression of protein-coding. Each miRNA is thought to have multiple target genes that are regulated at the post-transcriptional level. Inter-individual variation of miRNA gene expression is likely to influence the levels of target genes, and may therefore contribute to some phenotypic differences, including susceptibility to common disorders. The aim of this study was to characterize the natural variation in miRNA expression levels present in different individuals, and to identify loci that control this variation.

We established primary fibroblasts from 200 unrelated umbilical cord samples of Caucasian origin (GenCord collection). All of these samples have been genotyped using the Illumina Hap550 SNP array. After multiple filtering steps 433'000 were retained for statistical analyses. Taqman real-time PCR in all cell lines was used to measure the expression of 365 known mature microRNAs in each sample. This revealed substantial differences in miRNA expression levels between individuals, which were up to 50-fold in some cases. Normalized miRNA levels for each individual were used to perform quantitative whole genome association studies using the Plink software. We will present the detailed genome-wide association analysis of SNPs that control in cis- or trans- miRNA expression.

This is the first attempt to characterize the genetic regulation of miRNA expression levels. Loci identified through this approach are likely to be important determinants of human phenotypes.

C13.6

Comparison of different methods to estimate genetic ancestry and control for stratification in genome-wide association studies

E. Salvi^{1,2}, G. Guffanti¹, A. Orrò², F. Torri¹, S. Lupoli³, J. Turner⁴, D. Keator⁴, J. Fallori⁴, S. Potkin⁴, C. Barlassina¹, D. Cusi¹, L. Milanese¹, F. Macciardi¹;

¹Department of Science and Biomedical Technology, University of Milan, Milan, Italy, ²ITB CNR, Segrate, Milan, Italy, ³INSPE, Milan, Italy, ⁴Department of Psychiatry and Human Behavior University of California, Irvine, CA, United States.

In case-control association studies, population subdivision or admixture can lead to spurious associations between a phenotype and unlinked candidate loci. Population stratification can occur in case-control association studies when allele frequencies differ between cases and controls because of ancestry.

We evaluated five methods (Fst, Genomic Control, STRUCTURE, PLINK and EIGENSTRAT) using 317K SNPs (Illumina HumanHap300) in a case-control sample of 200 American subjects with different races (Caucasian, African and Asian) in order to identify and to correct for stratification. Fst, Structure and Genomic Control are based on the usage of few genetic markers while PLINK and EIGENSTRAT are computationally tractable on a genome-wide scale. Fst, STRUCTURE and Genomic Control did not detect a significant stratification in our sample, as well as EIGENSTRAT and PLINK. However, these last two methods, using a much larger information from the whole set of SNPs, graphically suggested the presence of a partial stratification, due to African and Asian individuals while the estimated inflation factor of 1 didn't statistically confirm stratification. This brought to the decision to further enlarge the sample with hundreds of controls coming from Caucasian populations. When we enlarged the sample to 650 individuals we found a high value of inflation factor as statistical confirmation of the population stratification. The substructure still depends only on African and Asian subjects that are separated from the Caucasian homogeneous sample. Therefore the sample size is crucial to get enough power to detect a possible stratification.

C14.1

The ethics of undertaking research in other countries

L. Skene;

University of Melbourne, University of Melbourne, Australia.

There are many reasons for scientists to undertake research with colleagues in other countries: to share knowledge and experience with

colleagues; to obtain funding directed to transnational projects; to gain access to facilities and research participants; to acquire kudos, academic advancement, or commercial benefits; or to undertake activities that would not be permitted in their own country, due to legal or ethical constraints.

This paper considers the last reason and when it is ethical for scientists to do research abroad that is banned at home. The author argues that such research may sometimes be ethical, provided it is scientifically rigorous and accords with international ethical principles and ethical oversight requirements. But it is not ethical when the proposed research is widely regarded as unethical in the home country. The author uses her own image of *Skene's Ethico-Legal Barometer* to gauge the activities that attract this degree of sensitivity and would be unethical wherever they are done. This research is in the red zone of the barometer and the closer an activity falls to the red zone, the greater the need for ethical review and oversight before being ethically acceptable in the home country.

The author illustrates these arguments with examples like human embryonic stem cell research, somatic cell nuclear transfer and research involving human subjects.

C14.2

Direct-to-consumer services. A review of the debate

P. Borry;

Centre for Biomedical Ethics and Law, Leuven, Belgium.

Background. The rapid expansion of the internet has meant that there is now a global marketplace for a multitude of health care products and services that are available directly to the consumer. Related to this, in the field of genetics, the rapid expansion of knowledge about the relationship between genetics and human disease has set the groundwork for commercial enterprises that use direct-to-consumer (DTC) advertising for genetic tests and, in some cases, bypass the supervision of a health professional to offer DTC purchase of the tests. Various companies (e.g. Sciona (UK), DNA direct (US), Genelink (US), Test Kimball Genetics (US), Geneticom (The Netherlands)...) have been identified where direct-to-consumer tests are offered (e.g. for paternity testing, ancestry testing, susceptibility tests for cardiovascular diseases, hereditary hemochromatosis, osteoporosis, Factor V Leiden, type 2 diabetes...).

Objective. This paper wants to investigate the existing ethical and legal framework of direct-to-consumer services.

Method. It will offer a review of the debate through a systematic analysis of the position papers, reports, guidelines or statements emanating from international and national organisations, bioethics committees, and professional associations, together with the academic literature identified after an extensive literature search.

Results. This paper offers an overview of the debate. It identified weaknesses in the existing regulatory framework and suggested further pathways for research.

C14.3

Preventive genetic screening in the isolated community: lessons learned

L. Basel-Vanagaite^{1,2}, E. Taub³, L. Rainshtein², V. Drasinover³, N. Magal³, J. Zlotogora⁴, M. Shohat³;

¹SCMCI and Rabin Medical Center, Petah Tikva, Israel, ²Tel Aviv University, Tel Aviv, Israel, ³Rabin Medical Center, Petah Tikva, Israel, ⁴Department of Community Genetics, Ministry of Health and Hadassah Medical School Hebrew University, Jerusalem, Israel, Tel Hashomer, Israel.

In the countries with high rates of consanguinity, many inherited diseases are present with a high frequency only in a limited geographical region. We present a comprehensive strategy for genetic diseases prevention program in the isolated community in Israel and examine the impact of the screening on the population.

During years 2003-2007, we carried out carrier screening among the residents of an isolated village of 10,500 inhabitants with a high frequency of non-syndromic mental retardation (MRT3), spinal muscular atrophy, spinal muscular atrophy with respiratory distress and cystic fibrosis. The subjects were pregnant women visiting the women's health station for routine monitoring. The medical geneticist or genetic counselor provided counseling. A three-generation pedigree was constructed by interviewing the women and the nurses. The screening was provided free of charge, financed by the Israeli Ministry of Health. We

identified 215 carriers for one of the diseases and 14 carrier couples. Carrier frequency for MRT3, SMA, SMARD and cystic fibrosis was 1:11, 1:13 and 1:10 and 1:21, respectively. Among carrier couples, 15 pregnancies were recorded and 2 pregnancies of affected fetuses terminated. More than 50% of carrier couples accepted prenatal testing. While the women in the village were willing to collaborate, an increase in the willingness to collaborate among men was observed gradually. The availability of genetic counseling locally and education of the population are essential for the success of the prevention program. Ethical aspects of preventative programs based on genetic screening of premarital, pre-conceptual couples or couples during pregnancy will be discussed.

C14.4

Differences and similarities in breast cancer risk assessment models in clinical practice: which model to choose?

C. J. Van Asperen¹, G. H. De Bock², B. Siegerink^{1,3}, C. E. Jacob³;

¹Center for Human and Clinical Genetics, Leiden, The Netherlands, ²Dept. Epidemiology, University Medical Center Groningen, Groningen, The Netherlands, ³Dept. Medical Decision Making, Leiden, The Netherlands.

Background: Models regarding breast cancer risk assessment focus on family history and some use personal risk factors additionally. Aim of this study is to show differences and similarities between the different models in risk estimates for breast cancer in healthy women from BRCA1/2-negative or untested families.

Methods: After a systematic literature search seven models were selected: Gail-2, Claus Model, Claus Tables, BOADICEA, Jonker Model, Claus-Extended Formula, and Tyrer-Cuzick. Life-time risks (LTRs) for developing breast cancer were estimated for two healthy counselees with variety in family histories and personal risk factors. The estimated LTRs and the threshold for individual mammographic screening based on guidelines were compared.

Results: Without a clinically significant family history LTRs varied from 6.7% (Gail-2 model) to 12.8% (Tyrer-Cuzick Model). For counselees with low and moderate risk, the models mostly agreed. Difficulties in screening decisions were encountered in some moderate and high risk individuals, and when including personal risk factors into the estimations.

Conclusion: Older models (i.e. Gail-2 and Claus) are likely to underestimate the LTR for developing breast cancer as their baseline risk for women without a significant history of breast cancer is too low. Current guidelines have been formulated on breast cancer risks based on family history alone. When models include personal risk factors, surveillance thresholds have to be reformulated as other factors are applied. For current clinical practice, the Tyrer-Cuzick Model and the BOADICEA Model seem good choices.

C14.5

Treatable and untreatable diseases in the neonatal-screening programme: the opinion of future parents in The Netherlands

A. C. Plass^{1,2}, L. Krijgsmann^{1,2}, L. Gieling^{1,2}, C. G. van El^{1,2}, T. Pieters¹, M. C. Cornel^{1,2};

¹VU University medical center, Amsterdam, The Netherlands, ²EMGO-institute, Amsterdam, The Netherlands.

In the Netherlands, in 2007, the neonatal screening program was expanded from 3 to 17 disorders for which screening met the Wilson and Jungner criteria, especially regarding treatability. The decision whether or not to add diseases to the newborn screening programme has often been made by expert groups, whereas the opinion of those whom it concerns: the parents-to-be remains unknown. In our research we investigated the opinion of future parents concerning screening newborns also for incurable, but to some extent treatable or even untreatable disorders.

A structured questionnaire consisting of 3 parts in which similar questions were posed about treatable, incurable, but treatable, and untreatable childhood onset disorder was posted on the website of a national pregnancy fair. 1631 prospective parents filled out the questionnaire. 259 were excluded because they did not meet our inclusion criteria.

In contrast to current policy, overall they showed a positive attitude towards inclusion of incurable, but treatable [88%] or non-treatable disorders [73%] within the national newborns screening programme. Respondents who already had children at the time of filling out the questionnaire were even more in favour of uptake of childhood dis-

orders, especially untreatable diseases. The most important reason mentioned was: to prevent a long diagnostic quest. Obtaining information to enable reproductive choices in future pregnancies was hardly mentioned.

Since a relevant part of the Dutch population seems interested in considering screening newborns for untreatable disorders we argue that further debate is needed between policy, public and health care professionals to discuss pros and cons.

C14.6

Promoting clinically relevant genetics education for medical trainees: the importance of educational outcomes and resources for each stage of medical training

M. Martyn¹, S. Burke², C. Bennett¹, A. Stone³, E. Harvey¹, R. Newton¹, P. Fardon¹;

¹NHS National Genetics Education and Development Centre, Birmingham, United Kingdom, ²Centre for Research in Medical and Dental Education, Birmingham, United Kingdom, ³Thornley Street Practice, 40 Thornley Street, Wolverhampton, United Kingdom.

It is widely acknowledged that the genetics education of healthcare staff across the world has not kept pace with advances in genetics. The NHS National Genetics Education and Development Centre is working to address this situation in the UK by promoting clinically relevant genetics education for healthcare professionals across all stages of education and training. To achieve this, it is important to develop clinically relevant educational outcomes and to identify and develop resources to support these across all stages of training. This will be illustrated by results from the UK.

The first step in promoting clinically relevant genetics education was to develop educational outcomes linked to clinical practice at each stage of training. Outcomes have been developed for medical students and general practice and specialty trainees by working with health professionals to define genetics relevant to practice for these stages of training. To promote incorporation of these outcomes into curricula, the Centre worked with education bodies to raise awareness of the importance of clinically relevant genetics education.

Now the outcomes have been incorporated into medical training curricula, the Centre is focusing on supporting teachers and learners through the development and evaluation of learning and teaching resources and professional development for educators. Resources covering core genetics concepts for medical students and resources to support general practice training are currently being developed.

The educational outcomes and many of the resources will be made freely available online at www.geneticseducation.nhs.uk and may be of use to those involved in genetics education across Europe.

C15.1

Systemic antisense-mediated exon skipping studies in mouse models for Duchenne muscular dystrophy

A. Aartsma-Rus¹, H. A. Heemskerk¹, C. L. de Winter¹, M. van Putten¹, A. A. M. Janson², S. de Kimppe², J. C. T. van Deutekom², G. B. van Ommen¹;

¹Leiden University Medical Center, Leiden, The Netherlands, ²Prosensa BV, Leiden, The Netherlands.

Duchenne muscular dystrophy (DMD) is a severe, progressive neuromuscular disorder leading to loss of muscle function and generally premature death before the age of 30. The disease is caused by mutations in the *DMD* gene that disrupt the open reading frame and lead to complete abolishment of functional dystrophin. Our group has pioneered antisense-based exon skipping to restore the reading frame. Here, antisense oligoribonucleotides (AONs) induce specific exon skipping during pre-mRNA splicing. They have been successful in repairing the disrupted open reading frame and the generation of internally deleted, partially functional Becker-like dystrophins. Proof of concept has been achieved in cultured muscle cells from patients and the *mdx* mouse model. Recently, exon 51 skipping and dystrophin restoration was confirmed after a single intramuscular dose of AON in a local-administration clinical trial in 4 patients. Our current research focuses on optimizing systemic delivery of 2'-O-methyl phosphorothioate AONs and comparison of different routes of administration and dosing regimes. We show that after systemic injection, AONs are preferentially taken up by dystrophic muscle compared to healthy fibers. Furthermore, we were able to induce exon skipping and dystrophin restoration in all muscles, including the heart after short term treatment with high AON

doses and long term treatment with lower doses. This was accompanied by functional improvement and improved muscle integrity, without any apparent toxicity. These findings are encouraging for future clinical trials and eventual systemic application of this approach.

Restoration of aberrant splicing and neurofibromin function in three NF1 deep intronic mutations by antisense morpholino oligonucleotides (AMOs)

E. Pros^{1,2}, J. Fernández¹, B. Canet¹, L. Benito³, A. Benavides⁴, F. J. Ramos⁵, M. A. López-Ariztegui⁶, G. Capellá¹, I. Blanco⁷, E. Serra⁸, C. Lázaro¹;

¹Laboratori Recerca Translacional, Institut Català d'Oncologia, Hospitalet de Llobregat, Barcelona, Spain, ²Genetics Department, IDIBELL, L'Hospitalet de Llobregat, Barcelona, Spain, ³Unitat Consell Genètic, Institut Català d'Oncologia, Hospitalet de Llobregat, Barcelona, Spain, ⁴Genética, Hospital Universitario Central de Asturias (HUCA), Oviedo, Spain, ⁵Dpto. Pediatría, Facultad de Medicina, Universidad de Zaragoza, Zaragoza, Spain, ⁶Genética, Hospital de Cruces, Bilbao, Vizcaya, Spain, ⁷Unitat de Consell Genètic, Institut Català d'Oncologia, Hospitalet de Llobregat, Barcelona, Spain, ⁸Genetics Department, IDIBELL, Hospitalet de Llobregat, Barcelona, Spain.

Neurofibromatosis type 1 (NF1) is a common autosomal dominant disorder caused by mutations in the *NF1* gene. Approximately 2% of the germline mutations identified in our population consists in deep intronic mutations. Such nucleotide changes create new splice sites that produce the insertion of a cryptic exon in the mature mRNA. We used antisense morpholino oligonucleotides (AMOs) to restore normal splicing in three *NF1* deep intronic mutations (c.288+2025T>G, c.5749+332A>G and c.7908-321C>G). All of them generate a cryptic 5' splice donor site and result in the inclusion of a cryptic exon in the mature RNA by the use of an existent 3' cryptic splice site. AMOs were designed to target the newly created 5' splice sites in order to avoid the incorporation of cryptic exons and promote the use of wild-type splice sites, by the splicing machinery. Our results demonstrate that AMOs treatment effectively restore normal *NF1* splicing at the mRNA level in primary fibroblast and lymphocyte cell lines derived from different patients carrying the three deep intronic mutations. In addition, we observed a decrease in the amount of Ras-GTP (equivalent to wild type fibroblast levels) in primary fibroblasts from patients after AMOs treatment, consistent with the restoration of neurofibromin function. To our knowledge this is the first time that an antisense technique is used successfully to restore *NF1* mutations, opening the possibility of a therapeutic strategy for this type of *NF1* mutations.

C15.3

Antisense therapeutics for a new deep intronic variation identified in two Methylmalonic Acidemia patients

A. Rincón, L. R. Desviat, M. Ugarte, B. Pérez;

Centro de Biología Molecular Severo Ochoa. CIBERER, Madrid, Spain.

Isolated methylmalonic acidemia (MMA) is a life threatening organic acidemia caused by defects in the methylmalonyl-CoA mutase (MCM) or in enzymes involved in the synthesis of the active cofactor adenosylcobalamin. In this work we describe a new point change identified in two MMA affected patients located deep in intron 11 of the MUT gene (IVS11-898A>G). This change increases the splicing score of a 5' cryptic splice site and provokes the intronic inclusion of 76 bp (r.1957ins76) between exons 11 and 12. Using a splicing assay we have demonstrated that the change caused exonization of this intronic sequence and by morpholino antisense oligonucleotide transfection we have demonstrated that the insertion is a disease-causing mutation in these two patients. The antisense oligonucleotide was targeted to the 5' cryptic splice sites to block access of the splicing machinery to the pseudoexonic region in the pre-mRNA. After transfection of the patient's fibroblasts we have performed RT-PCR analysis and enzymatic assay to determine MCM activity. Using this antisense therapeutics we have obtained correctly spliced mRNA that was effectively translated and methylmalonyl CoA mutase activity was rescued in patient's fibroblasts close to 100% of control activity. The effect of AMO is sequence and dose dependent and was not effective in patients where the insertion was produced by splicing background noise. These findings add to previous results providing a new therapeutic strategy in this genetic disorder and potentially applicable to large numbers of cases with deep intronic changes that, at the moment, remain undetected by standard mutation-detection techniques

C15.4

Rescue of a Lethal Murine Model of Methylmalonic Acidemia using AAV 8 Mediated Gene Therapy

R. J. Chandler, C. Venditti;

National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, United States.

Methylmalonic acidemia (MMA), a severe organic acidemia, is caused by deficient activity of the ubiquitous mitochondrial enzyme methylmalonyl-CoA mutase (MUT). MMA patients exhibit increased methylmalonic acid levels in the plasma, urine and CSF and display a clinical phenotype of lethal metabolic decompensation, growth retardation, renal failure and metabolic strokes. To assess the potential of genetic therapy for MUT MMA, we employed a mouse model of MMA that produces no detectable Mut transcript or protein. AAV 8 CBA-Mut was injected directly into the liver of newborn Mut^{-/-} pups. Currently, 28 out of the 29 Mut^{-/-} mice injected with 1 or 2x10¹¹GC of AAV 8 CBA-Mut are alive beyond DOL 90 with some treated Mut^{-/-} mice older than 200 days. All the untreated mutants (n=21) perished before DOL 72. The treated Mut^{-/-} mice are thriving and indistinguishable from their wild-type (WT) littermates. AAV 8 CBA-Mut treated Mut^{-/-} mice achieved body weights comparable to controls while untreated mutants experienced post-natal growth retardation and reached only 40% of the weight of the WT. Plasma methylmalonic acid levels in the treated mutant mice on an unrestricted diet were significantly reduced compared to uncorrected animals, indicating that substantial Mut enzymatic activity was restored after AAV therapy. At DOL 90 the liver from a treated Mut^{-/-} mouse had WT levels of Mut protein by Western blot analysis. These experiments provide the first evidence that gene therapy has clinical utility in treatment of MMA and support the development of gene therapy for other organic acidemias

C15.5

Evaluating suppression of nonsense mutations by aminoglycoside antibiotics as an intervention for vision loss in type I Usher syndrome

A. Rebibo Sabbah¹, I. Nudelmar², Z. M. Ahmed³, T. B. Friedman³, T. Baasov², T. Ben-Yosef¹;

¹Genetics Department, Rappaport Faculty of Medicine, Technion, Haifa, Israel, ²Department of chemistry, Institute of Catalysis Science and Technology, Technion, Haifa, Israel, ³Laboratory of Molecular Genetics, National Institute on Deafness and other Communication Disorders, NIH, Rockville, MD, United States.

Type 1 Usher syndrome (USH1) is a recessively-inherited condition, characterized by profound prelingual deafness, vestibular areflexia, and prepubertal onset of retinitis pigmentosa (RP), which to date has no effective treatment. USH1 can be caused by mutations in each of at least six genes. While truncating mutations of these genes cause USH1, missense mutations of some of the same genes cause nonsyndromic deafness, suggesting that partial or low level activity of the encoded proteins may be sufficient for normal retinal function, although not for normal hearing. Interventions to enable at least some translation of full-length protein, may delay the onset and/or progression of RP in individuals with USH1 due to nonsense mutations. One such possible therapeutic approach is suppression of nonsense mutations by aminoglycosides. We demonstrated up to 91% suppression of *PCDH15* nonsense mutations by commercial aminoglycosides *in vitro*. We also demonstrated *ex vivo* suppression, by the same aminoglycosides, of the R245X mutation. We are now testing suppression of several *CDH23* nonsense mutations. In parallel, we are developing a series of new aminoglycoside-derived compounds, which includes two new promising derivatives, NB30 and NB54. Based on cell toxicity assays and on acute toxicity measurements in mice, the toxicity of both compounds is significantly reduced, in comparison to commercially available aminoglycosides. Based on *in vitro* and *ex vivo* experiments, their suppressive activity is maintained. The research described here will have important implications for development of targeted interventions that are effective for patients with USH1 and nonsyndromic RP caused by various nonsense mutations.

Most Encountered Genetic Disorders in Egypt: Classification & Registry

M. O. Elrubby;

National Research Center, Cairo, Egypt.

Diseases with genetic bases have been a major health problem to every society. Heavy economic, social and health burdens are imposed on the afflicted family as well as the society. In general genetic diseases are relatively prevalent among the Arab population. Incidence of congenital malformations among Egyptians ranges from 1,16 to 3,17 %. This is probably due to the high consanguinity rate (20 - 40 %). Early diagnosis of various genetic disorders with proper intervention will reduce the burdens of genetic disorders at the all levels.

A comprehensive classification system is necessary for genetic diseases in order to provide a framework in which to study the etiology, pathogenesis and treatment of diseases in an orderly fashion. Such system gives clinical geneticists a way to organize the health care needs of their patients. We revised different classifications to determine which classification to follow. However these classifications were based on the etiological diagnosis, pathological diagnosis, phenotypic diagnosis and / or mode of inheritance. Therefore, we established our own classification, as a modification of the previously mentioned. The main purpose of our classification is to include four major descriptive categories (axes), that geneticists consider to identify the genetic disorders. The Final Report of the study (1/7/2004 - 30/6/ 2007) included 3417 cases. We established an integrated classification for the genetic disorders referred to Genetic Clinic. This classification considers the etiological, phenotypic, differential diagnosis and referral axes & is entitled "Genetic/Diagnostic/Referral Classification

Genetics Epidemiology Study of Bashkortostan Republic

S. S. Murzabaeva¹, Y. I. Grinberg², I. M. Khidiyatova², E. K. Khusnutdinova², R. A. Zinchenko³, E. K. Ginter³;

¹Bashkirs state medical university, Ufa, Russian Federation, ²Institute of Biochemistry and Genetics of Ufa Science Center of Russian Academy of Sciences, Ufa, Russian Federation, ³Research Center for Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russian Federation.

The results of genetic epidemiological study of five Districts (Burzyansky, Baimaksky, Abzelilovsky, Salavatsky and Archangelsky) of Bashkortostan Republic are reviewed. The total size of the investigated population was 168050 persons, including 135748 southern- east and northern-east ethnographic group the Bashkir. Medical genetic research included all population of five districts, indigently of a nationality and was carried out under the standard report developed in laboratory genetic epidemiology Research Centre for Medical Genetics. Segregation analysis demonstrated good agreement between the observed and expected segregation frequencies for both AR and AD diseases. The prevalence rates of hereditary disorders (autosomal dominant, autosomal recessive and X-linked) for urban and rural, Bashkirs and other ethnic groups were calculated. Significant differences in the prevalence rates were revealed between the prevalence rates AD and AR disorders in rural and urban populations. The prevalence rare for AD and AR disorders was twice lower in the urban populations than those in the rural ones . The prevalence rate of all Mendelian disorders varied in the investigated populations from 1.54 in Baymak city from 6.12 per 1000 persons in Burzyansky District. Spectrum of AD diseases consisted of 83, spectrum of AR diseases - 48 nosological forms, and X-linked - 13 forms.

The National Register of Congenital Malformations in Moldova: Comparative Analysis for Years 2005-2007

V. V. Egorov, V. C. Sacara, A. Varzar, L. P. Rusu;

National Center of Reproductive Health and Medical Genetics, Chisinau, Republic of Moldova.

Objectives. Since 1989 conform to Order of Ministry of Health N-129 from 27.04.89 was introduced a national system of monitoring of con-

genital malformations (CM). Assistance in creation of modern National register of Congenital malformations and hereditary disorders corresponding to European standards.

Methods. Were obtained 747, 598 and 453 questionnaires for the period of 2005 - 2007, respectively. Were used standard methods of statistical analysis.

Results. The prevalence of CM per 10000 births decreased from 2005 to 2007 and was 199.29 in 2005, 160.00 in 2006 ($X^2=15.795$, $OR=1.246$, $p<0.001$) and 118.96 in 2007 ($X^2=22.196$, $OR=1.345$, $p<0.001$). We are investigated changes in prevalence of sentinel CM. In 2006 decreased frequency of anal atrezia (4.80 v. 1.07, $X^2=7.642$, $OR=4.487$, $p=0.006$), esophageal atresia (6.40 v. 1.07, $X^2=12.833$, $OR=5.983$, $p=0.003$), limbs reduction (7.20 v. 0.54, $X^2=19.785$, $OR=13.461$, $p<0.001$), polydactilia (14.41 v. 2.67, $X^2=28.741$, $OR=5.384$, $p<0.001$), omphalocele (14.41 v. 3.21, $X^2=28.741$, $OR=5.384$, $p<0.001$), Down syndrome (25.61 v. 6.42, $X^2=41.735$, $OR=3.989$, $p<0.001$) and multiple CM (22.41 v. 10.70, $X^2=14.762$, $OR=2.094$, $p<0.001$). In 2007 decreased frequency of omphalocele (3.20 v. 0.54, $X^2=4.688$, $OR=4.545$, $p=0.030$), dysplasia of hip joints (36.55 v. 12.31, $X^2=20.146$, $OR=2.256$, $p<0.001$), and increased frequency of polydactilia (2.67 v. 5.08, $X^2=4.888$, $OR=0.399$, $p=0.030$).

Conclusion. The data from Moldavian Registers are valid statistical tool to make surveillance of CM in the region. Cooperation with EU-ROCAT register can improve planning of medical service in Moldova and will enlarge European database of CM cases.

P01.004

Sensitivity and Specificity of MCV Test for Screening of α and β Thalassemia traits

M. Mohammadi, M. Jafari Nezhad, Z. Moghadam, B. Zarbakhsh, A. Kordafshari, M. Karimipour, S. Zeinali;

Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

Aim: To evaluate the sensitivity and specificity of mean corpuscular volume (MCV) for screening of both Alpha and Beta thalassemia trait
Method: Diagnostic test was conducted on 1500 patients; MCV was measured in all samples using an automated hematology Analyzer [sysmexkx21]. HemoglobinA2 measured by column chromatography. Cut off value for HbA2 was 3.5%. PCR tests were done in all cases for detecting about 4 different deletional mutations in α - globin genes such as- $\alpha^{3,7}$, - $\alpha^{4,2}$, - $\alpha^{20,5}$, and --MED for other non detectable mutation we used sequencing and analysis about 25 different mutation. MCV \leq 80 fl showed a sensitivity of 93.5% and specificity 91.5%.

Conclusion: MCV evaluation is a useful tool for screening of alpha thalassemia and β thalassemia traits because of its simplicity, low cost and high sensitive.

P01.005

Molecular Characterization of Two Families With $\delta\beta$ Thalassemia

F. Bayat, A. Valaei, A. Amirian, A. Kordafshari, M. Karimipour, S. Zeinali;

Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

β - thalassemia is the most common genetic disorder in Iran, caused by reduced or absence of globin gene synthesis in β -globin chain. More than 180 different mutations in the β -globin gene have been reported. Most of these mutations are point mutations, and large deletions are not common. $\delta\beta$ thalassemia normally results from deletions involving either the δ, β globin genes or the $A\gamma, \delta$ and β genes. It is useful to broadly divide $\delta\beta$ -thalassemia in to the $(\delta\beta)^+$ and $(\delta\beta)^0$ thalassaemia to indicate whether there is any output of δ and β chains from the affected chromosome. $(\delta\beta)^0$ thalassaemia usually results from large deletions involving the $\epsilon\gamma\delta\beta$ -globin-gene cluster, which remove the β, δ genes but which leave either one or both of the γ -globin genes intact. As already mentioned they can be divided in to the $(\delta\beta)^+$ and $(A\gamma\delta\beta)^0$ thalassaemia, depending on the length of the deletion, that is, whether the $A\gamma$ genes are involved or not. Carriers of thalassemia that were referred to the Primary Health Center were investigated. 5 ml of blood for molecular analysis and 2 ml of fresh blood for hematological lab was used. In this study, two families are investigated because of low MCV and MCH, normal HbA2 and high HbF. First, specific primers for $\delta\beta$ -thalassaemia were designed. DNA fragments were amplified by PCR. Known deletions causing δ β -thalassaemia and HPFH were screened for in these families by gap-PCR method. DNA fragments were visualized on a 2%

agarose gel. The results showed that two families are carriers for the Asian-Indian inversion and deletion. Genotype-phenotype correlation was performed the same as globin gene server database.

P01.006

Genotyping of α -globin genes in Iranian α -thalassemia carriers

E. Shafieiye, M. Karimipour, Z. Kaini Moghaddam, A. Kordafshari, S. Zeinali; *Institute Pasteur, Tehran, Islamic Republic of Iran.*

Introduction:

Alpha thalassemia is more often caused by deletions involving one or both of the α -globin genes.

A small number of point mutations, usually within the $\alpha 2$, have been characterized. The aim of

This study was molecular analysis of α -globin genes in some Iranian people with low MCV, MCH and normal HbA2 and HbF.

Materials and Methods:

After obtaining informed consent, DNA was extracted from blood samples of 100 individuals referred from Primary Health Care (PHC) centers by salting out method. Multiplex Gap-PCR for common α -globin gene deletions was performed. Then for individuals who did not have known deletions, $\alpha 2$ and $\alpha 1$ -globin genes were sequenced by chain termination method.

The sequences were aligned against Z84721 accession number in GenBank and results were compared with globin gene server database.

Results:

Among 100 individuals, 47 individuals have had deletions in α -globin gene including:

$-\alpha^{3.7}(27)$, $-\alpha^{\text{Med}}(8)$, $-\alpha^{4.2}(7)$, $-\alpha^{20.5}(5)$.

of the 53 remaining individuals who did not have known deletions in α -globin genes, 23 samples had different mutations; including: PolyA₄(8), PolyA₅ & 5nt (5), C.S(1), hemoglobin Adana, Cd28. The most common deletions and point mutation were $-\alpha^{3.7}$ and PolyA, respectively.

Conclusion: Non deletion mutations can interact with each other or α^0 thalassemia deletions to produce severe forms of HbH disease or even Hb hydrops fetalis. Thus screening for α -thalassemia should be considered during genetics counseling of high risk couples of thalassemia for prenatal diagnosis. In addition, α -thalassemia may alter the hematologic parameter in β -thalassemia carriers.

P01.007

A new polymorphism causes different restriction pattern by β -Rsal in β -globin cluster: application in PND

A. Valaei, F. Bayat, M. Taghavi, M. Karimipour, S. Zeinali; *Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.*

The β -globin cluster is located at chromosome 11 and contains five functional genes. There are at least nine RFLP markers distributed all over the cluster. These markers are used routinely for carrier testing, prenatal diagnosis and haplotype analysis.

Working on the β -globin cluster haplotypes of some Iranian β -thalassemia carriers and their families, we observed a different pattern of digestion by RsaI restriction enzyme in many people. The aim of this study was to find out the cause of this pattern.

This study was performed on carriers of β -thalassemia and normal controls. After obtaining informed consent, DNA was extracted from peripheral blood. ARMS-PCR method was exploited for finding the common mutations in β -globin gene. PCR-RFLP was performed on β -RsaI polymorphic site. The primers and PCR conditions are from Weatherall & Clegg's. DNA sequencing was performed on PCR products of β -RsaI marker by the same primers.

Some of the carriers of β -thalassemia and their parents had a different digestion pattern in β -RsaI polymorphic site. In the carrier people different mutations were found (IVSII-1, IVSI-110, IVSI-6, -88). When polymorphic restriction site of RsaI is absent in the sample, after digestion, the 1200 bp PCR product is cut to 694, 411 and 95 bp bands due to two constant restriction sites. In our cases the constant restriction site at position 411 has been changed (GTAC to GCAG) in heterozygous form. Hence, the restriction pattern by this enzyme creates 694 and 506 bp bands. This polymorphism is not associated to a specific mutation in β -globin gene and also was found in normal control people.

P01.008

Co-inheritance of Hemoglobin D and β -Thalassemia Trait in three Iranian families

M. Taghavi, M. Karimipour, M. Jafarinejad, L. Katouzian, A. Valaei, A. Amirian, F. Bayat, A. Kordafshari, N. Saeedi, S. Zeinali; *Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.*

β -thalassemia is the most common genetic disorder in Iran, occurring more frequently in Northern and Southern areas. IVSII-1 and IVSI-5 are the most common mutations reported in the country. HbD, a hemoglobin variant occurs mainly in north-west India, Pakistan and Iran and differs structurally from normal HbA at 121 positions on β chain. Co-inheritance of HbD and thalassemia minor is not common and may alter the Hb electrophoresis pattern. Here we report three cases with combination of β -thalassemia and Hb D. None of them had symptoms of profound anemia and hematological indices were similar to the β -thalassemia heterozygote. Hb variant level in carriers was increased and no HbA was detected electrophoretically. After obtaining informed consent, the blood samples were collected in tubes containing EDTA. Genomic DNA was extracted using the salting out method. The mutation in β -globin gene was revealed by ARMS-PCR technique and confirmed by DNA sequencing. The region containing exon 3 was amplified for HbD and the PCR product of this amplicon was digested by EcoRI. The electrophoresis pattern suggested that all cases were homozygote for HbD. But, molecular analysis confirmed the presence of Cd 121 GAA>CAA in heterozygous form in combination with IVS II-1 and IVS I-5. Hematological family study showed the mutations and HbD are in trans position. These mutations produce an unstable mRNA without any product and almost all of the globin output is from the chromosome carries HbD.

P01.009

Analysis of haplotypes associated with IVSI nt 130 of beta-globin gene reveals intriguing results

M. Feizpour¹, P. Fouladi¹, S. Foroughi¹, F. Rahiminejad¹, F. S. Hashemi¹, R. Vahidi¹, **S. Zeinali²**;

¹Kawsar Biotech Research Center, Tehran, Islamic Republic of Iran, ²Pasteur Institute and Kawsar Biotech Research Center, Tehran, Islamic Republic of Iran.

Prevention of thalassemia is a national program. Premarital screening and prenatal diagnosis (PND) is in effect. For performing PND, we usually use direct mutation detection techniques like ARMS PCR. We routinely screen for more than 42 mutations identified in our center so far. If now mutation is detected we resort to direct DNA sequencing. We also use beta-globin gene linked RFLPs or SNPs for PND to increase the accuracy of PND. Sometimes haplotype analysis can be very helpful as well.

We have so far analyzed more than 6394 chromosomes from carriers of beta-thalassemia and in 16 cases the mutation was IVSI nt 130. This mutation is regarded as rare mutation in Iranian population. The families were mostly from two distinct geographical areas, namely Aghghola in Golestan province, west of Caspian Sea in the north of Iran (6 cases or 37%) and Meshkin shahr in Ardabil province, east of Caspian Sea, in north of Iran (5 cases or 31%). The other 4 cases were from Khuzestan in South West and Gilan in North of Iran equally. Since populations in these two regions do not have much in common we decided to see if they share the same haplotype. We tested Hind III $\psi\beta$, AvaII β , and HinfI β RFLP sites for this purpose. All cases from Aghghola were + - + and all cases from Meshkin Shahr were - - + for these sites.

This shows that there were two different founder effects for this mutation.

P01.010

Non-Invasive prenatal diagnosis of β -thalassaemia by SNP analysis using PNAs and Arrayed Primer Extension (APEX)

T. Papisavva¹, A. Kyrr², L. Cremonesi², S. Galbiati², M. Kleanthous¹;

¹The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, ²Thalassaemia Center, Archbishop Makarios III Hospital, Nicosia, Cyprus, ³Fondazione Centro San Raffaele del Monte Tabor, Milan, Italy.

The recent discovery of relatively abundant quantities of cell free fetal DNA in maternal plasma and serum has opened up new possibilities for the non-invasive prenatal diagnosis. β -thalassaemia is one of the most common autosomal recessive single-gene disorders in Cyprus.

In Cyprus, the mutation IVS1-110 accounts for 81% of all the cases. Therefore, the development of a non-invasive method for the Cyprus population is based on the detection of paternally inherited Single Nucleotide Polymorphisms (SNPs) as well as the direct detection of paternal beta-thal mutations.

Eleven SNPs with high degree of heterozygosity in the Cypriot population were selected and analyzed on 34 families and the informative SNPs were determined. In order to find a higher number of informative SNPs, the degree of heterozygosity in the Cypriot population was determined for 130 SNPs on 75 random samples using the Sequenom® MALDI-TOFF Mass Array genotyping analysis.

One of the approaches that are being developed is the Arrayed Primer Extension (APEX) method on the Genorama® QuattroImager™. We developed a DNA chip called "thalasso-chip" that contains 60 beta-thal mutations and 10 SNPs linked to the beta-globin locus. The APEX assay was applied on maternal plasma of 7 families using the informative SNPs; paternal allele of the fetus was non-invasively detected in 5 families.

Peptide Nucleic Acids (PNA) probes are used to suppress amplification of the maternal allele and unmask the fetal allele. The efficiency of PNA-mediated PCR clumping technique was tested on APEX and sequencing analysis.

P01.011

Delineation of deletions in beta globin gene cluster causing HPFH in Iran

M. T. Akbari¹, M. T. Akbari², B. Keikhaee³, S. Zare-Kariz², M. Karimipour⁴, L. Mottagh²;

¹Tarbiat Modares University, Tehran, Islamic Republic of Iran, ²Tehran Medical Genetics Laboratory, Tehran, Islamic Republic of Iran, ³Ahwaz Medical Sciences University, Ahwaz, Islamic Republic of Iran, ⁴Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

Background: Hereditary persistence of fetal hemoglobin (HPFH) and $\alpha\alpha$ thalassemia are heterogeneous disorders characterized by elevated levels of fetal hemoglobin (HbF) in adult life. The distinction between these conditions is subtle and is made on clinical and hematological grounds. Most HPFHs are caused by large deletions involving a variable extent of DNA segment on the beta-globin gene cluster. There are eight common forms of such deletions reported in different populations. In this study ten unrelated individuals with characteristic HPFH hematological profile were investigated to delineate their beta-globin gene cluster deletions.

Aims and objectives: Molecular analysis of 10 Iranian patients with low MCV and MCH, Normal HbA2 and high level of HbF (5%-15%) was carried out. They were referred from primary health care centers involving in the national prevention program for thalassemia.

Materials and methods: After obtaining informed consent, genomic DNA was extracted from peripheral blood. Multiplex gap PCR method was exploited for characterizing of 8 different deletions in beta-globin cluster causing delta-beta thalassemia or HPFH.

Results and discussion: Seven individuals from this group were shown to be heterozygous for the 13.4 kb Sicilian deletion, two were heterozygous for the Asian-Indian form of inversion-deletion Ggamma(Agamma-delta-beta)⁰ thalassemia and mutation for one of them was not identified. So far three types of deletional mutations in Iranian patients have been reported. These results confirm the previous findings.

P01.012

Reporting of Beta Thalassemia mutations frequency by DNA sequencing analysis in Iran

M. Sajedifar^{1,2,3}, M. Moshirazin^{1,2}, S. Mousavi^{1,2}, Z. Shahab Movahed^{1,2}, A. Joodaki^{1,2}, S. Zeinali^{1,2,4};

¹Kawsar Human Genetic Research Center- KGBC, Tehran, Islamic Republic of Iran, ²Medical Genetics Lab of Dr Zeinali, Tehran, Islamic Republic of Iran, ³Researchers Club of research and science branch of Islamic Azad University, Tehran, Islamic Republic of Iran, ⁴Human Genetics Unit, Dept of Biotech Pasteur Institute, Tehran, Islamic Republic of Iran, Tehran, Islamic Republic of Iran.

Beta-thalassemia is the most prevalent genetic disorder in Iran. In order to control this autosomal recessive disorder several plans are in effect, including premarital genetic counseling and blood tests. Our unit has been chosen as National Reference Center for Prenatal Diagnosis. We are actively involved in prenatal diagnosis, carrier detection

and molecular analysis of mutations in β -globin gene. We have started to perform DNA sequencing for all samples especially for unknown cases since July of 2005. We find that DNA sequencing is very suitable and informative for screening of mutations except deletions. DNA samples are usually tested for mutations like IVS-II-1, IVS1-5, IVS-I-110, codon 5, codon 17, codon 41/42(-TTCT) and many common mutations and deletions. We have decided to use a comprehensive mutation screening approach and sequenced the gene by 3130 Genetic Analyzer. After detection of 2654 sequences in 2 years, we have found very different abundance for these mutations: -28tata box, -29tata box, -30 tata box, -88, -101, codon 2, codon 15, codon 36-37, codon 39, codon 82-83, codon 121, IVS-I-5, IVS-I-110, IVS-II-1, IVS-II-666 and more than 35 other mutations.

Molecular characterization of beta-thalassemia intermedia in Antalya population, Turkey

I. Keser¹, A. D. Sanlioglu¹, E. A. Aydemir¹, A. Yesilipek², D. Canatan³, G. Luleci¹;

¹Akdeniz University, Medical Faculty, Department of Medical Genetics, Antalya, Turkey, ²Akdeniz University, Medical Faculty, Department of Pediatrics, Antalya, Turkey, ³The State Hospital, Thalassemia Center, Antalya, Turkey.

Beta-thalassemia intermedia (Beta-TI) is a term used to define a group of patients with β -thalassemia in whom the clinical severity of the disease is somewhere between the mild symptoms of the β -thalassemia trait and the severe manifestations of β -thalassemia major. Beta-TI shows both clinic and genetic heterogeneity. The purpose of this study was to analyze the relation between the genotype and phenotype in Turkish patients with beta-TI living in Antalya, Turkey. A total of 32 patients with beta-TI were evaluated for mutations and their clinical findings. Eight different mutations [-30 (T-A), Cod 3 (+T), Cod 8(-AA), Cod 39 (C-T), IVS1.6 (T-C), IVS1.110 (G-A), IVS2.1 (G-A), IVS2.745 (C-G)] were found in our study. The IVS1.6 (T-C) was the commonest beta-mutation, occurring in both homozygous state in five patients and compound heterozygous state in eight patients. The IVS2.1 (G-A) was the second beta-mutation in eight patients as homozygous state in two patients. In a family with beta-thalassemia, two sibs were compound heterozygote for IVS2.1(G-A) and IVS1.110 (G-A). One of them was female with beta-TI, while other was male with beta-thalassemia major. In addition, our findings were compared with literature and the mutation profile in beta-TI patients was differently found in our population than others. In conclusion, our data suggest that modifier genes should be screened together with beta-globin gene mutations in patients with beta-thalassemia intermedia to give correct genetic counseling and to provide the effective treatment.

P01.014

Effect of α -gene numbers and XmnI Polymorphism on the phenotype of HbE/ β thalassemia patients

V. Sharma, B. Kumar, R. Saxena;

All India Institute of Medical Sciences, New Delhi, India.

Introduction: HbE [β 26 (B8) Glu-Lys] with β thalassemia (HbE/ β thalassemia) results in a clinically severe condition. HbE/ β thalassemia has a very variable clinical phenotype. Some of the possible explanations for the observed variable clinical severity are coinheritance of α -thalassemia and XmnI polymorphism. **Objective:** To determine the frequency of XmnI polymorphism, α deletion and triplication in HbE/ β thalassemia patients and to study their effect on the phenotype of Patients. **Material and Methods:** Subjects were 85 HbE/ β thalassemia patients. Patients were divided into three subgroups according to a scoring system based on seven clinical criteria as mild (score 0-3.5), moderate (score 4-7) and severe (score 7.5-10). α deletions and XmnI polymorphism were studied by GAP-PCR and PCR-RFLP respectively. **Results:** α deletion was found in 18 (21.2%) out of these 18 patients 12(11 $\alpha\alpha$ - α ^{3.7} & 1 $\alpha\alpha$ -SA) were from Gp1 and 6($\alpha\alpha$ - α ^{3.7}) were from Gp2. α triplication was found in 7(8.2%) out of these 7 patients 5 were ($\alpha\alpha$ / $\alpha\alpha$ ^{anti-3.7}) from Gp3 and 2 were ($\alpha\alpha$ / $\alpha\alpha$ ^{anti-3.7}) from Gp 2. XmnI was found in 53(62.3%), out of which 43 were heterozygous(+/-) & 10 were homozygous(+/+). XmnI +/- was present in 6 Gp1 & 4 Gp2 patients, while XmnI +/- was present in 8 Gp1, 15 Gp2 & 20 Gp3 patients. **Conclusion:** Patients with coexisting α deletion, required lesser transfusions and had less severe phenotype while patients with α triplication were on frequent transfusions and had severe phenotype. XmnI poly-

morphism in homozygous state was observed to alleviate the severity while in heterozygous state it had no effect on the disease severity.

P01.015

Delineation of deletions causing $\delta\beta$ thalassemia and HPFH in Iran

M. Akbari^{1,2}, **M. Karimipour**^{2,3}, **S. Zare kariz**², **B. Keikhaee**⁴, **M. Izadyar**⁶, **L. Mottag**⁵;

¹Department of Medical Genetics, Tarbiat Modares university, Tehran, Islamic Republic of Iran, ²Tehran Medical Genetics Laboratory, Tehran, Islamic Republic of Iran, ³Molecular Medicine Dept., Biotechnology Research Center, Pasteur Institute of Iran, Tehran, Islamic Republic of Iran, ⁴Ahwaz Medical sciences university, Ahwaz, Islamic Republic of Iran, ⁵Children Medical center, Tehran university of Medical Sciences, Tehran, Islamic Republic of Iran.

Hereditary persistence of fetal hemoglobin (HPFH) and $\delta\beta$ thalassemia are heterogeneous disorders characterized by elevated levels of fetal hemoglobin (HbF) in adult life. The distinction between these conditions is subtle and is made on clinical and hematological grounds. Most HPFHs are caused by large deletions involving a variable extent of DNA segment on the β -globin gene cluster. There are eight common forms of such deletions reported in different populations. In this study ten unrelated individuals with characteristic HPFH hematological profile were investigated to delineate their β -globin gene cluster deletions.

Aims and objectives: Molecular analysis of 10 individuals with low MCV and MCH, Normal HbA2 and high level of HbF (5%-15%) was carried out. They were referred from primary health care centers involving in the national prevention program for thalassemia.

Materials and methods: After obtaining informed consent, genomic DNA was extracted from peripheral blood. Multiplex gap PCR method was exploited for characterizing of 8 different deletions in β -globin cluster causing $\delta\beta$ thalassemia or HPFH.

Results and discussion: Seven individuals from this group were shown to be heterozygous for the 13.4 kb Sicilian deletion, two were heterozygous for the Asian-Indian form of inversion-deletion $G\gamma(A\gamma\delta\beta)^0$ thalassemia and mutation for one of them was not identified. So far three types of deletional mutations in Iranian patients have been reported. These results confirm the previous findings.

P01.016

Detection of the most prevalent deletional and non deletional mutation among Iranian carriers of Alpha-Thalassemia

B. Zarbakhsh, **S. Zeinali**, **M. Karimipour**, **R. Habibi**;

Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

Background: A variety of deletions and point mutations have been described which decrease α globin gene expression. Most affected fetuses do not survive till birth or die shortly thereafter.

Objectives: The exact determination of gene defect for thalassemia carriers is essential for premarital screening. It will also help the genetic counselor to advise the family accordingly.

Methods: One hundred and thirty subjects having referred to us. Multiplex Gap PCR, And some molecular methods was carried out to detect any existing deletional or nondeletional mutation in their alpha globin genes.

Results: The following genotypes were identified:

$\{-\alpha^4.2/\alpha\alpha\}$, $\{-\alpha^{3.7}/-\alpha^{3.7}\}$, $\{-\alpha^{3.7}/-\alpha^{4.2}\}$

Poly A signal mutation (AATAAA > AATAAG)

Termination codon Mutation (TAA > CAA) Or: -5nt deletion;

$(\alpha^{3.7} / -\alpha^{20.5})$ & $(-Med / \alpha)$

Frequencies of these mutations was determined which revealed the 3.7 Kb deletion as the predominant mutation among alpha-thalassemia carriers in this study. The frequency of all other types were less than 35%.

Conclusions: Among nondeletional mutation, α^{5nt} , was the most frequent allele in our study population (9.25%) Followed by $\alpha^{PA-2(4A>G)}$ (4.12%). In regard to cd19 that has a 12.2% prevalence in south of Iran (Harteveld, et al,2003) it seems that this mutation is not dominant in our studied population.

Dominant mutations in poly A signal in our study was $\alpha^{PA-2(4A>G)}$ which has a replacement in nucleotide 4 A>G.

P01.017

Molecular analysis of thalassemia intermedia in Iran

M. Karimipour¹, **A. Arab**¹, **A. Rajab**², **K. Arjmand**³, **S. Zeinali**¹;

¹Pasteur Institute of Iran, Tehran, Islamic Republic of Iran, ²Tarbiat Modares University, Tehran, Islamic Republic of Iran, ³Aliasghar hospital, Tehran, Islamic Republic of Iran.

Background: β -thalassemia is an autosomal recessive disorder caused by more than 200 different mutations in gene coding for β -globin (HBB) of the hemoglobin tetramer Thalassemia intermedia is a clinical definition applied to patients whose clinical phenotype is milder than thalassemia major.

Aims and objectives: Molecular analysis on α - and β -globin genes mutations in 49 Iranian thalassemia intermedia patients.

Materials and Methods: After obtaining informed consent the patients were included in the study. The genomic DNA was extracted from peripheral blood using standard salting out method. Allele-specific polymerase chain reaction was performed for common β -thalassemia alleles and then direct β -globin gene sequencing amplification was performed. β -globin gene haplotypes were constructed from eight restriction fragment length polymorphism (RFLPs) in the β -globin cluster and also -158GgXmnl (C to T). Screening of common α -globin gene deletions and triplication was performed by Gap-PCR.

Results and discussion: Among 49 thalassemia intermedia patients, 17 had IVSII-1 (G to A) mutation in homozygous form and 10 in compound heterozygous with other mutations. $-\alpha^{3.7}$ and $-\text{MED}$ gene deletions were found in heterozygous form in two and one of the above cases, respectively. In five cases only one mutation was found in β -globin gene and in these patients one had α -globin gene triplication. Analysis of polymorphic markers in patients with IVSII-1 mutation showed haplotype III and allele T in XmnI marker.

These data show the heterogeneity of molecular basis of thalassemia intermedia in Iran and suggest the role of modifier genes other than α -globin gene determinants.

P01.018

A novel frameshift mutation (-G) at codon 24 of the beta-globin gene in an Iranian woman

P. Fouladi, **S. Ghahremani**, **S. Foroughi**, **F. Rahiminejad**, **M. Feyzpour**, **R. Vahidi**, **S. Zeinali**;

Kawsar Genetics Research Center, Tehran, Islamic Republic of Iran.

Thalassemia is an inherited disorder characterized by an imbalance in the synthesis of α - or β -globin chains. This leads to a decreased hemoglobin synthesis and causes a hypochromic microcytic anemia.

Since 1997, in Iran, every couple that wants to marry is referred to one of the Primary Health Centers (PHC) by the marriage registry offices. These couple to be are tested for thalassemia by doing cell blood count (CBC0 and A2 level measurement. Eventually they may be sent to one of several medical genetics centers dedicated for prenatal diagnosis of thalassemia.

Individuals with low MCV (<80 fl) and MCH (<27 pg) and high Hb A2(>3.5%) level are referred for further investigation which may include prenatal diagnosis.

During investigating one of these couples with low MCV and MCH and raised A2 were investigated by molecular methods. A previously undescribed mutation causing a frameshift [(-G) Codon 24] in the beta-globin gene was identified in a 23 years old Iranian woman. The hematological data for this lady was (MCV=63.0, MCH=19.0, A2=5.9, F=0.2). Her DNA was tested for 19 common beta-globin gene mutations. No mutation was detected. Direct DNA sequencing showed absence of a G nucleotide in Codon 24 on both strands. We looked up data bases and available references for this mutation. No reported case was seen. We believe that this is a novel mutation causing a frameshift. We are in the process of investigating the frequency of this mutation by designing ARMS/PCR primers.

P01.019

Molecular analysis of two families with Hb Lepore

A. Amirian, **M. Karimipour**, **Z. Moghaddam**, **A. Kordafshari**, **A. Valaei**, **M.**

Taghavi, **L. Katouzian**, **F. Bayat**, **M. Jafarinegad**, **N. Saeidi**, **A. Sanjari**, **M. Choubini**, **M. Mohammadi**, **S. Zeinali**;

Pasteur Institute of Iran, Tehran, Islamic Republic of Iran.

Thalassemia syndromes are among hemoglobinopathy disorders inherited as autosomal recessive trait, caused by mutation in β -globin

gene. Most of these mutations are point mutation and large deletions are not common. A considerable number of deletions of variable size and position that involve the β -globin gene cluster on chromosome 11 are associated with the clinical entities of $\delta\beta$ thalassaemia.

$\delta\beta$ -thalassaemia normally results from deletion involving either δ - and β -globin genes or the $A\gamma$ -, δ - and β -globin genes.

In this study six individual from two families were investigated because of low MCV and MCH, high HbF and normal HbA2 referred from primary health care (PHC) centers to our lab for further investigations.

PCR amplification was performed for known deletions causing $\delta\beta$ -thalassaemia and HPFH by gap-PCR methods.

In Hb electrophoresis an extra band was appeared. Molecular analysis showed that the two affected individuals from one of the families are homozygous for Hb Lepore and the remaining four cases carry Hb Lepore in heterozygous form. One of the affected cases was transfusion dependent. Genotype Phenotype correlation was compatible with cases presented in globin gene server database. Hb Lepore usually causes mild anemia with microcytosis and hypochromia in the heterozygote (beta+thal). The molecular basis of this Hb variant is a (aprox) 7 kb deletion from the distal part of δ -globin gene to proximal region of β -globin gene.

P01.020

Hb F Malta I in association with Hb F Sardegna and Hb Valletta; triple heterozygosity at the human $G\gamma$, $A\gamma$ and β globin genes suggest interplay between flanking regulatory sequences in the developmental control of globin gene switching

J. Borg, R. Galdies, W. Cassar, C. A. Scerri, A. E. Felice; Laboratory of Molecular Genetics, Faculty of Medicine, University of Malta, and Section of Molecular Genetics, Mater Dei Hospital., Msida, Malta.

Here we document for the first time data on unique families from Malta in whom heterozygosities at the $G\gamma$, $A\gamma$, and β globin genes have segregated among families to produce probands that were heterozygotes at the three major non- α genes, such that the six globin products could be separated and quantified. 136 newborn were found with Hb F Malta I on isoelectric focusing. Further testing by reverse phase LC showed heterozygosities at the β globin gene ($\beta A / \beta^{Valletta}$) and the $A\gamma$ globin gene ($A\gamma I / A\gamma T$) confirmed by DNA sequencing in 8. The probands were genotyped at the Xmn I site in the 5' $G\gamma$ promoter that is known to be associated with increased γ globin gene output in anaemic adults and the $(AT)_x T_y$ polymorphism in the 5' β globin gene region known to down-regulate β globin gene expression subject to BP1 binding. Seven were Xmn I negative and $(AT)_7 T_7$ and with $[G\gamma^{FMalta} + A\gamma I] / [G\gamma 0 + A\gamma T] = 0.90$ that was significantly different from the other triple heterozygote with Xmn I negative and $(AT)_9 T_5$ and $[G\gamma^{FMalta} + A\gamma I] / [G\gamma 0 + A\gamma T] = 0.80$ ($p < 0.037$). The data suggested interplay between the Xmn I and the $(AT)_x T_y$ sites around a fulcrum of the Y / PYR sequences close to the pseudo- β sequences and that acted to control globin gene expression differentially between neonates and adults.

P01.021

A case of Hb Torino in an Italian family

C. Lodrini, M. Garatti, D. A. Coviello, A. Biasi, C. Melles, R. Salvi, C. Domzelli, C. Curcio;

Fondazione IRCCS, Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy.

Alfa thalassaemias are haematologic diseases arising from more than 80 different genetic alterations, affecting one or both copies of the duplicated α globin genes ($\alpha 1$ and $\alpha 2$) located in 16p13.3.

Although most causative alterations are large genomic deletions, at least 48 non-deletional point mutations have also been reported so far.

We report here a case of Hb Torino found in an Italian family: the proband is a young boy aged six, who presented haematological parameters similar to α thalassaemia.

The α -globin2-specific PCR product were amplified. Direct sequencing of amplified PCR product showed the presence of Hb Torino (Cod43 TTC->GTC, Phe->Val) in both chromosomes in the proband. Since Hb Torino was detected in the homozygous state and it is quite a rare variant we decided to extend the analysis to patient's parents.

The father resulted to be a heterozygous carrier for Hb Torino, while the mother had a 3.7 deletion in the heterozygous state. Then we concluded that proband had the Hb Torino in one chromosome and α 3.7

deletion in the other chromosome.

The correct diagnosis, improved after the case history, included the presence of the base substitution causing Hb Torino and the α 3.7 deletion, both in the heterozygous state.

Our data underline that the molecular screening of α thalassaemia, associated to the family study are useful to better characterize the genotypes involved and perform an appropriate genetic counselling.

P01.022

Hemoglobin Lepore chromosome in Serbia: a report of a novel Lepore haplotype

S. Pavlovic¹, B. Zukic¹, M. Stojiljkovic¹, L. Perisic¹, J. Jovanovic¹, L. Dokmanovic², D. Janic²;

¹Institute of Molecular Genetics and Genetic Engineering, Belgrade, Serbia,

²University Children's Hospital, Belgrade, Serbia.

Hemoglobin (Hb) Lepore is a thalassaemic hemoglobin variant characterized by normal alpha-globin and fused delta/beta-globin chains. Heterozygosity for this abnormality resembles a beta-thalassaemia trait, while homozygotes have a severe form of beta-thalassaemia. Hb Lepore-Boston Washington (BW) is the most common type of Hb Lepore. The chromosomal background heterogeneity has been assessed in Hb Lepore BW chromosomes, suggesting its multicentric origin. Molecular characterization of Serbian patients with thalassaemia syndromes in last ten years revealed that Hb Lepore is the most common cause of thalassaemia phenotype in the population of Serbia (25%). Three thalassaemia major patients (compound heterozygotes for Hb Lepore and beta-thalassaemia mutation) and 36 heterozygous Hb Lepore carriers were characterized in 15 unrelated families. Molecular detection of Hb Lepore gen was carried out by gap-PCR analysis. Sequencing analysis showed that all Hb Lepore genes were of BW type. Moreover, they were all associated with the same intragenic beta-globin gene polymorphisms, framework 2. Additionally, we have studied beta-globin gene cluster haplotypes and their association with Hb Lepore gene in Serbian population by PCR-RFLP analysis of 8 polymorphic sites (Hinc II/epsilon, Xmn I/5'Ggamma, Hind III/Ggamma, Hind III/Agamma, Hinc II/pseudobeta, Hinc II/3'pseudobeta, Ava II/beta, BamHI/3'beta). Haplotype analysis revealed a novel haplotype associated with Hb Lepore BW gene (+----+). The same haplotype was found in healthy individuals of Serbian descent. The high frequency of Hb Lepore BW hemoglobin variant in Serbian population, the homogeneity of Hb Lepore BW haplotype, as well as its uniqueness, suggest that it most probably originated in Serbia.

P01.023

Control of Thalassaemia in Iran, a National Success Story

S. Zeinali¹, A. Samavaei²;

¹Pasteur Institute of Iran, Tehran, Islamic Republic of Iran, ²Center for Disease Control, Ministry of Health, Tehran, Islamic Republic of Iran.

Thalassaemia is the most prevalent single gene disorder in Iran and most part of the world. Now more than 18000 patients live in Iran.

Prenatal diagnosis of thalassaemia started, in Iran, as early as 1991 by sending samples abroad and as early as 1994 it became feasible to do it in Iran. National Program for Prevention of Thalassaemia has been started in 1997 and the religious FATWA was given in 1996 to allow prenatal diagnosis (PND). From 1997 every couple who wants to get married is tested for being a carrier of thalassaemia. If both partners are carriers or are in doubt of their carrier status are referred to one of several prenatal diagnosis centers throughout the country. Regular visits and inspections are carried out to ensure the best performance. Every PND done is reported to the Genetics Office at CDC.

There are more than 10 medical genetics labs in Iran and most of them active in doing PND for thalassaemia. Most of these laboratories have been organized as being a network and families are referred to one of these labs via the Health Centers throughout country.

In our medical genetics lab at Kawsar Genomics and Biotechnology Complex we have performed more than 2000 PNDs. We have also analyzed more than 4000 samples referred to us for thalassaemia. Only one mistake has been made out of 2000 PNDs which may indicate application of best QA and QC.

P01.024

Molecular mechanisms underlying thalassemia intermedia in Iran

M. Neishabury¹, A. Azarkeivan², C. Oberkanins³, F. Esteghamat¹, N. Amirizadeh², N. Amirizadeh², H. Najmabadi^{1,4};

¹Genetics Research center University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran, ²Thalassemia Clinic and Research Center, Iranian Blood Transfusion Organization (IBTO), Tehran, Islamic Republic of Iran, ³ViennaLab Diagnostics GmbH, Vienna, Austria, ⁴Kariminejad and Najmabadi Pathology and Genetics Center, Tehran, Islamic Republic of Iran.

To improve the differentiation of thalassemia intermedia from other hemoglobinopathies in Iran, four known genetic mechanisms, including *XmnI* C_γ polymorphism, inheritance of mild and silent β-thalassemia alleles, δβ deletion and coinheritance of α- and β-thalassemia, were investigated in 52 Iranian individuals, suspected to have thalassemia intermedia based on clinical and hematological characteristics. Beta-globin mutations were studied using a reverse-hybridization assay and sequencing of the total β-globin gene. The *XmnI* C_γ polymorphism, the Sicilian δβ deletion and four α-globin mutations (-α^{3,7}, -α^{4,2}, -MED, αα^{anti-3,7}) were studied using PCR-based techniques. The inheritance of the *XmnI* C_γ polymorphism with severe β-thalassemia alleles in the homozygous or compound heterozygous state was the predominant mechanism observed in 56.5% of individuals. In 8.7% of cases, this status overlapped with the -α^{3,7}/αα genotype. The second most frequent cause for thalassemia intermedia (15.2%) was the inheritance of mild β-thalassemia alleles, including IVS-I-6 (T>C), -88 (C>A) and +113 (A>G). In 4.3% of subjects the Sicilian δβ deletion was identified. HbS in association with β⁰-thalassemia was found in 2.2% of patients, who had been misdiagnosed as thalassemia intermedia. In 21.7% of cases no causative genetic alteration could be identified. Our results reflect the diversity underlying thalassemia intermedia in Iran, and the limitations of the applied clinical, hematological and molecular approaches for correct diagnosis. Some of our unresolved cases will offer an opportunity to discover additional molecular mechanisms leading to thalassemia intermedia.

P01.025

Prenatal diagnosis of cystic fibrosis: the 18-year experience of Brittany (western France)

I. Duguépéroux^{1,2}, V. Scotet¹, M. Audrézet^{1,2}, M. Blayau³, P. Boisseau⁴, H. Journef⁵, P. Parenf⁶, C. Férec^{1,2};

¹INSERM U-613, Brest, France, ²CHU - Lab Génétique Moléculaire, Brest, France, ³CHU - Lab Génétique Moléculaire, Rennes, France, ⁴CHU - Lab Génétique Moléculaire, Nantes, France, ⁵CH - Unité Génétique Médicale, Vannes, France, ⁶CHU - Dpt Pédiatrie et Génétique Médicale, Brest, France.

Objective: This study reports 18 years of experience in prenatal diagnosis (PD) of cystic fibrosis (CF) in a region where CF is frequent and the uptake of PD common (Brittany, western France). **Method:** All PDs made over the period 1989-2006 in women living in Brittany were collected. **Results:** We recorded 268 PDs made in 1 in 4 risk couples, plus 22 PDs directly made following the sonographic finding of echogenic bowel. Most of the 268 PDs were done in couples already having CF child(ren) (n=195, 72.8%). Close to one fifth followed cascade screening (n=49, 18.3%), which identified 26 new 1 in 4 risk couples among the relatives of CF patients or of carriers identified through newborn screening. The remaining PDs were mainly made in couples whose 1 in 4 risk was evidenced following the diagnosis of echogenic bowel in a previous pregnancy (n=22, 8.2%). Although patients' life expectancy has considerably improved, in our population the great majority of couples chose pregnancy termination when PD indicated that the fetus had CF (95.9%). **Conclusion:** This study describes the distribution of PDs according to the decisions in which the 1 in 4 risk was discovered and highlights the real decisions of couples as regards pregnancy termination after a positive PD.

P01.026

Strategy for prenatal diagnosis of cystic fibrosis in Serbia

D. Radivojevic, T. Lalic, M. Djuricic, M. Guc-Scokic, M. Miskovic, V. Ivanovski; Mother and Child Health Institute of Serbia, Belgrade, Serbia.

Cystic fibrosis is the most common autosomal recessive disease in Caucasians, caused by more than 1500 mutations in CFTR gene. In Serbian CF patients 21 different CF mutations were found accounting for 82% of CF alleles.

Since 1996, we have performed 102 prenatal diagnoses for 76 couples with 11 different genotypes. One case included twin pregnancy and another a CF affected mother. In one family-at-risk parent was a carrier of complex allele (two mutations in *cis*).

Total of 63 families were fully informative for direct DNA analysis, which was performed using heteroduplex analysis (PAGE), ARMS-PCR (Elucigene[™] CF 29 kit, Orchid) and DGGE analysis of PCR amplified exons 1-24. In other 13 families, only one parental mutation was known, so prenatal analysis was done by indirect DNA analysis (haplotype analysis for 6 diallelic sites and one tetranucleotide repeat). Materials used for fetal DNA analysis were mostly CVS samples (68 cases), amniocytes in 28 cases and fetal blood in 6 cases. Results showed that 19 fetuses were affected, 50 were carriers and 33 fetuses were healthy.

Since 2006, we have started screening for the presence of CFTR mutations in couples with echogenic bowel detected on ultrasound investigation during the second trimester of pregnancy. From 21 cases, in 16 only the couple was tested, and in 3 cases both parents and fetus were tested. No positive cases were found.

If the causative mutations were identified before pregnancy, results were given within few days, indicating that the current strategy using a combination of methods mentioned above provide rapid and reliable prenatal diagnosis for all families at risk in our country.

P01.027

CFTR haplotypes associated with p.S466X mutation among Iranian CF patients

R. Alibakhshi^{1,2}, M. Zaman³, R. Kianishirazi⁴, J. Cassiman⁴, H. Cuppens⁴;

¹Department of Biochemistry, Faculty of Medicine, Kermanshah University of Medical Sciences (KUMS), Kermanshah, Islamic Republic of Iran, ²Division of Medical Genetics, Reference Laboratory, Kermanshah University of Medical Sciences, Kermanshah, Islamic Republic of Iran, ³Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran, ⁴Center for human Genetics, KU Leuven, Leuven, Belgium.

Cystic fibrosis (CF) is the most common inherited disorder in Caucasian populations, with over 1400 mutations identified in the Cystic Fibrosis Transmembrane conductance Regulator (CFTR) gene. We have screened 69 Iranian CF patients, and 1 CBAVD patient for mutations and polymorphic sites in the complete coding region, and its exon/intron junctions, of their CFTR genes, using different methods, such as ARMS (amplification refractory mutation system)-PCR, SSCP (single stranded conformation polymorphism) analysis, restriction enzyme digestion analysis, direct sequencing, and MLPA (Multiplex Ligation mediated Probe Amplification).

Based on our work, the third most prevalent mutation in Iran was p.S466X. It was found in 5.7% (8/140) of the CFTR genes from Iranian CF patients, and was only observed in homozygous state. These 4 patients were from Tehran, Khorasan, Hamadan and Markazi provinces. The parents of these patients all had consanguine marriages, however since that the mutation was present in families from different regions; it seems to be a relative frequent mutation in Iran. This mutation is rare worldwide, but has a frequency of 0.5% in Serbia and Montenegro. Interestingly, the patients with p.S466X mutation were homozygous at some of intragenic polymorphic sites and showed similar haplotypes. These were: IVS8 TGm and Tn (TG12-T7__TG12-T7), IVS6a (TTGA6/TTGA6), intron 9 nt1525-61 (G/G) and exon 10 nt1540 (A/A; M470/M470). The polymorphisms were seen in direct sequencing.

P01.028

Identification and characterization of three CFTR gene partial duplications

M. Legendre¹, A. Le Floch¹, F. Niel¹, C. Gameiro¹, J. Martin¹, D. Grenet¹, J. Derelle², V. Izard³, C. Costa¹, M. Goossens¹, E. Girodon¹;

¹CHU Henri Mondor, Créteil, France, ²Hôpital Foch, Pneumologie, Suresnes, France, ³Hôpital d'Enfants, Médecine infantile, Vandoeuvre-les-Nancy, France, ⁴CHU Bicêtre, Urologie, Le Kremlin-Bicêtre, France.

Background: Cystic fibrosis and disorders related to Cystic Fibrosis transmembrane Conductance Regulator (CFTR) pathology are mainly due to point mutations scattered over the whole CFTR gene. Search for large CFTR rearrangements using semi-quantitative fluorescent multiplex (QFM) PCR assays is now part of the molecular diagnosis and allows to identify 2% of CF alleles. Rearrangements mainly comprise single or multiple exon deletions; duplications are rare and

are indeed more difficult to detect and characterize. Of the four *CFTR* duplications reported, three were detected in our laboratory by QFM-PCR, in two CF patients and a CBAVD patient. They involved exons 4-8, 10-18 and 11-13, respectively, in trans of another *CFTR* mutation. Methods: The duplications were characterized by using a combination of long-range (LR) PCR, digestion of LR-PCR products and sequencing. Results: Two duplications were fully characterized, in direct tandem each: dup10_18 (≈70kb long), and dup11_13 (≈17kb long). Characterization of the remaining dup4_8 is in process. However, given the classical CF phenotype of the patient, we hypothesize that the duplicated region is located inside the *CFTR* gene and interferes with the transcription, translation or maturation process, thus resulting in a null mutation. Conclusion: Effective tools are required to detect duplications, which may indeed be under-diagnosed. Refinement of the breakpoints is important to confirm a deleterious effect and should contribute to understand the duplication mechanism.

Background: The R117H-associated phenotypes vary from classical CF to no clinical disease and have made genetic counselling difficult. Since implementation of CF NBS, the observed high R117H frequency among neonates with elevated IRT and two mutations has reinforced this issue. Methods: Two retrospective studies were conducted: 1) a phenotypic study on 263 patients with two *CFTR* mutations including at least one R117H; 2) a retrospective 2002-2005 epidemiological study, aimed to determine the frequency of R117H and other frequent mutations in about 6000 healthy individuals without family history of *CFTR* pathology. Results: 1) Among the 263 patients, including 92 neonates, detailed clinical features were available for 247: severe classical CF, n= 2; isolated CBAVD, n= 60; other *CFTR*-related disorders (*CFTR*-RD), n= 109; healthy, n= 76 (65 neonates, reduced follow up period); 2) Based on R117H and F508del allelic frequencies in the general population of 0.25% and 1.0%, respectively, the [F508del]+[R117H] genotype prevalence was evaluated at 1/20,000, the *CFTR*-RD penetrance at 4.2% and the CF penetrance at 0.06%. Conclusion: The very low penetrance of R117H with regard to classical CF leads to consider R117H no longer as a CF-causing mutation and to reassure patients and their families in view of genetic counselling.

P01.030

The molecular genetic study *CFTR* gene in the group of Russia CF-patients

A. A. Stepanova, N. V. Petrova, A. V. Polyakov;

Research Centre for Medical Genetics, Moscow, Russian Federation.

Cystic fibrosis (CF) is a common and generally severe autosomal recessive disorder in the European population, caused by mutations in the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) on chromosome 7q31.

In the Russian population, cystic fibrosis is characterized by the presence of two prevalent mutations, the F508del and *CFTR*dle2,3, which account for ~55% and ~6% of the CF alleles, respectively.

This study includes 120 unrelated Russian CF patients affected by a classical form of cystic fibrosis.

Using a comprehensive *CFTR* gene analysis protocol (ΔF508, ΔI507,

1677delTA, 2143delT, 2184insA, 394delTT, 3821delT, L138ins, G542X, W1282X, N1303K, 3849+1C-T, R334W, *CFTR*dle2,3) mutations have been previously identified in 112/120 (93,3%) patients including 76 (63,3%) with two revealed mutations and 36 (30%) with one revealed mutation. The current study present the result of investigations by using a commercial kit (*CF OLA* assay, Abbot, Rungis-France) in the 44 remaining samples with only one or without revealed *CFTR* mutation. Three *CFTR* mutations at four patients have been in addition identified. Mutation 2789+5g>a was identified in two patients (0,8%). Two mutations were identified in one patient each (0,4%): R1162X, 3120+1g>a. Mutations identified by using a commercial kit in addition in 4 (1,6%) of the 240 *CFTR* chromosomes in investigated group.

Identification of novel mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (*CFTR*) gene in the Greek population

M. Poulou¹, M. Mastrominas², K. Pantos³, S. Doudounakis⁴, E. Kanavakis¹, M. Tzetis¹;

¹Department of Medical Genetics, Athens University, Athens, Greece, ²Embryogenesis Centre for Reproductive and Fertility Studies, Athens, Greece, ³Centre for Human Reproduction, Genesis Hospital, Athens, Greece, ⁴Cystic Fibrosis Clinic, St Sophia's Children's Hospital, Athens, Greece.

Cystic Fibrosis is the most common autosomal recessive disorder, with 5% carrier rate in the Greek population. The Greek population has one of the highest rates of *CFTR* mutation heterogeneity.

In this study we report 16 novel variants in the *CFTR* gene identified by DGGE analysis and direct sequencing. Of these five were synonymous variants, 7 missense mutations, 2 frameshift mutations leading to premature termination codon and two intronic substitutions. The effects of these mutations were assessed in combination with the clinical phenotype and using *in silico* analysis. The missense mutations were assessed using "PolyPhen" and "SIFT". The impact of the silent mutations and the intronic substitutions on splicing elements was analysed using "SSF: Splicing Sequences Finder". Majority of findings included changes in splicing factor binding.

Case	Novel Mutation/variant	Other <i>CFTR</i> mutation/ variant	Clinical Phenotype	Polyphen	SIFT
1	c.538_539insAC (L136H-fs153X)	F508del	111.5 mEq/L; Classical CF: 3 mos

Molecular-genetic and clinical analysis of cystic fibrosis in Republic of Moldova

N. I. Barbova¹, V. V. Egorov², A. P. Gavriluic²;

¹State University of Medicine and Pharmaceuticals "N. Testemitanu", Chisinau, Republic of Moldova, Chisinau, Republic of Moldova, ²National Center of Reproductive Health and Medical Genetics, Chisinau, Republic of Moldova.

Objective: We intended to study relations between genetic and clinic polymorphism in patients with cystic fibrosis (CF).

Methods: Were investigated 78 patients with CF aged from 2 months to 2 years, 46 boys and 32 girls by mean of polymerase chain reaction (PCR).

Results: In 64,1% were detected mutations - delTAF508 - in 57,7% (15,4% homozygous and 42,3% heterozygous), R334W - heterozygous - 3,8%, N1303K - heterozygous - 1,3%, Meth polymorphism - homozygous - 1,3%. In all homozygous and in 88% of heterozygous of delTAF508 was mentioned pancreatic insufficiency and extremely severe injury of lungs. In 94,3% of patients the process starts before one year. From 8 died patients 75% were homozygous for delTAF508. In 35% of patients with this mutation was revealed Ps. Aeruginosa, in 40% of patients was hypotrophy. R334W characterized by slow progression of broncho-pulmonary injury and absence of pancreatic insufficiency. In homozygous of Meth polymorphism the disease was slowly progressive, despite early start in 3 months. 12 patients (15,4%) were older than 18 years. In half of them were delTAF508 mutation (heterozygous), in 8.3% - homozygous. In 16,7% mutations were not identified.

Conclusion. The clinical pattern and prognosis of CF depends from type of mutations. The frequency of delTAF508 in Moldova is 57,7%. In 64,1% of cases mutations are identifiable. In 47,7% patients was determined only one mutation from compound with delTAF508, R334W, N1303K. It diminishes the possibilities of prenatal diagnosis and lead to necessity to wide range of major mutations of causal gene.

P01.033

Association of polymorphism in the endothelial nitric oxide synthase gene and clinical features in Russian CF patients homozygous for F508del mutation

E. E. Tymkovskaya, N. V. Petrova, N. J. Kashirskaya, R. A. Zinchenko; Research Center for Medical Genetics, Moscow, Russian Federation.

The association of 27 b.p.VNTR polymorphism in 4 intron of *eNOS* gene and the clinical features of cystic fibrosis was investigated in 101 Russian CF patients homozygous for F508del mutation. All patients were subdivided for groups according to their *eNOS* genotype, the first group - A/A and A/B genotypes (33 patients); the second group - B/B genotypes (68 patients). The age of onset of lung and intestinal disease symptoms, the age of diagnosis, severity of disease progression, FVC index, height-weight indexes, colonization by *S.aureus* and *P.aeruginosa* and other microorganisms, hepatobiliary disease, meconium ileus and distal intestinal obstructive syndrome in anamneses were evaluated. FVC index was significant lower in patients with A/A and A/B *eNOS* genotypes (69,37±4,09%) than patients with B/B genotype (80,57±3,31%; $p=0,032$). Liver cirrhosis was more frequent among patients with B/B *eNOS* genotype (22,1%) than in patients with A/A and A/B *eNOS* genotypes (6,1%; $p<0,05$). No other associations were revealed.

P01.034

MBL influence cystic fibrosis associated liver disease in children?

I. M. Ciuca¹, I. Popa¹, L. Pop¹, Z. Popa², L. Tamas³, A. Rosca⁴, R. Cioaca⁵;

¹Pediatric II Department, Timisoara, Romania, ²National Cystic Fibrosis Centre, Timisoara, Romania, ³Molecular Genetic Department, Timisoara, Romania, ⁴Laboratory Department, Clinical County Hospital, Timisoara, Romania, ⁵Immunology Department, Timisoara, Romania.

Background: Genetic modifiers like mannose binding lectine (MBL2) gene influence occurrence and severity of CF associated liver disease (CFLD). Variants of MBL genotypes encode low serum levels of MBL protein. Aim study was to asses the MBL serum levels in CFLD patients (pts), comparing to CF pts without liver disease. Methods: Study was performed in Pediatric II Department and National Cystic Fibrosis Centre Romania. 35 CF children aged 2-18 years, presented to annual assessment were evaluated. We consider 3 groups of patients, as follows: group 1(21 CFLD patients), group 2(11 pts CF no CFLD), group 3(15 controls). Groups were age matched. Patients associating diseases who influence MBL level were excluded. MBL assay procedure was performed using MBL Oligomer ELISA kit. Data were statistically analyzed with ANOVA. Results: Among CFLD pts (group 1) MBL average was half of control's average ($p=0.001$). Group 2 had an average lower with 13% comparing to controls. 46% CFLD pts were MBL deficient. Conclusions: Lower MBL average in CFLD patients sustains that MBL deficiency is associated factor for CFLD.

Increased MBL levels in CFLD patients could be resultant of increase growth hormone levels in childhood or predominance of "wild" MBL2 genotype in our patients. MBL2 genotyping is necessary to identify the patients predisposed to develop CFLD.

P01.035

CFTR and ENaC genes study in African patients with cystic fibrosis-like disease

L. Mutesa¹, A. Abul Kalam², C. Verhaeghe¹, K. Segers¹, J. Vanbellinghen¹, L. Ngendahayo³, E. Rusingiza⁴, C. Oury¹, L. Koulisher¹, H. Cuppens², V. Bours¹; ¹University of Liège, Liège, Belgium, ²Katholieke Universiteit Leuven, Leuven, Belgium, ³National University of Rwanda, Butare, Rwanda, ⁴National University of Rwanda, Kigali, Rwanda.

The defect in chloride and sodium transport in cystic fibrosis (CF) patients is a consequence of loss of functional interaction between cystic fibrosis transmembrane conductance regulator (CFTR) and the epithelial sodium channel (ENaC).

To study patients with CF-like symptoms and to relate the disease to gene mutations of both CFTR and ENaC genes, we collected clinical data and DNA samples from 60 African patients with CF phenotype. The CFTR gene was first analysed for mutations in all patients by DH-PLC followed by direct sequencing, whereas the SCNN1A, SCNN1B and SCNN1G subunits of ENaC gene were analysed by sequencing in all patients who carried only one CF mutation. The frequency of all identified ENaC variants was established in control group of 200 health individuals.

In total, four different CFTR mutations, including one previously undescribed missense mutation (p.A204T) were identified in five patients. In addition, ENaC gene sequencing in these 5 patients detected 8 ENaC variants, (c.72T/C and p.V573I) in SCNN1A, (p.V348M, p.G442V, c.1473+28C/T, and p.T577T) in SCNN1B, and (p.S212S, c.1176+30G/C) in SCNN1G. The missense mutation (p.V348M) was not found in the control group. We could also not find any p.T577T silent polymorphism nor any c.1176+30G/C intronic nucleotide change.

Our data thus show that an exploration of African patients with CF-like symptoms is mandatory and should include ENaC gene sequencing in absence of identified two CFTR causing mutations. The combination of mutations in both genes could provide a genetic explanation for an involvement in disease.

P01.036

Detection of CFTR gene rearrangements in Spanish population

M. Ramos, L. Masvidal, J. Gimenez, T. Casals; Idibell, Barcelona, Spain.

Over 1,500 mutations have been reported in the CFTR gene. We have identified more than 200 CF mutations in Spanish families ($n=1,020$) accounting for 97% of CF alleles. The CFTR50kdel mutation is a complex rearrangement involving exons 4-7 and 11-18. This deletion is relatively common in Spanish population (0.3%). In order to provide a faster detection than Southern blot we have applied quantitative real-time PCR analysis to asses this deletion in 11 uncharacterized alleles from patients fulfilling CF criteria diagnosis. We have designed primers (Primer express 3.0 software) for 10 exons, 8 concerning the flanking regions (3, 4, 7, 8, 10, 11, 18, 19) and two other into the deleted regions (6a, 17a). Genomic DNA samples were scanned for each CFTR region as well as for the b2-microglobuline, as endogenous gene, using Power SYBR Green PCR Master Mix in a quantitative real-time PCR (ABI 7300). Positive CF controls and wild type samples were included in the study. Comparative analysis of normalized C_t ($2^{-\Delta\Delta C_t}$) from patients and controls permitted us to estimate the dosage. We have detected dosage changes in four samples out of 11 analyzed. The CFTR50kdel was detected in two patients. Another deletion and one insertion were also identified.

We conclude that this technique shows a high sensitivity and is suitable to identify CFTR large rearrangements, deletions and insertions, permitting us to improve the detection rate in Spanish CF patients.

P01.037**Validating assays for relative quantification of CFTR cDNA from nasal epithelial brushing**L. Masvidal¹, A. Alvarez², L. Ruano², X. de Gracia², T. Casals¹;¹Medical and Molecular Genetics Centre. IDIBELL, Barcelona, Spain, ²Cystic Fibrosis Unit. Hospital Vall d'Hebron, Barcelona, Spain.

Real-time PCR has proven to be a useful method to quantify gene expression in samples with small number of cells. We have applied this technology to validate the relative quantification of CFTR RNA from nasal brushing of CF patients in a Taqman assay (ABI 7300). Four endogenous genes have been evaluated (HPRT1, beta2-M, GUSB, PMCA4). Standard curves were performed for CFTR and endogenous genes from the cell line HEK293 over expressing CFTR, nasal polyp and nasal epithelial (NE) samples. The selection of suitable endogenous genes for normalization is a prerequisite for accurate determination of expression level. Hence, PCR efficiencies have been determined and two different software programs (NormFinder, qBase) have been used to evaluate expression stability in NE samples from CF patients (n=9) and controls (n=9). DNAs from all individuals were analyzed for CFTR gene. RNA quality was determined and only samples with a RIN above 5.2 were included. The experiment has been carried out twice from two independent RT reactions and each sample was analyzed in triplicate. We have identified three endogenous genes suitable for accurate normalization of CFTR data expression. Supported by Spanish ISCiii project PI050804.

P01.038**A diagnostic approach for characterization of the CFTR gene defects by mRNA analysis**

L. Porcaro, L. Costantino, V. Paracchini, D. Coviello, L. Claut, M. Di Cicco, A. Monti, P. Capasso, D. Degiorgio, C. Colombo, M. Seia; Fondazione Policlinico Mangiagalli e Regina Elena, Milan, Italy.

A significant percentage of CF alleles remain unidentified in most population, even after extensive studies of the CFTR gene by PCR based procedure. We believe that mRNA analysis may allow researchers to define the pathogenic role of sequence variations not yet defined and particularly splicing defects. After an extensive analysis at DNA level, in a cohort of 745 CF patients, 81 alleles (6%) were still unknown. Aim of this work was to evaluate the role of the CFTR analysis at mRNA level as a diagnostic method for the characterization of molecular defects in CF patients who still had one or two unidentified alleles. RNA was extracted from nasal epithelial cells and collected using cyto-brush from 7 CF patients and 3 non-CF controls. The cDNA was amplified in six overlapping fragments spanning the entire CFTR gene. Disease-related mutations were identified in two patients; mRNA analysis performed on two other related patients with a deletion of exon 2 at DNA level, showed two novel transcription products carrying a deletion of exon 2-3 and an insertion of intron sequence of about 80bp near exon 6b, respectively. Two patients presented low level of mRNA product and should be analyzed by quantitative technique. One patient showed a normal profile. In conclusion our data suggest that the defects at RNA level could explain the pathogenic role of abnormal mRNA products in Cystic Fibrosis onset. In our experience, CFTR mRNA analysis represents an effective diagnostic tool for the identification of unknown molecular defects of the CFTR gene.

P01.039**MALDI-TOF based multiplex assay for Cystic Fibrosis newborn screening**P. Raña¹, C. Color², A. Carracedo¹, F. Barros¹;¹Fundación Pública Galega de Medicina Xenómica, Santiago de Compostela, Spain, ²Hospital Clínico Universitario de Santiago, Santiago de Compostela, Spain.

Cystic fibrosis (CF) is a heterogeneous disease and one of the most common autosomal recessive diseases known in the European population. Since the identification of the responsible gene, CFTR, more than one thousand mutations have been identified, most of which are very rare. The number and the selection of mutations tested for vary among laboratories and countries, being common to tailor the mutation panels to local patient population served. Limited sets of mutations, as the ACMG/ACOG 25 mutations and commercially available panels, are insufficiently sensitive for certain groups within a diverse population. We developed and evaluated a MALDI-TOF based mul-

tiplex genotyping assay to detect 185 CF mutations. The methodology is extremely sensitive, allowing the genotyping of very small dried blood spot samples usually employed in newborn screening programs. Furthermore, the Sequenom MALDI-TOF platform is a rapid and high throughput system, allowing to process a high number of samples simultaneously in a cost-effective manner. We validated the system by performing the assay on 348 dried blood samples in the Galician CF newborn screening pilot program, and 75 samples in the American CF proficiency testing (CDC) and the European CF aqality assessment scheme (CF European Network). In the 2006-2007 period we detected 11 new CF cases, of wich 4 cases would be missed using the ACMG/ACOG minimal panel of 25 mutations.

P01.040**A retrospective analysis of patients tested for cystic fibrosis mutations in a reference Genetics center in Izmir, Turkey**B. Durmaz¹, H. Onay², G. Itirif, H. Akir², O. Cogulu¹, F. Ozkinay¹;¹Department of Pediatrics, Ege University, Faculty of Medicine, Izmir, Turkey,²Department of Medical Genetics, Ege University, Faculty of Medicine, Izmir, Turkey.

Cystic fibrosis (CF) is an autosomal recessive disorder of epithelial ion transport caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. The CFTR gene is located at 7q31.2 and functions as a chloride channel and controls the regulation of other transport pathways. More than 900 mutations and variants have been described in the CFTR gene. We have retrospectively evaluated the molecular test results of 550 CF patients referred to the Molecular Genetics Laboratory of Medical Genetics Department, Faculty of Medicine, Ege University, Izmir - Turkey in the last three years. Patients had been tested for 36 mutations in the CFTR gene using the strip assay method (Innogenetics, Belgium). Out of 550 patients (1100 alleles) tested, 488 (88.73%) did not carry any mutations, while 27 patients (4.91%) were either homozygous or compound heterozygous, 35 (6.36%) carried only one detected mutation. Allelic frequencies for the six most common mutations in the positive groups were 41.57% (F508del), 14.61% (I148T), 11.24% (2183AA-G), 7.87% (N1303K), 4.49% (W1282X) and 4.49% (R347P). The rest of the alleles (15.73%) showed rare mutations which were 3210+1G-A, 3199del6, 621+1GT, G85E, 2789+5GA, G542X, R117H, 3849+10kbCT. No patient showed the mutations 2184delA, I507del, 1717-1GA, R334W, 3659delC, G551D, 1078delT, R1162X, R560T, A455E, 711+5GA, R553X, Q552X, 394delTT, E60X, 2143delT, 3905insT, CFTRdele2,3(2.1kb), 711+1G-T, 3272-26A-T, 1898+1G-A. In conclusion, the referrals for CF mutation analysis increased annually. The low mutation detection rate may be associated with the physicians' attitudes as they started to use molecular testing in the differential diagnosis of the diseases.

P01.041**Allelic heterogeneity of glycogen storage disease type III: a study of 34 patients**M. Hebert¹, F. M. Petit¹, A. Nadaf², L. Capel¹, F. Parisot¹, A. Mollet-Boudjemline³, P. Laforêt², P. Labrune³;¹Department of biochemistry, harmonology and genetics, Antoine Béclère Hospital (AP-HP), Clamart, France, ²Institute of Myology, Pitié-Salpêtrière Hospital (AP-HP), Paris, France, ³Department of paediatrics and genetics, referral Center for Inherited Metabolic Liver Diseases, Antoine Béclère Hospital (AP-HP), Clamart, France.

Introduction

Glycogen storage disease type III (GSDIII) is due to the deficiency of the glycogen debranching enzyme (AGL). Deficiency of AGL activities causes an incomplete glycogenolysis resulting in the accumulation, in liver and/or muscle of an abnormal glycogen. Clinical symptoms include variable tolerance to fasting, hypoglycaemia and hepatomegaly, frequently accompanied by muscular hypotonia and hypertrophic cardiomyopathy. To date, 71 genetic alterations of AGL gene have been described in GSDIII patients.

Material

Here we report the molecular characterisation of 34 GSDIII patients. The 33 AGL gene coding exons were screened by single strand conformation polymorphism and sequenced when an abnormal electrophoretic profile was observed. The allelic distribution of the c.3199C>T and c.3343G>A polymorphisms were determined on 64 control healthy patients by PCR-amplification and enzymatic digestion.

Results and discussion

In this population 65/68 pathologic alleles were identified, including 21 new mutations. Our molecular study on French GSDIII patients of various ethnic ancestries confirms both the allelic heterogeneity of AGL gene mutations and the strong influence of individual genetic background on genotype-phenotype relationships. Nevertheless in some ethnical groups, some specific mutations were prevalent, probably because of founder effects. As previously reported, we were not able to show genotype-phenotype correlations. Even so we raise the hypothesis of the role of the c.3199C>T and c.3343G>A polymorphisms on the severity of the clinical symptoms. We postulate that these mutations do not confer by themselves GSDIII phenotype, but their association with other disease-causing mutations could accentuate muscular manifestations.

P01.042**Clinical and molecular findings of metachromatic leukodystrophy; A case report of an Iranian family**

S. Seyedhassani^{1,2}, T. Majidzadeh^{2,3}, M. Rostami³, M. Dehghan Manshadi³, M. Houshmand³;

¹Research and clinical center for infertility, Yazd, Islamic Republic of Iran, ²National institute of genetic engineering and biotechnology, Tehran, Islamic Republic of Iran, ³Special medical center, Tehran, Islamic Republic of Iran.

Metachromatic leukodystrophy (MLD) is a rare autosomal recessive disorder of impaired breakdown of sulfatides that occur throughout the body, but are found in greatest abundance in nervous tissue, kidneys, and testes. The three clinical subtypes of MLD include late-infantile MLD, comprising 50-60% of cases; juvenile MLD, comprising about 20-30%; and adult MLD, comprising about 15-20%. Age of onset within a family is usually similar. All individuals eventually lose motor and intellectual functions. The disease course may be from three to ten or more years in the late infantile-onset form and up to 20 years or more in the juvenile- and adult-onset forms.

ARSA is the only gene associated with arylsulfatase A deficiency. This is located on chromosome 22q13, consists of eight exons encoding the 507 amino acid enzyme. Over 90 largely missense mutations and polymorphisms have been identified in the ARSA gene. The majority of mutations identified in patients with MLD are unique within individual families.

The patient was 5 years old boy and was referred with delayed development, mental retardation, loss of speech, urinary incontinence, seizure, spastic quadriplegia and hyporeflexia. EEG was abnormal and brain advanced dysmyelogenesis was reported in MRI. His parents had consanguineous marriage and three similar cases were seen in familial pedigree. The identity of the mutation was confirmed by amplifying all eight exons by PCR which was followed by direct DNA sequencing. The individual described in our study showed a homozygous known missense mutation at c.1173C>G (p.T391S) in exon 7.

P01.043**Two cases of Morquio IVB type in Bulgaria**

E. Paschke¹, M. Stancheva², B. Radeva²;

¹University of Graz, Laboratory of Metabolic diseases, Department of Pediatrics, Graz, Austria, ²University Children's Hospital, Sofia, Bulgaria.

The authors report two cases with Morquio IVB type. The first child present with typical clinical presentation -normal intelligence, dysostosis multiplex. The DMB test showed increased level of MPS. Electrophoresis showed chondroitin sulfate. The diagnosis was confirmed by low beta-galactosidase in leukocytes. The DNA analysis showed the most common in Europe mutation W273L/W273L. The second child present with skeletal anomalies, coarse facial features, astigmatism, myopia, joint hyperflexibility, dyslalia, cortical atrophy with enlarged subarachnoidal spaces on the convex, ventricles and basal cisterns, slightly expressed hypotonia. The electrophoresis showed unidentified oligosaccharides. The enzyme assays -low beta galactosidase in leukocytes and fibroblasts. The DNA -analysis showed two nonpathogenic polymorphisms c.29C>T/heterozygote/, c.34T>C/homozygote/ and a heterozygous state for a common mutation R201H in exon 6 of GLB1 gene and a novel mutation P597S in exon 16 of GLB1 gene. A genetic counseling, carrier testing was proceeded to the parents and the brother of the child.

P01.044**Monozygotic sisters with MPS I: a year later**

M. O. Mkhaidze¹, D. S. Poliakov², M. M. Schavlovsky¹;

¹Medical Academy for postgraduate study, St.Petersburg, Russian Federation, ²Paediatric Medical Academy, St.Petersburg, Russian Federation.

Mucopolysaccharidose type 1 (MPS1, Hurler syndrome) is an hereditary disease caused by a deficiency of the lysosomal enzyme alpha-L-iduronidase (IDUA; EC 3.2.1.76). Non degraded glycosaminoglycans (GAGs) are stored in the lysosomes and excreted with urine. Last year we reported on a family with monozygotic sisters suffered from MPS1 (EJHG 2007,15(S1):77). The probands are homozygous for Q70X/Q70X. Last year they were under observation by a geneticist, a lung diseases specialist, a neurologist, an orthopedist, an otorhinolaryngologist, a pediatrician and a surgeon. Every specialist found a lot of the pathologic features. The disease was taking a severe progressive course. Clinical symptoms of MPS I become progressively worse. Children's general state is serious. It was possible to launch an enzyme treatment (Aldurazyme® (laronidase)). Each child was treated with enzyme infusion five times. After this treatment, both the liver and the spleen enlarged were found to abate their size, however some allergic symptoms appeared. The immunological study has revealed antibodies to Aldurazyme. Probands need a complex follow-up.

P01.045**Niemann-Pick disease, Clinical Course and Molecular Findings; A Case Report of an Iranian Patient**

T. Majidzadeh^{1,2}, M. Dehghan Manshadi², M. Rostami², M. Banoei¹, K. Bani-hashemi², M. Sanati¹, M. Houshmand^{1,2};

¹National Institute of Genetic Engineering & Biotechnology, Tehran, Islamic Republic of Iran, ²Special Medical Center, Tehran, Islamic Republic of Iran.

Niemann-Pick disease (NPD) is an autosomal recessive inherited lipid storage disorder that results from deficiency of the enzyme-acid sphingomyelinase. In people with this condition, this enzymatic defect causes harmful amounts of lipids to accumulate in the spleen, liver, lungs, bone marrow, and brain. Thus patients present with progressive lung disease, hepatosplenomegaly, short stature and pancytopenia. NPD is divided into four main types based on the genetic cause and the signs and symptoms (Niemann-Pick disease type A., B, C & D). Mutations in the SMPD1 gene cause NPD types A (neurodegenerative form) and B (visceral form). This gene provides instructions for producing an enzyme called acid sphingomyelinase. Mutations in either the NPC1 or NPC2 gene cause NPD type C. The NPC1 gene provides instructions for producing a protein that is involved in the movement of cholesterol and lipids within cells.

The SMPD1 gene consists of six exons located on chromosome 11q and the NPC1 gene contains of 20 exons located on 18q11-q12 are found responsible for the most NPD cases.

A 16 year old girl second of two children born of third degree consanguineous marriage was referred to our clinic. The long term of jaundice, delayed motor milestones, abnormal function of liver and Bone marrow aspiration were showing Niemann Pick's Disease. Using direct-sequencing of the entire coding region and splice junctions of the SMPD1 and NPC1 genes is obtained and analyzed. A G/C mutation at exon 5 was found in SMPD1 gene.

P01.046**Growth and nutritional status of some micronutrients and trace elements in patients with phenylketonuria**

E. R. Raouf, N. A. Mohamed;

National Research Center, Cairo - Giza, Egypt.

certain micronutrient deficiencies occur either due to rigid therapeutic dietary restriction, aversion to certain food stuffs or due to recurrent episodes of vomiting and diarrhea. Semi-synthetic formula containing low phenylalanine (Phe) content provides the majority of protein and energy in the diet while the rest of phenylalanine are met by low protein natural foods. Restricted intake of high biological value protein, let children with phenylketonuria (PKU) vulnerable to have lower than normal plasma concentrations of certain micronutrients. Aim of the study is to assess the effects of phenylalanine restricted diet on the growth of our PKU patients after one year of dietary management. We also aimed to investigate the nutritional status of the following trace elements and micronutrients; zinc, copper, vitamins C, E, A, and B-carotene among

17 PKU patients following dietary intervention coupled with multivitamin supplementation. Data were compared to those of their matched normal controls. PKU patients have marginal vitamin A deficiency (mean plasma level ; 25.2+/-6.62ug/dl versus 48.5+/-10.1ug /dl of control; highly significant ($p > 0.0001$). Mean plasma levels of B-carotene was also less than that of controls with a highly significant difference (50.65+/-15.37ug/dl vs. 75.80+/-19.60 ug /dl; $p < 0.001$). Mean plasma levels of zinc, copper, vitamins C and E were comparable to those of controls without statistical significance ($p < 0.05$). Physical growth parameters were not significantly different between the two groups. Nutritional care plan for dietary intervention managing PKU children should involve periodic assessment of protein and calorie nutritional status in addition to regular careful evaluation of micronutrients.

P01.047

The role of Copper metabolism in the clinical and biochemical polymorphism in Phenylketonuria

N. Usurelu¹, V. Tsourea², V. Gordiichiuk², O. Usurelu³;

¹The National Center of Reproductive Health and Medical Genetics, Chisinau, Republic of Moldova, ²State University of Medicine & Pharmacy "N. Testemitanu", Chisinau, Republic of Moldova, ³Ass. of Rehabilitation of Children with Phenylketonuria, Chisinau, Republic of Moldova.

Phenylketonuria (PKU) is an inborn poly-enzymatic multi-system pathology of the metabolism, its primary block being the Phenylalanine (Phe) hydroxylation that leads to severe mental retardation with clinical and biochemical polymorphism. The activity of other participating enzymes depends on the presence of microelements. Microelements determine the conformation of the protein part of enzymes and their activity. The Copper is included in Phe metabolic way. There is an antagonism between the elements: Cu-Zn. The correlation change of microelements brings to the irregularity of the enzymes' activity.

Methods: 30 PKU children presented the troubles of sleep (83%), skin rashes (exudativ, maculoerythematous papules, sclerodermic)-63%, tics, convulsions (13%), motor stereotypy (47%), 60% children were absolutely blond. They were investigated for the blood level of Copper, Zinc and ceruloplasmin, along with the level of free amino acids in blood and urine.

Results: In addition to the amino acids troubles, the medium level of Copper was 23.38±1.05 µmol/l, the Zinc level -10.5±0.52 µmol/l, the ceruloplasmin level -234.88±11.93 mg/l. The low level of Zinc leads to the process when Copper takes the place of Zinc in enzymes, and it leads to functional abnormalities of enzymatic systems containing Zinc with their clinical manifestations.

We added to the traditional diet the drug metabolical correction containing the preparations of Zinc (25-50 mg/day). As the result, the skin rashes, troubles of sleep, motor stereotypy, tics disappeared; the hair color became darker.

Conclusion: The effectiveness of the PKU treatment increases if combining the low Phe diet with drug metabolical correction, considering all metabolical components.

P01.048

Cardiomyopathy the presenting feature pathology in propionic acidaemia

S. Farshidi, S. Saber;

Welfare Organization, Tehran, Islamic Republic of Iran.

We describe cardiomyopathy as the presenting feature in two teenage years boys with propionic acidaemia. 15 year old and 13 year old brothers were well and normally active until the occurrence of chest pain and dyspnoea in the elder boy. The parents were first cousins and a 7 year old sister had died of an idiopathic cardiomyopathy 20 years earlier. Mitochondrial vitamin & cofactor cocktail therapy and carnitine therapy did not alter his symptoms; the carnitine level was normal. During his workup an elevated propionyl-carnitine level was detected, similar to that observed in severe neonatal propionic acidaemia. Direct assay of propionyl-CoA carboxylase (pcc) revealed 4% residual activity. Mutation analysis demonstrated that both brothers had G188R and N536D mutations resulting from c.562 G>A and c.1606 A>G. These brothers represent unique cases of propionic acidaemia with initially normal cardiac function. This presentation of metabolic cardiomyopathy may be amenable to medical therapy if detected before irreversible cardiomyopathy has occurred.

P01.049

Novel mutations in ATP7B gene detected in patients with Wilson disease from Bashkortostan

A. Magzhanova¹, A. Karunas², R. Magzhanov¹, E. Khusnutdinova²;

¹Bashkirian State Medical University, Ufa, Russian Federation, ²Institute of Biochemistry & Genetics of Ufa Scientific Center Russian Academy Science, Ufa, Russian Federation.

Wilson disease is an autosomal recessive disorder of hepatic copper metabolism caused by mutation in the gene encoding a copper-transporting P-type ATPase (13q14.3-q21.1) and leading to heavy hepatic and neurological disorders. The purpose of this research was the analysis of correlation between clinical features (neurological, neuropsychological and liver disorders) and types of mutations.

We observed 71 patients and 96 members of their families from Bashkortostan, using clinical examination, biochemical analyses of blood and instrumental methods (hepatic scanning, hepatography).

We had carried mutation analysis in 28 families with WD from Bashkortostan.

Using SSCP analysis followed by sequencing 19 exons (2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20) of ATP7B gene were identified 8 mutations and 3 polymorphisms in 83,9 % of chromosomes. We have detected 2 novel mutations: Ala718Pro and Lys1315_Arg1316delinsGlu. The most common mutation in Bashkortostan were His1069Gln - 48,2% and Lys1315_Arg1316delinsGlu - 10,7%. We found correlation between type of mutation and clinical manifestations. Patients with new deletion had more severe clinics with early manifestation and hard liver disorders.

P01.050

Functional characterization of 4 CBS mutations found in homocystinuric patients

M. Cozar^{1,2}, C. Esteves¹, R. Urreiziti^{1,2}, D. Grinberg^{1,2}, S. Balcells^{1,2};

¹Departament de Genetica; IBUB, Universitat de Barcelona, Barcelona, Spain,

²Centro de Investigacion Biomedica en Red de Enfermedades Raras (CIBER-ER), ISCIII, Barcelona, Spain.

Homocystinuria due to CBS deficiency (MIM#236200) is a rare autosomal recessive disorder characterized by extremely elevated levels of homocysteine (Hcy) in plasma. More than 140 different mutations have been described worldwide and near 1/3 of these mutations have been heterologously expressed and tested for CBS activity. In the Iberian Peninsula and South America the p.T191M mutation is particularly prevalent and accounts for approximately 50-70% of the alleles. The remaining mutations are found in a few pedigrees being mostly private. We had found 3 new mutations (p.M173del, p.P200L and p.D281N) and a previously described one (p.P49L) in four homocystinuric patients (tree Spanish and one Indian).

With the aim to assess the pathogenicity of these mutations they were expressed heterologously in *E. coli* and their enzyme activities were assayed in vitro, both in the absence and presence of the CBS activators PLP and SAM. The wild-type CBS activity in the presence of PLP was taken as reference (100%). The expression of the mutant proteins was confirmed by Western-blotting in denaturing conditions. Mutations p.M173del and p.D281N showed null activity and a complete lack of response to the activators, confirming their pathogenicity, whereas p.P49L and p.P200L exhibited activities close to 30% and a strong response to PLP. Furthermore, p.P200L showed good response to SAM. These mutations were found in two patients with a mild phenotype. Mutation p.P49L was found, in combination with p.R125Q, in a 53 year-old male who presented with a stroke and in his asymptomatic 51 year-old sister.

P01.051

Hereditary hyperferritinemia cataract syndrome: characterization of two mutations in the L-ferritin gene

O. M. Messina-Baas¹, L. M. Gonzalez-Huerta², V. Ramirez-Sanchez¹, S. A.

Cuevas-Covarrubias³;

¹Hospita General de Mexico, Mexico D.F., Mexico, ²Hospital General de Mexico, Mexico D.F., Mexico, ³Hospita General de Mexico, Fac Medicina, UNAM,

Mexico D.F., Mexico.

Hereditary hyperferritinemia cataract syndrome, an autosomal dominant disease, is characterized by early onset bilateral cataract. Affected individuals show high levels of serum ferritin without iron overload. Elevated serum ferritin results from misregulation of L-ferritin transla-

tion. Ferritin is the major intracellular iron store protein and consists H (heavy) and L (light) subunits which are encoded in chromosomes 11 and 19, respectively. The iron responsive element (IRE) in the 5' untranslated region (5'-UTR) of L-ferritin mRNA interacts with trans-acting iron regulatory proteins (IRPs) to regulate ferritin translation. Mutations in the 5'UTR of the L-ferritin gene, result in reduced affinity for IRPs and subsequently in constitutive L-ferritin synthesis which results in congenital cataract. In the present study, we analyzed two families with early onset bilateral cataract and marked hyperferritinemia. Genomic DNA was isolated from peripheral blood and the IRE L-ferritin gene was completely sequenced. Morphology of cataracts of both families showed different phenotypes. Onset of cataract symptoms ranged from 15 year-old to 40 year-old. No other ocular or systemic anomalies were found to be present. Propositi underwent surgery with satisfactory results. Levels of ferritin serum were compatible with hyperferritinemia. DNA analysis of both families detected two different missense mutations in the loop region of the L-ferritin gene, one of them previously reported, these mutations in the L-ferritin gene result hereditary hyperferritinemia cataract syndrome.

P01.052

Analysis of the CTNS gene in Spanish patients with cystinosis disease

J. Macias, M. Rodes, J. M. Hernandez, M. J. Coll;

Institut de Bioquímica Clínica, Hospital Clínic. CIBERER, Barcelona, Spain.

Cystinosis (MIM #219800) is an autosomal recessive disorder characterized by intra-lysosomal accumulation of cystine due to an impaired transport of free cystine out of lysosomes.

Three phenotypical forms have been described according to the age of onset and severity of the clinical symptoms: infantile, juvenile and ocular nonnephropathic cystinosis.

The gene for cystinosis, CTNS, has 12 exons and encodes a 367 amino-acid lysosomal membrane protein called cystinosin. Up to now 84 different mutations have been described.

We have analyzed the CTNS exons and intron boundaries, as well as the promoter region in 21 unrelated Spanish cystinosis patients, in order to find possible genotype-phenotype correlations and to enable identification of carriers and prenatal diagnosis. In this study, 11 different mutations were identified, 5 of which are novel. The 57-kb deletion is the most prevalent mutation in our country (33,3% of the alleles), as seen in other studied populations. This deletion together with other 4 mutations (previously described p.T7fsX6, p.T216fsX11, p.G308R and p.M1T which is novel) accounted for 80% of the alleles, which facilitates molecular diagnosis and genetic counselling in this disease.

P01.053

Characterization of cystinuria double knockout for b^{0,+}AT and rBAT

M. Espino Guarch¹, M. Font-Llitjós^{1,2}, R. Silluó^{1,2}, S. Mañas¹, J. Visa³, M. Palacín^{4,5}, V. Nunes^{1,5};

¹Centro de Genética Médica y Molecular IDIBELL, L'Hospitalet de Llobregat, Spain, ²CIBERER-U730, Barcelona, Spain, ³Animal Facility Service IDIBELL, L'Hospitalet de Llobregat, Spain, ⁴Parc Científic de Barcelona, Barcelona, Spain, ⁵Universitat de Barcelona, Barcelona, Spain.

Cystinuria is a common recessive disorder of renal reabsorption of cystine and dibasic amino acids that results in urolithiasis of cystine. Cystinuria is caused by defects in the amino acid transporter rBAT/b^{0,+}AT. Mutations in SLC3A1 (rBAT) cause cystinuria type A, characterized by a silent phenotype in heterozygotes (phenotype I). Mutations in SLC7A9 (b^{0,+}AT) cause cystinuria type B, which heterozygotes in most cases hyperexcrete cystine and dibasic amino acids (phenotype non-I). The Slc7a9 null knockout mouse model (Stones) and the Slc3a1 knockin (Pebbles) develop cystinuria B and A respectively. All homozygous mutants hyperexcrete cystine and the three dibasic amino acids, and ~40% of them present cystine calculi in the urinary system. To facilitate in vivo investigation of cystinuria we have generated double knockout mice by crossing the two cystinuria mice models (Stone and Pebbles) and we have characterized the nine genotype combinations of the F2 in mixed background C57BL/6J-C3H.

Mice were X-ray analyzed at 2.5 and 8 months to appraise calculi formation. Histopathology studies and metabolic cage experiments to collect urine to quantify amino acids excretion were also performed. Preliminary results indicate that double knockout mice has more se-

vere phenotype than single knockouts: single mutants which are heterozygote for the other subunit and double mutants show less viability, higher stone rate and a more severe urinary system damage.

Supported by MEC (SAF2003-08940-01/02 and BFU2006-14600-C02-01/02/BMC), The European Union (EUGINDAT; LSHM-CT-2003-502852), Generalitat de Catalunya (2006 SGR00018 and 2005 SGR00947).

P01.054

Single exon deletions in the PAH gene in Polish PKU patients

M. Bik-Multanowski, J. J. Pietrzyk;

Chair of Pediatrics, Jagiellonian University, Krakow, Poland.

The majority of molecular defects causing phenylketonuria (PKU) are missense mutations of the phenylalanine hydroxylase gene (PAH), which are detectable with use of classical molecular techniques basing on single exon amplification, heteroduplex analysis and sequencing. The cumulative mutation detection rate in various groups of PKU-patients reaches 90-99%. However, the above procedure fails to detect single exon deletions.

The aim of this study was to establish simple, non-laborious PCR-based methods for detection of three PKU-causing single exon deletions and to assess their frequency in Polish PKU-patients.

Methods: An attempt to detect Ex5del955, Ex5del4232ins268 and EX3del4765 deletions was undertaken with use of published data on the mutated sequence of the PAH gene. DNA samples from 25 PKU Polish patients were analyzed, in whom only one or no PKU-causing mutations (a single case) were identified despite extensive analysis performed with classical methods (in the remaining 245 patients, in whom DNA samples were tested, both mutations were found).

Results: PCR protocols for amplification of mutated alleles were successfully established. Following PCR primers were used: Exon-5del955for-gcaccattggaatccacagcaagg,

Exon5del955rev-gtctctagactctaggaggtcccccag, Exon5del4232for-gttccattctgtcagttgctg, Exon5del4232rev-ggaggatctgtctccgctctc, Exon3del4765nestedfor-gcattgtccaagtacagctctgg (nested PCR), Exon-3del4765for-acaggcacacaccaccatgc and Exon3del4765rev-gccactatgggattgggtgacc. In the tested samples, six cases of Ex5del4232ins268 deletion were found as well as one case of each of the other deletions, which were interestingly detected in the same patient's sample.

Conclusion: Ex5del955, Ex5del4232ins268 and EX3del4765 deletions in the PAH gene can be detected with use of simple PCR-based methods and are present in around 2%-3% of Polish PKU-patients.

Supported by government grant for scientific research (N40708032/3085)

P01.055

Detection of mutations in two families with Ethylmalonic encephalopathy using real-time PCR

V. Tiranti¹, R. Minerì¹, T. Georgiou², G. Stylianidou³, A. Drousiotou²;

¹Unit of Molecular Neurogenetics, Pierfranco and Luisa Mariani Center for the Study of Children's Mitochondrial Disorders, National Neurological Institute "Carlo Besta", Milan, Italy, ²Department of Biochemical Genetics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, ³Department of Paediatric Neurology, Archbishop Makarios III Hospital, Nicosia, Cyprus.

Ethylmalonic encephalopathy (EE, OMIM # 602473) was diagnosed in three children from two unrelated Cypriot families. They presented with neurodevelopmental delay, prominent pyramidal and extrapyramidal signs, recurrent petechiae, orthostatic acrocyanosis and abnormal MRI images. They had persistent lactic acidemia, markedly elevated urinary excretion of ethylmalonic acid, 2-methylsuccinate, isobutyrylglycine and isovalerylglycine, and moderately raised butyrylcarnitine in blood. In one patient muscle cytochrome C oxidase activity was greatly reduced. The diagnosis was confirmed by westernblot analysis in fibroblasts which showed the absence of the ETHE1 protein. Molecular analysis of the ETHE1 gene was carried out using both PCR and sequencing. The proband of the first family was a compound heterozygote for a deletion in exon 4 and a missense mutation in exon 5, L185R. In order to establish the presence of the deletion in a heterozygous state, we carried out quantitative real-time PCR on DNA extracted from both the patient and his healthy parents. The proband from the second family was homozygous for the deletion in exon 4 and in this case quantitative real-time PCR demonstrated that the parents were both heterozygotes for the deletion. The exon 4 deletion and the

L185R missense mutation, previously reported in EE patients, were shown to be associated with the absence of the ETHE1 protein.

P01.056

Mutation analysis of Fabry disease in Argentina

G. P. Serebrinsky¹, F. M. Masllorens², H. Amartino³, R. Valdez⁴, A. Fainboim⁵, G. Cabrera⁶, J. M. Politei⁷;

¹Laboratorio de Biología y Patología Molecular, Buenos Aires, Argentina,

²Hospital Nacional Profesor A. Posadas, Buenos Aires, Argentina, ³Hospital Universitario Austral, Servicio de Neurología Infantil, Pilar, Provincia de Buenos Aires, Argentina, ⁴Hospital Alemán, Servicio de Genética Médica, Buenos Aires, Argentina, ⁵Hospital de Niños Ricardo Gutiérrez, Centro de enfermedades lisosomales, Buenos Aires, Argentina, ⁶Clínica Adventista, Buenos Aires, Argentina, ⁷Sección Neurología, Instituto de Neurociencias, Fundación Favaloro, Buenos Aires, Argentina.

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism, resulting from mutations in the alpha-galactosidase A gene (GLA). Very few reports on mutation analysis for Fabry disease in the Argentinean population are available in literature. Here we report mutation analysis in 16 unrelated Argentinean families with Fabry disease. Methods: Genomic DNA was isolated from affected males and female relatives, and the entire alpha-Gal A coding as well as flanking intronic sequences were amplified by PCR and analyzed by automated sequencing.

Results: Thirteen different mutations were identified, including eight missense mutations (D155H, C174G, C202Y, N215S, Y216C, D264Y, A292T, L415P); two nonsense (R227X, E398X); one splice site mutation IVS4-1G→A and two small deletions: one complex G144fsX15 (del c.431-442, del c.448-459) and K374fsX15 (del c.1122-1125 del AGGA). Six were novel mutations (underlined) and seven were previously described. Mutation analysis provided precise identification of 33 heterozygotes among female relatives and detected a de novo mutation (IVS4-1G→A). Discussion: It is generally assumed that Fabry mutations are private; however this does not seem to be the case of our sample. Mutation L415P was found in four different families presumably unrelated by pedigree analysis. Haplotype analyses with microsatellite markers tightly linked to the GLA gene are being performed in order to define whether this mutation is recurrent in Argentina or the result of a founder effect. These studies further define the heterogeneity of mutations causing Fabry disease and permit precise carrier identification, which has consequences for genetic counselling and for treatment.

Screening for Fabry disease using alpha-galactosidase assay on dried blood discs : a prospective nationwide multicentric study

D. P. Germain¹, N. Mir², T. Damy³, K. Ly⁴, A. Millaire⁵, P. Charron⁶, A. Martin-Mista⁷, K. Benistar⁸, T. Tran⁹, E. Caudron⁷, P. Prognon⁷, L. Gouya⁸, C. Boileau⁸, A. Bouzamondo⁹, C. Boucly², A. Hagège¹⁰;

¹Université de Versailles - St Quentin en Yvelines, Garches, France, ²Hôpital Raymond Poincaré, Garches, France, ³Hôpital Henri Mondor, Créteil, France,

⁴CHU, Limoges, France, ⁵CHRU, Lille, France, ⁶Hôpital Pitié-Salpêtrière, Paris, France, ⁷Faculté de Pharmacie, Chatenay-Malabry, France, ⁸Hôpital Ambroise Paré, Boulogne, France, ⁹Société Française de Cardiologie, Paris, France,

¹⁰Hôpital européen Georges Pompidou, Paris, France.

Background. Fabry disease (FD, OMIM 301500) is a multisystemic and clinically heterogeneous disease resulting from a deficiency of the lysosomal enzyme alpha-galactosidase A. Hypertrophic cardiomyopathy is a frequent symptom of the classic form of the disease and a cardiac variant, characterized by residual alpha-galactosidase A activity and a milder phenotype, has also been reported. In a prospective nationwide multicentric study, we have studied the prevalence of Fabry disease in a hypertrophic cardiomyopathy referral population.

Methods. We have developed and validated an assay of alpha-galactosidase A activity on dried blood paper discs. Using this method, we have assayed alpha-galactosidase A activity in 330 adult patients affected with hypertrophic cardiomyopathy who had never been diagnosed with FD. Results. Three patients (0.9%) were found to exhibit low alpha-galactosidase A activity in dried blood spots. This was confirmed by a second determination of alpha-galactosidase activity in leukocytes. The three patients presented neither the typical clinical signs of classic FD, such as acroparesthesias or hypohidrosis, nor kidney insufficiency, suggesting a variant form of FD. All patients with low alpha-galactosidase activity had

mutations in the GLA gene. DNA sequencing also allowed the identification of two additional hemizygotes (half-brothers of the proband) in one family.

Discussion. Screening for Fabry disease should be considered in all cases of unexplained hypertrophic cardiomyopathy. Its recognition is important since specific enzyme replacement therapy is now available. The proposed novel filter paper method favours the collection, storage and shipment of samples. It is simple and efficient for screening programs.

P01.058

An update in the molecular analysis of classical galactosaemia in Spain and Portugal: Eight new mutations in seventeen new patients

L. Gort¹, E. Quintana¹, S. Moliner¹, L. González-Quereda¹, T. López-Hernández¹, P. Briones^{1,2};

¹Institut de Bioquímica Clínica - CIBERER, Barcelona, Spain, ²CSIC, Barcelona, Spain.

Classical galactosaemia is an autosomal recessive inherited metabolic disorder due to mutations in the galactose-1-phosphate uridylyltransferase gene (GALT).

We previously reported molecular analysis of 83 Spanish and Portuguese galactosaemic patients. Here we present the molecular results of another seventeen unreported affected individuals.

Thirteen patients of Spanish origin were analysed. We detected six alleles carrying p.Q188R, accounting for 23%. Other six alleles (23%) were identified with the mutation p.K285N. Remarkably, the two patients that were homozygous for this change were of North African origin. We also identified seven novel mutations: p.Q9X, c.328+2T>C, c.328+33G>A, p.I170N, p.C180F, p.V233L, p.P257L. Taking into account all the Spanish galactosaemic diagnosed patients, mutation p.Q188R is still the most frequent mutation identified (43.7%). The second most frequent mutation is p.L195P (13.3%) followed by p.K285N (12.5%).

Four new Portuguese patients were analysed. In four alleles p.Q188R was detected, representing 50%. One novel mutation was identified, p.F171C. Mutations p.L195P and p.K285N still remain undetected in Portuguese patients. In the whole group of 36 Portuguese patients we have analysed until now, mutation p.Q188R remains the most frequent identified (57%). It is worth mentioning that this is the only frequent mutation as the rest of changes identified were found only in one or two alleles each.

Our results confirm the already published observation that p.Q188R is the most frequent mutation in Iberian Peninsula galactosaemic patients (48,5%).

Moreover, our molecular analyses on these seventeen new galactosaemic patients provide eight novel mutations to the database with more than 200 disease-causing mutations already reported.

P01.059

Normal HPRT coding region in complete and partial HPRT deficiency.

M. G. García, R. J. Torres, C. Prior, J. G. Puig; Hospital La Paz, Madrid, Spain.

Lesch-Nyhan syndrome is an X-linked recessive inborn error of metabolism due to a virtually complete lack of hypoxanthine-guanine phosphoribosyltransferase (HPRT) activity (OMIM 300322). Partial deficiency of HPRT (OMIM 300323) is characterized by the effects of excess uric acid synthesis and a continuum spectrum of neurological manifestations, without the manifestations of full-blown Lesch-Nyhan syndrome. Both diseases have been associated with mutations in the HPRT gene. These mutations are heterogeneous and disperse throughout the entire HPRT gene. In 2005 Dawson et al described, for the first time, an individual with gout in whom HPRT deficiency appeared to be due to a defect in gene regulation.

Patients and methods: Four patients with partial HPRT deficiency and one patient with Lesch-Nyhan syndrome were studied. The RNA and RNA-free genomic DNA samples were isolated from whole blood. Analysis of HPRT coding region was performed by Reverse transcription of patients RNA, amplification of HPRT cDNA by PCR and automated sequencing. HPRT mRNA expression was determined by Real-Time PCR technology. All nine exons of the human HPRT gene, its intronic flanking sequences, and gene regulatory sequences were amplified and automated sequenced. Results: All patients showed a nor-

mal HPRT coding sequence. Determined by mean of Real-Time PCR technology, these patients showed markedly decreased HPRT mRNA expression. Finally, we have analysed genomic regulatory sequences from HPRT gene in these patients but no mutation was found. Conclusions: This is the first report of a patient with Lesch-Nyhan syndrome due to a defect in HPRT gene expression regulation.

P01.060

Clinical, biochemical, and molecular diagnosis of L-2-hydroxyglutaric aciduria; Report of three Iranian families with six affected cases

Y. Shafeghati^{1,2}, G. Vakili³, M. Noruzinia⁴, R. Colombo PhD⁵;

¹Genetics Research Center, Tehran, Islamic Republic of Iran, ²Medical genetics department, Sarem women's hospital, Tehran, Islamic Republic of Iran, ³private general practitioner, Tehran, Islamic Republic of Iran, ⁴2- Medical Genetics Department, Sarem Women's Hospital, Tehran, Islamic Republic of Iran, ⁵3- Laboratory of Human Molecular Biology and Genetics Catholic University of the Sacred Heart, Milan, Italy.

Background: L-2-Hydroxyglutaric aciduria is a novel autosomal recessive neurometabolic disorder. First described by "Duran" in 1980 about 100 cases have been reported. It is characterized by slowly progressive neurological dysfunction with cerebellar ataxia, pyramidal sign, intellectual decline, seizure etc.. MRI scanning is highly characteristic and screening for organic acid(L-2-Hydroxyglutaric acid) in the urine, serum, and CSF is diagnostic.

Materials & Methods: We have investigated three Iranian families with six affected children aged (4 to 16 years) who were suspected for this rare disorder, by urine organic acid assay and MRI scanning. In two families we analyzed the Duranin gene which is responsible for hydroxy-glutarate dehydrogenase.

Results: Affected cases were evaluated because of clinical findings. Urine levels of L-2-Hydroxyglutaric acid were strongly increased. MRI scanning of the brain showed hyper intense signal on T2 weighted images of the sub-cortical white matter, and basal ganglia in all of the patients. We have identified the mutation in one of the families. It was a large deletion encompassing at least exons 7 and 8, the process is ongoing yet. In this family, because the mother became pregnant we did PND, unfortunately the fetus was affected in homozygote state.

Conclusions: Because of its inheritance pattern(autosomal recessive), and high rate of consanguineous marriages in Iran, the prevalence of this disorder might be higher, between mentally handicapped patients, especially those with macrocephaly. So we should consider this rare entity in our differential diagnosis.

Lysosomal membrane permeabilization triggers cathepsin D secretion and cell death in lysosomal storage diseases

D. L. Medina, R. de Pablo, V. Bouché, A. Ballabio;

Telethon Institute of Genetics and Medicine, Naples, Italy.

Lysosomal storage diseases (LSDs) are a group of inherited metabolic disorders due to the defective activity of lysosomal hydrolases and characterized by accumulation of undegraded substrates in the lysosomes, leading to peripheral organ cell damage, neurodegeneration, and premature death in most cases (Saftig et al, 2005). Here we have used our mouse model for Multiple Sulfatase Deficiency (MSD) (Settembre et al, 2007), to study the intracellular signals triggered by intralysosomal storage. Using fluorescent weak bases to examine the acidic lysosomal compartment from isolated splenocytes and mouse embryonic fibroblasts, we have found an increased lysosomal membrane permeabilization (LMP) in MSD cells compared with their wild-type counterparts. These results suggest a loss of the intralysosomal acidic pH that can be mimicked in wild-type cells by the addition of the specific inhibitor of vesicular proton pump, Bafilomycin A1. Lysosomal destabilization in MSD cells correlates with several hallmarks of apoptosis such as lysosomal secretion of the aspartate protease cathepsin D, loss of mitochondrial membrane potential, release of cytochrome C, activation of caspase-3, and annexin V staining. Interestingly, LMP seems to be a common sign of other LSDs as suggested by the increased LMP observed in splenocytes from a mouse model of Hunter disease. Together, these evidences support the role of LMP and the release of lysosomal proteases in the initiation and execution of apoptosis in pathological situations such as LSDs.

Mutational spectrum and phenotype-genotype correlation in Spanish Methylmalonic Acidemia with Homocystinuria, cbIC type

B. Pérez, A. Jorge-Finnigan, B. Merinero, L. R. Desviat, F. Leal, E. Richard, M. Ugarte;

Centro de Biología Molecular Severo Ochoa. CIBERER, Madrid, Spain.

Methylmalonic acidemia with homocystinuria, cbIC type is the most frequent genetic disorder of vitamin B₁₂ metabolism. We present the mutational spectrum of 22 patients, classified belonging to the cbIC complementation group by biochemical and cellular approaches, to provide insight on the phenotype-genotype correlations and on the search for new therapeutical targets. The mutational spectrum included five previously described mutations (M1L, R91fs, R132X, R153X, R161X) and one new splicing change (IVS1nt2T>G). The most frequent change was the known mutation R91fs caused by a single nucleotide duplication in position 271 which accounted for 82% of the mutant alleles characterized and 77% of the cbIC in homozygous fashion. Up to date only some family studies have been performed to rule out the presence of a big deletion. The frequency of c.271dupA is higher than described in other studied populations such as the Italian and the Portuguese cases. These results allow the confirmation of the disease in our population by specific mutational analysis. The other changes were rare mutations identified in one or two alleles (2 to 4%). All the mutations found produce a premature truncation codon. The majority of the patients exhibited a neonatal severe presentation. Although most patients responded biochemically to B12 they exhibited a fatal outcome. Further studies of the physiopathology of the disease to provide insight about the severity of the symptoms despite of B12 responsiveness as well as the in vitro use of drugs to read-through the PTC mutations will be discussed.

P01.063

Identification of 4 novel mutations in the NPC1 gene in Spanish patients with Niemann-Pick type C disease

L. Rodríguez Pascual^{1,2,3}, G. Sánchez Ollé^{1,2,3}, J. Macias^{4,3}, M. Coll^{4,3}, L. Vilagellu^{1,2,3}, D. Grinberg^{1,2,3};

¹Universitat de Barcelona, Barcelona, Spain, ²IBUB, Barcelona, Spain, ³CIBERER, Barcelona, Spain, ⁴Institut de Bioquímica Clínica, Hospital Clínic, Barcelona, Spain.

Niemann-Pick type C (NPC) is a rare autosomal-recessive lysosomal storage disorder characterised by severe progressive neurological deterioration. The disease is caused by mutations in the *NPC1* or *NPC2* genes. Approximately 95% of patients bear mutations in the *NPC1* gene, which encodes a late endosomal integral membrane glycoprotein, and about 5% of the patients show mutations in the *NPC2* gene, encoding a small soluble lysosomal protein with cholesterol-binding properties. Both genes are involved in cholesterol and glycolipid trafficking and transport, so NPC patients show accumulation of unesterified cholesterol and glycosphingolipids in the lysosomal/late endosomal system.

A mutational analysis was carried out in 5 non-related individuals affected by this disorder. Genomic and cDNA from the patients were amplified and sequenced. All the *NPC1* mutant alleles were identified; 4 of them have not been described before and were not found in 100 control alleles. The new changes were: one missense mutation: p.F1079S (c.3236T>C); one nonsense mutation: p.E1089X (c.3265G>T) and two intronic changes that affect the splicing process: c.2604+5G>A in the donor splice site of intron 17 which promotes skipping of exon 17 and c.1554-1009G>A that is located in intron 9 and results in the incorporation of 194 pb of intron 9 in the cDNA as a new exon. Some of the mutant alleles caused degradation of the mRNA by the nonsense-mediated RNA decay mechanism. To identify these mutations, cycloheximide treatment of cultured fibroblast was required.

The financial support from Fundación Niemann-Pick España and from CIBERER (INTRA/07/720.1) is acknowledged.

P01.064

Isolation and characterization of a novel CHO cell mutant defective in peroxisome biogenesis factor, PEX16, containing aberrant huge peroxisomesK. Ghaedi^{1,2,3}, Y. Fujiki^{4,5};¹Biology Dept., Isfahan, Islamic Republic of Iran, ²Royan Institute, Isfahan Research campus, Isfahan, Islamic Republic of Iran, ³Biology Dept, Faculty of sciences, Kyushu University, Fukuoka, Japan, ⁴Biology Dept., Faculty of Sciences, Kyushu University, Fukuoka, Japan, ⁵JST, SORST, Tokyo, Japan.

Peroxisomal Biogenesis Disorders (PBDs) are characterized as the congenital cerebro-hepato-renal disorders which are mostly due to the defects in the biogenesis of peroxisomes. In order to study molecular mechanisms of peroxisome biogenesis, CHO-K1 cells have been widely used by our group as the best model cells. Using CHO-K1 cells stably transformed dually with *PEX2* (to prevent frequent isolation of *peX2* mutant cells) and EGFP fused downstream of N-terminally 40 amino acid residues of Pex3p, termed TkaEG3-40 cells, we have started a procedure of mutagenizing with MNNG as a chemical mutagenic component and following culture in the presence of P9OH with subsequently an exposure to UV. By the above approach, we have isolated several CHO cell mutant cell lines defective in peroxisome biogenesis which were resemble to the patients' fibroblasts of the PBDs. One of CHO cell mutant colonies which, showed to have morphologic aberrant huge peroxisomes but very few in numbers, termed ZPEG301 cells. ZPEG301 cells belonged to the *PEX16* complementation group as numerous punctuate structures of peroxisomes were restored after its cDNA transfection in to those cells. Moreover temperature shift assay to permissive temperature at 30 degrees of centigrade showed a moderate increase in peroxisomal structures in ZPEG301 cells which is presumably due to the stabilization of peroxisomal membrane proteins such as PMP70. Biochemical pattern of peroxisomal proteins have documented our hypothesis. Taken together these results demonstrate that Pex16p is involved in morphological control and division of peroxisome in mammals besides of its main role in peroxisomal biogenesis.

Molecular diagnostics of phenylketonuriaE. Polák¹, A. Ficek¹, L. Kádaš²;¹Comenius University, Faculty of Natural Sciences, Department of Molecular Biology, Bratislava, Slovakia, ²Institute of Molecular Physiology and Genetics, Slovak Academy of Science, Bratislava, Slovakia.

Phenylketonuria (PKU) is an autosomal recessive inherited disorder arising from the deficiency of phenylalanine hydroxylase (PAH), which catalyses the essential conversion of phenylalanine (Phe) to tyrosine (Tyr). In the majority of cases, PKU is caused by mutations in the *PAH* gene, and it presents with different phenotypes which are classified according to Phe tolerance. More than 500 mutations have been described world-wide and the PAH enzyme has been fully characterized. The incidence of the disease in the Slovak population had been estimated to be 1:10 000 newborn. Seven causative mutations which have been so far identified make up 70 % of all PKU alleles. Thus the aim of our work was to carry out a complete mutation analysis in a sample of 48 unrelated PKU patients with 1 or with no known mutation. The DH-PLC (Denaturing High Performance Liquid Chromatography) method was applied for screening all 13 coding exons of the *PAH* gene. Identified heterozygous fragments were subsequently sequenced to characterize the DNA variants. Sequencing revealed 16 mutations (of which 1 is new) not previously found in the Slovak population, and 2 frequent polymorphisms in the coding region of the *PAH* gene. Corresponding frequencies for all mutations were estimated, and the classification according to phenotypic categories of PKU was identified.

P01.066

Assessment of the severity of the PAH gene mutations detected in Serbian population: genotype-phenotype correlation and functional studies in vitroM. Stojiljkovic¹, B. Perez², L. R. Desvia², C. Aguado², M. Ugarte², S. Pavlovic¹;¹Institute of Molecular Genetics and Genetic Engineering, Belgrade, Serbia,²Centro de Biología Molecular Severo Ochoa, Madrid, Spain.

Phenylketonuria (PKU) is caused by deficiency of hepatic enzyme, phenylalanine hydroxylase (PAH). Although numerous factors contribute to the PKU phenotype, several studies showed that mutations in

the PAH gene are main determinant of PKU severity. In the study on 34 unrelated patients with phenylketonuria from Serbia, we identified 19 disease-causing mutations: L48S, R408W, P281L, E390G, R261Q, R158Q, I306V, IVS12+1G>A, Q20X, R111X, V177L, P225T, R261X, L15/S16fsCTdel, S231F, R252Q, R297H, IVS10-11G>A and R413P. According to pretreatment serum phenylalanine level, patients were assigned to classic PKU (65%), mild PKU (35%) and MHP (0%). The most frequent mutation in Serbia is L48S. Since genotype-phenotype correlation inconsistency for L48S mutation has been previously reported, we investigated genotypes involving L48S and their correlation with phenotypes. The homozygous patient for L48S had classic PKU. Also, in combination with null mutations, L48S was associated with severe phenotype. Our findings on the effect of other mutations were mainly in concordance with previous European studies. However, functional and structural effect of the S231F mutation was not previously analyzed. Therefore, we characterized S231F PAH protein in prokaryotic and eukaryotic expression systems. In both systems the mutant enzyme was unstable. Its residual enzyme activity was lower than 10% showing that S231F is a severe mutation. We have found no GroESL chaperone effect and slightly positive effect of the BH4 on the stabilization of the protein structure. These findings elucidated severe phenotype of the patient with L48S/S231F genotype. In conclusion, we showed that L48S is consistently severe PAH gene mutation in Serbian population.

P01.067

Distribution of Xmn I alleles at the phenylalanine hydroxylase gene in Republic of MoldovaA. P. Gavriluc¹, S. A. Groppe²;¹National Center of Reproductive Health & Medical Genetics, Chisinau, Republic of Moldova, ²State University of Medicine & Pharmacology, Chisinau, Republic of Moldova.

Phenylketonuria (PKU) is a common autosomal recessive disease of amino acid metabolism caused by phenylalanine hydroxylase (PAH) deficiency. The human PAH gene has been localized to 12q22-24, comprises 13 exons spread over 90 kb of genomic DNA (Lidsky, 1984). The complete 2,4 kb cDNA (Kwok, 1985) can be used to detect ten different RFLPs located within the PAH locus.

Genomic DNA was extracted and examined by standard procedures from 68 families with classical PKU, i.e. 272 parental chromosomes. PCR amplification of a 205 bp fragment containing the Xmn I RFLP site was performed as described previously by Goltsov (1992). A total 136 mutant and 140 normal chromosomes were analyzed for Xmn I polymorphic restriction site (GAANN/NTTC) at the PAH gene region. Frequencies of normal alleles in population Republic of Moldova (0,593; 0,407) are not significantly different from European populations (0,618; 0,382) ($\chi^2 = 0,2$; $p > 0,7$). The level of observed heterozygosity in population of Moldova (0,48) is similar with European countries (0,47). The distribution of mutant PKU alleles (0,772; 0,228) in our study is differs significantly from those observed in European (0,654; 0,346) ($\chi^2 = 4,9$; $p < 0,05$). The Xmn I alleles in our populations had a significant difference in the distribution among normal and mutant chromosomes ($\chi^2 = 9,25$; $p < 0,01$). Frequency of informative cases by RFLP-analysis of Xmn I alleles from PKU families is 32,6% that provide a tool for molecular diagnosis of these disease and carrier status in Republic of Moldova.

P01.068

Mutational analysis of 11 Spanish Gangliosidosis GM2 (Sandhoff disease) patients

N. de Olano, A. Chabas, M. J. Coll;

Institut de Bioquímica Clínica, Hospital Clínic. CIBERER, Barcelona, Spain.

Sandhoff disease (OMIM #268800) is a recessively inherited neurodegenerative disorder in which the catabolism of ganglioside GM2 is impaired, leading to its intralysosomal accumulation primarily in neurons. The underlying genetic defect resides in the *HEXB* gene encoding the β subunit of β -hexosaminidase. We analyzed the *HEXB* exons and intron boundaries in 11 unrelated affected Spanish patients.

We found 11 different mutations, five of which were new. The novel changes detected, all corresponding to acute phenotypes, include a one-base deletion (c.171delG), two nonsense changes (p.R170X and p.W514X), a missense substitution (p.R533C), and an in-frame deletion of 6 amino acids (c.800_817del). In six patients, we identified six

mutations, all of them previously described in the literature: two juvenile patients, one of which was homozygous for p.R505Q and the other compound heterozygous for c.1509-26G>A; ,and four infantile patients homozygous for p.P417L, p.Y266D, c.782_785delCTTT and c.1305_1306delAG, respectively. Overall our findings point out to 3 particularly interesting aspects of the mutational spectrum of the Spanish population: Null frequency of the common 16 Kb deletion at 5' of the gene, an outstanding degree of homozygosity (72% of patients) and a remarkable prevalence of an allele carrying a deletion of a single nucleotide (c.171delG) which accounts for 27% of total mutant alleles.

P01.069

Mutation analysis in Spanish and Moroccan Patients with Mucopolysaccharidosis IIIC (Sanfilippo C Syndrome)

I. Canals^{1,2,3}, M. J. Coll^{4,3}, A. Chabás^{4,3}, D. Grinberg^{1,2,3}, L. Vilageliu^{1,2,3};

¹Universitat de Barcelona, Barcelona, Spain, ²IBUB, Barcelona, Spain, ³CIBERER, Barcelona, Spain, ⁴Institut de Bioquímica Clínica, Hospital Clínic, Barcelona, Spain.

Mucopolysaccharidosis (MPS) describes any inherited lysosomal storage disorder resulting from inability to catabolize glycosaminoglycans. MPS III, or Sanfilippo Syndrome, is the type of MPS that results from a deficient heparan sulfate degradation and presents an autosomal recessive inheritance. Clinical symptoms are similar for all types of MPS III and they are due to the lysosomal storage of heparan sulfate. The most important feature is the progressive and severe deterioration of the central nervous system during childhood.

HGSNAT is the gene responsible for MPS IIIC that has been recently identified. It encodes the acetyl CoA:α-glucosaminide N-acetyltransferase, which is a lysosomal membrane protein required to N-acetylate the terminal glucosamine residues of heparan sulfate. To date, about forty mutations have been described in MPS IIIC patients.

In this study we have identified the mutant alleles in five Spanish and one Moroccan patients. A total of six different alleles have been found in this mutational analysis, five of which are novel. One of these alleles contains a double mutation (c.318+1G>A, p.P265Q) previously described, three alleles bear splice-site mutations (c.456-2A>G, c.717+1G>A and c.1462-1G>A) and the other two contain missense mutations (p.G452V and p.L473P). Furthermore, two new possible single nucleotide polymorphisms (SNP) have been identified in intron 1 and intron 5, respectively. Samples from three new patients, one Spanish and two Moroccan, have recently arrived and are currently being analyzed.

This work is being carried out in collaboration with the MPS España. The financial support from this association is acknowledged.

P01.070

Novel mutation in Tay-Sachs (HEXA gene)

M. Rostami¹, M. Dehghan Manshadi¹, T. majidzadeh¹, M. Nategh², M. Houshmand¹;

¹National Institute Center Genetics Engineering & Biotechnology, Tehran, Islamic Republic of Iran, ²Special Medical Center, Tehran, Islamic Republic of Iran.

Tay-Sachs disease is a fatal genetic autosomal recessive disorder, most commonly occurring in children, those results in progressive destruction of the nervous system. Tay-Sachs is caused by the absence of a vital enzyme called hexosaminidase-A (Hex-A). Tay-Sachs disease, the prototype hexosaminidase A deficiency, is characterized by progressive weakness, loss of motor skills, decreased attentiveness, and increased startle response beginning between three and six months of age with progressive evidence of neurodegeneration, including seizures, blindness, spasticity, eventual total incapacitation, and death, usually before age four years. The infant gradually regresses, and is eventually unable to crawl, turn over, sit or reach out.

The HEXA gene provides instructions for making one part of enzyme called (beta-hexosaminidase A). Specifically, the HEXA gene carries instructions for the alpha subunit of this enzyme. One alpha subunit joins with one beta subunit (produced from the HEXB gene) to form a functioning enzyme. Mutations in the gene coding for the β subunit lead to a deficiency of both the HEX A and HEX B form of the enzyme .More than 100 mutations that cause Tay-Sachs disease have been identified in the HEXA gene. The HexA gene is located on the human 15q23-q24 chromosome.

In present study DNA was received from a consanguineous couple who had 1 affected child from who no sample was available. For each

sample we performed genetic analysis of HEXA gene by direct sequence analysis. It was found heterozygote delG mutation in exon 14 of HEXA (β subunit).

P01.071

Mutations in the urocanase gene UROC1 cause urocanic aciduria

C. Espinós¹, M. Pineda², D. Martínez-Rubio¹, A. Ormazabal¹, M. A. Vilaseca², L. J. M. Spaapen³, F. Palau¹, R. Artuch²;

¹Instituto de Biomedicina de Valencia, CSIC and Centro de Investigación Biomédica En Red de Enfermedades Raras (CIBERER), Valencia, Spain, ²Hospital Sant Joan de Déu and Centro de Investigación Biomédica En Red de Enfermedades Raras (CIBERER), Barcelona, Spain, ³University Hospital Maastricht, Maastricht, The Netherlands.

The urocanase deficiency (MIM 276880) is a rare disease with only two reported cases, due to the abnormal activity of the urocanase enzyme (histidine pathway) that catalyzes the transformation from urocanic acid to formiminoglutamate (FIGLU). The biochemical hallmark is the urocanic aciduria. We have investigated the urocanase gene UROC1 gene in a girl presenting ataxia with mental retardation (IQ = 54) and extremely high levels of urocanic acid in urine, ranging between 158-202 mmol/mol creatinine (normal values below 10 mmol/mol creatinine). The genetic analysis of the UROC1 gene revealed that the propositus is a compound heterozygote for the mutations p.L70P (c.209T>C) and p.R450C (c.1348C>T). Her healthy father was heterozygous carrier of the p.R450C mutation. *In silico* analysis showed that the L70 residue could form part of an α-helix, and then the change to proline may disrupt the α-helix, possibly resulting in an alteration of the structure of the N-terminal region. The R450 residue forms a salt-bridge with the urocanate, substrate of the urocanase. Presence of an arginine residue as the consequence of the mutation would interrupt the urocanase interaction with urocanate. Consequently, the *in silico* predictions suggest that both mutations in the UROC1 gene, p.L70P and p.R450C, are pathologic. We suggest that urocanase deficiency or urocanic aciduria is a Mendelian disorder of the histidine metabolism caused by mutations in the UROC1 gene. The toxic effect of the urocanic acid and also, the possible folate deficiency would play a notable role in the physiopathology of this rare condition.

P01.072

Mutation screening in genes coding for ATP7A, ATP7B and ATOX1 in Czech patients with Menkes disease and Wilson disease

L. Pospisilova¹, L. Kralik¹, R. Bruha², Z. Marecek², E. Flachsova¹, P. Fruhauf², A. Kral¹, J. Zeman¹, P. Martasek¹;

¹Department of Pediatrics, 1st School of Medicine, Charles University Prague, Prague 2, Czech Republic, ²Department of Internal Medicine 4, 1st School of Medicine, Charles University Prague, Prague 2, Czech Republic, ³Faculty General Hospital Prague, Department of Pediatrics, Prague 2, Czech Republic.

Copper plays an essential role as a cofactor for many enzymes. There are two intracellular copper transferring P-ATPases in human: ATP7A and ATP7B, and a chaperone ATOX1 which delivers copper to them. Deficiency of ATP7A causes X-linked Menkes disease (MD). A defect in ATP7B causes autosomally recessive inherited Wilson disease (WD). Here we report the mutational analysis of the ATP7A and ATP7B genes of 4 patients with MD and 130 patients with WD from the Czech Republic.

Genomic DNA was used to amplify 23 exons of the ATP7A gene and 21 exons of the ATP7B gene. PCR products were examined by RFLP and sequenced. We introduced fast mutation screening based on differences in melting temperature of DNA fragments with sequence variations. We performed mutation analysis of the ATOX1 gene in patients whose clinical and biochemical phenotypes suggest impaired copper transport, but no mutations were found within the ATP7A and ATP7B genes.

Molecular analysis revealed 4 mutations in the ATP7A gene, two of which have not been previously published (Q724X and E1249X). 14 mutations were found in the ATP7B gene (including prevalent H1069Q mutation, and the newly found A1135T mutation), and no mutations in ATOX1 gene.

Molecular analysis of the ATP7A gene allows for genetic counselling in families affected by MD. Screening for the prevalent H1069Q mutation in the ATP7B gene shows that the frequency- 38.8% of analysed al-

leles- is in accordance with its occurrence in Central Europe. Supported by Grants IGA MZ NR9406, NR9215, MSMT 1M0520 and GAUK 109/06.

P01.073

The molecular-genetic analysis of ATP7B gene at the Russian patients with Wilson disease

T. Matveeva¹, E. Zaklyazminskaya², A. Polyakov¹;

¹Research Centre for Medical Genetics, Moscow, Russian Federation, ²Centre of Molecular Genetics, Odintsovo, Moscow Region, Russian Federation.

Wilson's disease (hepatolenticular degeneration) is severe hereditary autosomal recessive disorder, representing combined injury of internal, first of all a liver, and a brain (the basal ganglia), that is caused by accumulation in their cells of copper. Defect of copper-transporting ATPase P-type, being a product of gene *ATP7B* responsible for development of Wilson disease, leads to abnormalities of inclusion copper into ceruloplasmin, responsible for its export.

The purpose of our investigation is search and determination of frequencies of mutations in *ATP7B* gene on materials of the Russian patients with the diagnosis «Wilson disease». In research the method of the SSCP-analysis with the following direct sequencing was used. Search and identification of mutations was spent at 104 unrelated probands (208 chromosomes). The frequency of the most frequent for the Russian population mutations in exon 14 (*H1069Q*) and exon 15 (*c.3400delC*) amounted at 40,4 % and 2,4 %, respectively.

Eight rare mutations were found in exon 5 *c.1744_1745delAT* at one patient, and *c.1770insT* at three patients; in exon 7 - *IVS7DS+3a>g* at one patient; in exon 8 - *c.2304_2305insC* at one patient; in exon 14 - *E1064K* at one patient and *c.3083_3085delAGA>G* also at one patient; in exon 15 - *Gly1111Asp* at one patient; and in exon 18 - *c.3888delC* also at one patient. All the rare mutations listed above have been detected in a heterozygous state. Mutations *c.1770insT*, *c.2304_2305insC* and *c.3888delC* have been identified for the first time. Also six polymorphisms were identified: *c.1-75C>A*, *c.1-122insGCCGC*, *c.1366G>C*, *K832R*, *Arg952Lis*, *A1140V*.

P01.074

Preliminary results of Neonatal Screening program for Wilson disease in Greece and reporting of novel variants in ATP7B gene

M. Tzetis¹, M. Poulou¹, N. Manolaki², T. Karpathios³, K. Lama⁴, E. Kanavakis¹;

¹Department of Medical Genetics, Athens University, Athens, Greece, ²1st Department of Paediatrics, University of Athens, St Sophia's Children's Hospital, Athens, Greece, ³2nd Department of Paediatrics, University of Athens, P. and A. Kyriakou Children's Hospital, Athens, Greece, ⁴Department of Paediatrics, Kalymnos General Hospital, Kalymnos, Greece.

Wilson disease (WND) is an autosomal recessive genetic disorder and heterozygous carriers do not show symptoms of the disease. WND is caused by mutations in the *ATP7B* gene and exhibits substantial allelic heterogeneity. WND is observed with a prevalence of approximately 1:30000, a carrier frequency of 1 in 90 and is similar among many ethnic groups.

However the gene frequency is increased in the Sardinian population and the Island of Grand Canaries. In these populations specific mutations reach high frequencies due to inbreeding and founder effects. Preliminary neonatal screening results have also shown increased carrier frequencies in certain parts of Greece. In order to estimate the exact carrier frequencies in areas with increased incidence of disease a neonatal screening program was established. Out of a 100 newborns tested, for the two commonest mutations (*H1069Q* and *R969Q*), from the Island of Kalymnos we identified 89 normal, 11 carriers and 2 asymptomatic patients. Taking into account the carrier frequency for the general population there is a statistically significant increase in this area with a p value of 0.07 (Pearson's Chi Square). The method used for the neonatal screening is a capture down protocol designed on Nanochip® 400 System.

We also report the identification of 6 novel variants in the *ATP7B* gene [p.I930M and p.V1036I (ex.12), p.Y1464S (ex.21), p.N1128Y (ex.15), c.4125-23A>G (IVS21), and c.1544-12C>T (IVS3)], identified by DGGE analysis and direct sequencing. The effects of these mutations were assessed in combination with the clinical phenotype and using *in silico* analysis ("PolyPhen" and "SIFT").

ABCD2 peroxisomal transporter in the metabolism of long-chain saturated and w9 monounsaturated fatty acids

Peroxisomes are essential organelles exerting key functions in fatty acid metabolism, such as the degradation of very long-chain fatty acids (VLCFAs). VLCFAs accumulate in X-adrenoleukodystrophy (X-ALD), a disease caused by a deficiency of the ABCD1 peroxisomal transporter. Its closest homologue, ABCD2, exhibits a high degree of functional redundancy on the catabolism of VLCFAs, being able to prevent X-ALD-related neurodegeneration (Pujol A. et al. 2004, Hum Mol Genet 13:2997-3006). In search for specific roles of ABCD2, we screened fatty acid profiles of mutant mice lacking *Abcd2* in adrenal glands, spinal cord and sciatic nerve, the target tissues of these mice (Ferrer et al.(2005) Hum Mol Genet 14(23):3565-3577), and in liver after different conditions such as fasting and feeding with a VLCFA-rich diet, by gas-liquid chromatography. Our results indicate that ABCD2 plays a role in the degradation of long-chain saturated and w9-mono-unsaturated fatty acids, enlarging the spectrum of functions attributed to date to peroxisomes.

X-linked adrenoleukodystrophy (X-ALD) is the most frequent inherited monogenic demyelinating disease (minimal incidence 1:17,000). X-ALD leads to death in boys or to motor disability in adults (adrenomyeloneuropathy or AMN). The disease is caused by loss of function of the ABCD1 gene, a peroxisomal ATP-binding cassette transporter, which function is related to defective β -oxidation of very long-chain fatty acids (VLCFA) in peroxisomes. Therefore, a hallmark of the disease is the accumulation of VLCFA in plasma and tissues. The mouse model for X-ALD (Ald knock-out) exhibit a late-onset phenotype closely related to adrenomyeloneuropathy, with neurodegenerative features beginning at 15 months of age (1,2). Using microarrays, Q-PCR and Western Blots of mouse spinal cords, we have identified a mitochondria depletion as very early event in the pathogenesis (3.5 months of age). RIP140 (Receptor interacting protein 140), a nuclear co-repressor of mitochondria biogenesis, is upregulated in spinal cord from Aldko mice. VLCFA are able to induce RIP140 in *ex vivo* organotypic spinal cord slice culture. We have also observed a mitochondria depletion in the affected white matter of CCALD (Cerebral Childhood ALD) and cerebral AMN compared to control individuals. This depletion is correlated to a higher level of RIP140 in the non-affected white matter of X-ALD patients. This could be disease causative, or at least, contribute significantly to the neurodegenerative cascade in X-ALD pathogenesis.

Molecular analysis of renal hypouricemia in Japan: evidence of a single origin for a common mutation G774A in SLC22A12

K. Ichida^{1,2}, N. Kamatani², M. Hosoyamada⁴, S. Kamitsuj⁵, I. Hisatome⁶, T. Hosoya²;

¹Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan, ²Jikei Univer-

sity School of Medicine, Tokyo, Japan, ³Tokyo Women's Medical University, Tokyo, Japan, ⁴Keio University, Tokyo, Japan, ⁵StaGen Co., Ltd., Tokyo, Japan, ⁶Tottori University, Yonago, Japan.

Renal hypouricemia is an inherited and heterogeneous disorder characterized by impaired tubular uric acid transport. Impairment of URAT1, the main transporter for uric acid reabsorption at the apical membrane of the renal tubules, causes renal hypouricemia. G774A mutation in SLC22A12 encoding URAT1 predominates in Japanese renal hypouricemia. We investigated whether the uncertain predominance of hypouricemia on survival or some effects such as founder effect leads to the expansion of G774A mutation in SLC22A12 in Japanese despite of the complications, nephrolithiasis and exercise-induced acute renal failure. Molecular analysis have been undertaken in sixty-nine Japanese renal hypouricemic patients and haplotypic analysis in 31 patients with homozygous G774A mutation using flanking 13 markers (12 single nucleotide polymorphisms and a dinucleotide insertion/deletion locus) around G774A locus. The sharing of the ancestral haplotype clearly implied a common origin of the mutation, the age of that being estimated to be approximately 6,820 years (95%CI 1,860 - 11,760 years, median 2,460 years). The age indicates that the origin of G774A mutation dates back from the time when Jomon people predominated in Japan to the time when Yayoi people started to migrate to Japan from the Korean peninsula. These data are consistent with a recent finding that G774A mutation was also predominant in Korean hypouricemia subjects and indicate that the Asian continent was the origin of G774A mutation. The G774A mutation in Japanese hypouricemia subjects had been brought by immigrant(s) from the continent and expanded in Japanese population either by founder effect or genetic drift (or both).

Microarray Resequencing Analysis of *Fumarylacetoacetate Hydrolase (FAH) Gene* in Tyrosinemia Patients

R. K. Özgül¹, L. Mesci², A. Dursun³;

¹Hacettepe University, Institute of Child Health&Department of Pediatrics, Metabolism and Nutrition Unit, Ankara, Turkey, ²Hacettepe University, Department of Pediatrics, Ankara, Turkey, ³Hacettepe University, Department of Pediatrics, Metabolism and Nutrition Unit, Ankara, Turkey.

Hereditary tyrosinemia type I (OMIM; 276700) is an autosomal recessive disease caused by defects in fumarylacetoacetate hydrolase (FAH) gene involved in the last step in tyrosine catabolic pathway. To date, over forty pathogenic mutations were described in the FAH gene.

In this study, a total of 22 Turkish tyrosinemia patients were genotyped to detect disease causing mutations in FAH by our design of a resequencing microarray. Our microarray was designed to sequence all exonic and their flanking intronic sequences of the FAH gene to detect sequence variations. In brief, FAH gene has been amplified from genomic DNA by short or long range PCR. After purification, all PCR products were quantitated and equimolar amount of them were pooled. After the fragmentation step, fragmented PCR products were end labeled using a biotin-labeling reagent and hybridised with DNA arrays. Then, arrays were processed by steps of washing and staining on fluidics station. Scanned arrays were analyzed using Affymetrix GeneChip Resequencing Analysis Software.

Mutation screening results showed that 12 different type of mutations were responsible of disease development in our cohort of Turkish tyrosinemia patients. Four different polymorphisms were also described in our patients. Detected mutations by DNA resequencing chip technology were also reevaluated and confirmed by direct DNA sequencing. To our knowledge, this work is the first report showing the application of DNA resequencing chip as rapid and reproducible mutation screening tool for genetic analysis of patients with hereditary tyrosinemia. Molecular and clinical findings in two Coffin-Lowry syndrome patients

D. Jurkiewicz, E. Popowska, K. Czornak, D. Piekutowska-Abramczuk, E. Ciara, M. Borucka-Mankiewicz, P. Kowalski, M. Gajdulewicz, K. Spodar, K. Chrzanowska, M. Krajewska-Walasek;

Children's Memorial Health Institute, Warsaw, Poland.

Coffin-Lowry syndrome (CLS, MIM#303600) is an X-linked semidominant disorder. Cardinal features in males include mental retardation, facial dysmorphism, digital tapering, and progressive spinal deformity. In females the intensity of symptoms is variable. The estimated frequency is 1:50000 - 1:100000 births. CLS is caused in the majority of cases by mutations of the *RSK2* gene (*RPS6KA3*), which maps to Xp22.2 and is split into 22 exons. The gene encodes for a serine/threonine kinase, RSK2, acting at the distal end of the MAPK/ERK signaling pathway.

We present two Polish patients with the clinical diagnosis of Coffin-Lowry syndrome confirmed on the molecular level. Patient 1 is a boy aged 4 years. He has moderate mental retardation, hypotonia, facial dysmorphism, digital tapering, dental anomalies, spinal deformities, seizure and cataplexia. Molecular analysis of the *RSK2* gene revealed the presence of a substitution G to A in the first position of intron 10 (c.845+1G>A). The mutation appeared *de novo*. Besides, a polymorphism in exon 10 (c.798C>A) was identified. Patient 2 is a girl aged 9 years. She presents moderate intellectual disability, hypotonia, a characteristic facial appearance, hands typical of CLS, dental anomalies. The rather severe symptoms of the female may be due to the presence of *de novo* one-nucleotide deletion (c.896delT) in exon 11 resulting in loss of important RSK2 domains, as well as observed non-random X-chromosome inactivation.

The study was supported by Polish Ministry of Science Project 0624/P01/2006/31 (N40103131/0624).

MECP2 gene R167W mutation in a girl with autism/Rett-like syndrome and her mildly mentally retarded mother

E. Popowska¹, A. Tylki-Szymanska¹, D. Jurkiewicz¹, M. Borucka-Mankiewicz¹, K. Czornak¹, E. Ciara¹, A. Kloska², P. Kowalski¹, D. Piekutowska-Abramczuk¹, M. Olszaniecka¹, K. Chrzanowska¹, M. Krajewska-Walasek¹;

¹The Children's Memorial Health Institute, Warsaw, Poland, ²University of Gdansk, Gdansk, Poland.

Rett syndrome (RTT) is a neurodevelopmental disorder affecting almost exclusively females. The disease is caused by mutations in the X-linked *MECP2* gene, encoding methyl CpG binding protein. Most cases of RTT are sporadic with the majority (99.5%) being caused by *de novo* mutation on the paternal copy of *MECP2*. Familial cases and clinically atypical cases (RTT variants, like preserved speech variant, congenital RTT) show a lower incidence of *MECP2* mutations. Recently *MECP2* mutations in males with severe encephalopathy or mental retardation have been described.

We report identification of *MECP2* gene R167W mutation in a 3 year old girl and her mother.

The girl presents unusual behavioral features: anxiety, emotional and eye contact disturbances, stereotypes (jigging, running, head shaking), sleep and awake breathing rhythm and peripheral circulation disturbances, stretching and paroxysmal cry or clamor. Besides, normal somatic and mental development with preserved speech and voluntary hand use is observed. Mother of the girl, obese woman with development on the edge of normal, presented in her infancy mild psychomotor retardation, hypoactivity, somnolence and lack of criticism. Currently she presents essential tremor and she is still clumsy and talk active. The identified R167W mutation results in substitution of tryptophan in place of arginine-167, situated in the region between MBD and TRD. The mutation occurred on the grandmaternal allele and was *de novo* in the mother. *MECP2* R167W mutation has been previously found in three-generation family with four non-specific X-linked mentally retarded males and unaffected mothers.

The study was supported by MNiSW Project 2P05A12129.

OPHN1 gene (MIM 300127) mutations are a well established cause of a distinctive phenotype characterized by mental retardation of variable degree, epilepsy, rostral ventricular enlargement and cerebellar hypoplasia. Duplication of this region has never been reported.

We describe the first familial case of a Xq12q13.1 duplication of 800 kb encompassing the *OPHN1* gene, detected by array-CGH. The proband phenotype is characterized by facial dysmorphisms and severe mental retardation associated to specific cerebral anomalies.

Our proband's phenotype never prompted the hypothesis of oligophrenin mutation. This might be due to the specific facial and NMR appearance of *OPHN1* mutated patients (deletions and point mutations). These patients are characterized by long face, wide forehead, deeply set eyes, hypothelorism, long tubular nose, short philtrum and prominent chin. The most striking hallmark shared by *OPHN-1* patients on NMR is posterior vermian dysplasia, including lobules VI and VII (declive, folium, and tuber) partial agenesis associated with a supplementary right vermian parasagittal cleft and a mild cerebellar hemispheric dysgenesis. Instead our patient showed an altered signal in the supratentorial white matter that was more pronounced at the inferior and posterior cerebral hemispheres. Lesions were also described in the pontine tegmentum, corpus callosum, posterior arms of inner capsules and central portions of pallidi nuclei.

To our knowledge this is the first report of a clinical phenotype associated with duplication of Xp12.

¹Programa de Medicina Molecular i Genètica, 08035 barcelona, Spain, ²Hospital Vall d'Hebrón, Barcelona, Spain, ³Servei de neuropediatria. Hospital Vall d'Hebrón, 08035 barcelona, Spain, ⁴CIBERER. Servei de Bioquímica i Genètica Molecular, Barcelona, Spain, ⁵Hospital Clínic Barcelona, Barcelona, Spain, ⁶Servei de Bioquímica i Genètica Molecular., Barcelona, Spain.

We report a new family with familiar mental retardation and seizures with few dysmorphic facial features.

The proband was born at term after an uncomplicated pregnancy. The boy was the first child from healthy non-consanguineous parents. At the age of 3 years he was referred to medical geneticists for diagnostic advice. The facial appearance was slightly dysmorphic with deeply set eyes, strabismus, a large philtrum, retrognathia and prominent incisors. He had generalised hypotonia, delayed psychomotor development (walking at 3 years), he had no language (he only say few words at 3 years) and significantly mentally retarded. He developed a first epileptic insult during the second year. The metabolic screening and the electroencephalogram were normal. His karyotype was normal, 46,XY.

On examination with 11 years old he had a brain magnetic resonance imaging, it showed large ventricles without hydrocephalus, a large cisterna magna with cerebellar hypoplasia.

He had a maternal uncle and maternal great-uncle with mental retard and facial appearance similar. His maternal uncle had a test for fragile X negative.

There was a syndromic X-linked mental retardation with cerebellar hypoplasia. We reevaluated the case with 11 years old and analyzed by Multiple Ligation PCR Amplification (MLPA) in the proband and his mother, but it was not possible in the maternal uncle, with deletion in the exons 3, 4, 5 and 6 of the oligophrenin-1 gene (*OPHN1* gene).

New Rett syndrome and Fragile X syndrome clinical scales for genotype-phenotype correlation studies

V. Y. Voïnova¹, I. Y. Iourov¹, S. A. Tushkevich², P. V. Novikov³, Y. B. Yurov¹, S. G. Vorsanova²;

¹Mental Health Research Centre RAMS, Moscow, Russian Federation, ²Moscow University of Psychology and Education, Moscow, Russian Federation, ³Institute of Pediatrics and Children's Surgery, Moscow, Russian Federation.

To investigate genotype-phenotype correlations new clinical scales were developed for providing quantitative measurements of 23 Rett syndrome (RTT) and 24 Fragile X syndrome (FXS) phenotypic signs. Scores for separate symptoms summarized to get a total phenotypic severity score.

Correlations between MECP2 mutation type, position and phenotype severity were found in 54 RTT patients. There were significant differences with more severe phenotypic manifestations in patients with truncating mutations compared with those with missense mutations in the phenotype severity scores ($P < 0.001$, Mann-Whitney test) and phenotypic manifestations scores including hand dyspraxia, impairment of oro-motor functions ($P < 0.01$), emotional communication, expressive speech, static functions, walking, head growth and foot size ($P < 0.05$). Analysis of phenotype severity dependence on mutation position showed that the most severe phenotypes were observed in patients with R168X, R255X, R270X mutations.

The FXS clinical scale has applied to demonstrate positive correlation ($R^2 = 0.7662$) between the total phenotype severity scores in 22 patients with FXS and percent of cells containing fragile chromosome X by an approach previously described (Vorsanova et al, 1998).

These results support genotype-phenotype correlations in RTT and FXS and illustrate both scales applicable for estimation of phenotype severity.

P01.084

X-linked mental retardation with pachygyria, marfanoid habitus and behavioral problems: a new syndrome?

C. du Souich, Y. Jingyi, T. Y. Oh, C. F. Boerkoel, M. I. Van Allen; University of British Columbia, Vancouver, BC, Canada.

X-linked mental retardation (XLMR) is a common cause of inherited mental retardation in males. To date, a total of 215 XLMR conditions have been reported in the literature. We report a 5 generation family segregating an X-linked disorder in which 7 affected males present with distinctive physical features, seizures, mental retardation and behavioral problems. The proband is a 17-year-old man with severe mental retardation, microcephaly, short stature, a marfanoid habitus, seizures, congenital heart defect, pachygyria, irritability, and aggression. Carrier females are physically unremarkable but have aggressive behavior and poor interpersonal skills. Results of laboratory investigations include a normal karyotype, *FMR1* triplet repeat size, serum electrolytes, thyroid function, *MED12* sequencing and biochemical investigations. Linkage analysis localized the disease locus in this family to Xq28. Phenotypically, our proband does not resemble any of the reported XLMR syndromes mapped to this region. Candidate genes in this region are presently being screened by direct sequencing. To our knowledge, the combination of phenotypic features seen in our proband has not been previously reported in any of the XLMR syndromes already mapped to our candidate region.

P01.085

Xq duplication in a male with mental retardation, facial dysmorphisms, broad thorax, genital anomalies and short stature

D. Lugtenberg, A. P. M. de Brouwer, A. R. Oudakker, R. Pfundt, B. C. J. Hamel, H. van Bokhoven, E. M. H. F. Bongers; Dept of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

In a male patient with severe mental retardation (MR), a typical facial appearance, a broad thorax, genital anomalies and a disproportionate short stature, a *de novo* Xq13.2q21.1 duplication was identified by array CGH. This 7 Mb duplication encompasses 23 known genes, including the XLMR genes *ATRX* and *SLC16A2*. The phenotype of this patient is similar to the phenotype described in more than ten previously reported cases with overlapping Xq duplications, encompassing MR, short stature, and genital abnormalities comprising cryptorchidism and/or small penis. By re-evaluation of the facial phenotype of these patients and the present patient we observed a similar facial appearance, comprising ptosis, midface hypoplasia with down-slanting palpebral fissures, small mouth, down-turned corners of the mouth and hypotonic facies. The minimal overlapping duplication interval includes the *ATRX* gene, which is known to carry inactivating mutations in patients with alpha-thalassemia/mental retardation syndrome (ATR-X). Detailed comparison of the clinical characteristics and the function of the genes located in the commonly duplicated regions of these patients and the phenotype of animal models with *ATRX* overexpression previously described in literature led us to the hypothesis that an in-

creased dosage of *ATRX* and perhaps other genes are involved in the pathogenic mechanism of this XLMR phenotype.

In conclusion, the association of MR, facial dysmorphisms, broad thorax, genital anomalies, and short stature might contribute to the recognition of male patients with a microduplication encompassing the entire *ATRX* gene. We suggest that male patients with a similar phenotype should be screened for duplications of the *ATRX* gene.

P01.086

Functional disomy Xqter du to duplication Mecp2 gene

A. A. Aboura¹, M. Mathieu², S. Drunat¹, A. Tabet¹, C. Dupont¹, B. Benzacken¹, F. Guimont¹, A. Verloes¹;

¹Robert debré, Bd Sérurier, France, ²Département de Génétique C.H.U nord, Amiens, France.

We report on three patients : 2 boys and a girl, with an additional Xq28 chromosome segment translocated onto 5pter, Ypter, and 13p. The karyotypes were 46,XY,der(5)t(X;5)(q28;pter) 46,X,der(Y)t(X;Y)(q28;pter) and 46,XX,der(13)t(X;13)(q28;p10). In all cases, the de novo cryptic unbalanced X-autosome translocation and Xq-Yp translocation resulted in a Xq28 chromosome functional disomy by duplication of *Mecp2* (methyl-CpG binding protein 2) gene. In all, 20 patients carrying a Xq28 functional disomy could be selected from the literature. Common craniofacial findings include microcephaly, a small mouth. Most patients have prenatal onset growth retardation. Postnatal growth retardation was present in all cases. Major axial hypotonia is constant and usually present at birth. Severe constipation frequently reported. Severe developmental delay is observed in most patients. Functional disomy for the Xq28 chromosome region yields a recognizable phenotype including distinctive facial features, major axial hypotonia, severe feeding difficulties, abnormal genitalia and proneness to infection (pneumonia). Severe developmental delay is almost constant. A clinically oriented FISH study using subtelomeric probes

P01.087

Functional characterization of the X-linked mental retardation gene *ACSL4*

I. Meloni¹, V. Parri¹, R. De Filippis¹, F. Ariani¹, M. Bruttini¹, I. Longo¹, F. Mari¹, C. G. Dott^{2,3}, A. Renieri¹;

¹Medical Genetics, Siena, Italy, ²Department of Human Genetics, University of Leuven Medical School, Leuven, Belgium, ³Department of Molecular and Developmental Genetics, Flanders Institute of Biotechnology (VIB 11), Leuven, Belgium.

ACSL4 is a gene involved in non-syndromic X-linked mental retardation. It encodes for a ubiquitous protein that adds Coenzyme-A to long-chain fatty acids, especially arachidonic acid; it presents a brain-specific isoform resulting from alternative splicing and containing 41 additional N-terminal aminoacids. In order to define how *ACSL4* absence causes mental retardation, we have characterized the protein and analyzed the consequences of its absence in neurons. Our data suggest that *ACSL4* is located in endoplasmic reticulum. Quantitative mRNA expression analyses indicate that *ACSL4* is expressed at higher levels in fetal than in adult brain. Moreover, differential expression of the alternative transcripts in different adult brain regions has been observed. Protein analysis has confirmed this variability and revealed a lack of linear correlation between mRNA and protein levels, suggesting the presence of post-transcriptional regulatory mechanisms. To characterize *ACSL4* function in neurons we have silenced the gene by siRNA technology in rat primary hippocampal neurons. Our data suggest that *ACSL4* might be important for dendritic spine formation and/or maintenance. In fact, *ACSL4* absence seems to cause a significant reduction in dendritic spine density and alteration in spine distribution among different morphological categories. Moreover, abnormal actin accumulation has been observed in a significant percentage of cells. This last finding suggests that *ACSL4* might directly or indirectly influence actin cytoskeleton organization; it could be thus hypothesized that the observed spine anomalies are a secondary effect of an abnormal actin organization due to *ACSL4* absence. Additional experiments will be necessary in order to confirm these hypotheses.

P01.088

Molecular characterization by aCGH of a 3,8 Mb duplication at Xq26.3 in a male with mental retardation

I. Madrigal¹, M. Fernández-Burriel², L. Rodríguez-Revenga¹, L. Armengol³, X. Estivil⁴, M. Milà⁴;

¹Centre for Biomedical Research on Rare Diseases (CIBERER), Barcelona, Spain, ²Unidad de Investigación. Hospital de Mérida., Badajoz, Spain, ³Genes and Disease Programme. CRG. Barcelona, Barcelona, Spain, ⁴Biochemistry and Molecular Genetics Department, Hospital Clínic and IDIBAPS, Barcelona, Spain.

Males with duplications in the distal long arm of the X chromosome are rare and in most cases are inherited from a carrier phenotypically normal. We report the clinical and molecular characterization of a Xq26.3 duplication in a male and his brother affected by MR. Chromosome analysis was normal and Multiplex Ligation Probe Amplification (MLPA) analysis detected a duplication of the *ARHGEF6* gene inherited from a carrier mother. Both affected brothers presented moderate mental retardation and displayed dysmorphic features. Further characterization of the duplication by array CGH and FISH experiments with specific BAC probes, revealed a deletion of 28 contiguous BAC clones, spanning a region of 3,8 Mb in Xq26.3. X-inactivation studies in the mother showed a complete skewed X-inactivation (100/0) inactivating the X-chromosome inherited by the patient. Among the 20 genes included within the duplicated region we discuss the implication of *ARHGEF6*, *PHF6* and *HPRT1* in the phenotype of the patient. Mutations or deletions in these three genes are responsible for syndromic and non-syndromic forms of mental retardation. Nowadays high-resolution technologies such as array CGH allow the detection of copy number aberrations in patients with MR. The characterization of these cryptic rearrangements is of clinical importance in order to provide a genetic counselling in carrier women for future pregnancies.

Fragile X syndrome and Xp deletion in a girl with autism and mental retardation

A. Vazna, Z. Musova, D. Novotna, M. Vlckova, M. Havlicovicova, Z. Sedlacek; Department of Biology and Medical Genetics, Charles University 2nd Medical School and University Hospital Motol, Prague, Czech Republic.

Autism is a complex behavioural disorder characterised by social and communication impairments, and restricted repetitive and stereotyped behaviour. It is often associated with mental retardation. Genetic factors play an important role in the aetiology of autism - heritability reaches 90 %, one of the highest among psychiatric disorders. The inheritance is most likely multifactorial with genetic heterogeneity and complex interactions. Despite of all efforts, until now the success in finding of autism susceptibility genes has been limited. Cytogenetic abnormalities and single-gene defects often associated with autism (e.g. the fragile X syndrome) together account for about 10% of cases. However, these are the only cases where diagnostics and exact risk assessment are possible. We present a 7-year-old girl with atypical autism, mental retardation, hyperactivity, developmental delay, facial dysmorphism and overweight. Her family showed no history of mental retardation or autism, but tremor was apparent from sixty years of age in her maternal grandfather. DNA testing of the patient revealed full mutation (460 CGG repeats) in the *FMR1* gene, consistent with the diagnosis of fragile X syndrome. In addition, cytogenetic analysis detected a large deletion on chromosome Xp. We attempted to define in more detail the breakpoints of the deletion and the inheritance of both genetic defects in the family. Microarray CGH mapped the 17.5 Mb deletion to Xp22.11-p22.31. The deleted segment harboured almost 100 protein-coding genes. The distal breakpoint of the deletion was located close to *NLGN4*, a gene implicated in autism and mental retardation. Supported by grants NR/9457-3 and MZO00064203

P01.090**Fragile X mosaic male detected by PCR/MS-MLPA**

T. Todorov¹, A. Todorova¹, A. Kirov², R. Carvalho³, I. Boneva⁴, V. Mitev¹;

¹Department of Chemistry and Biochemistry, Medical University, Sofia, Bulgaria,

²Genetic Medico-Diagnostic Laboratory Genica, Sofia, Bulgaria, ³MRC-Holland bv, Amsterdam, The Netherlands, ⁴Paediatric Hospital, Medical University, Sofia, Bulgaria.

We report on a fragile X syndrome (FXS) mosaic male full mutation/normal allele, detected by a combination of PCR and methylation-specific multiplex ligation-dependent probe amplification (MS-MLPA). This analysis provides a powerful, fast, cheap and easy to perform diagnostic approach for FXS. This is the first report on successful application of MS-MLPA for FXS diagnostic purposes. The combination of PCR and MS-MLPA gives the possibility in a few steps to detect normal *FMR1* alleles, to prognose the expanded ones, to assess the CpG islands methylation, as well as to determine copy number changes like large deletions/duplications, not only along the *FMR1*, but also along the *FMR2* gene.

Our PCR results showed one allele of 29 ± 1 repeats in the mother and one allele in the affected boy, but three repeats larger - 32 ± 1 repeats. The MS-MLPA results in the patient showed hypermethylated full mutation pattern in comparison to the normal control. The MS-MLPA data calculations were performed in Excel.

In our opinion, the mosaic pattern of normal size/full mutation alleles was a result from inheritance of a maternal unstable premuted allele. Most logical mechanism for normal size allele generation in our mosaic case is a deletion of a portion of the full mutation, restricted to the CGG repeat itself, as the primers for PCR were designed in the repeat flanking regions. The reported patient demonstrates atypical mild clinical manifestation of the disease, which might be due to the presence of a normal size allele in a large percentage of the patient's cells.

P01.091**No evidence for skewed X-inactivation in fragile X syndrome premutation carriers**

C. Berenguer^{1,2}, L. Rodriguez-Reventa³, I. Madrigal¹, C. Badenas¹, M. Milà¹;

¹Biochemistry and Molecular Genetics Department, Hospital Clínic, Barcelona, Spain, ²Fundació Clínic, Barcelona, Spain, ³Centre for Biomedical Research on Rare Diseases (CIBERER), ISCIII, Barcelona, Spain.

X-Chromosome inactivation (XCI) is the mechanism by which gene dosage equivalence is achieved between female (XX) and male (XY) mammals. In the general female population, the X-inactivation process is random, and therefore XCI ratios have a normal distribution (with average of 50:50) with only a small percentage of females (5-8%) showing a skewed X-inactivation ratio (>90:10). Fragile X syndrome (FXS) premutation carriers (55-200 CGG repeats) do not present FXS symptoms but it has been shown that they have a higher risk of developing premature ovarian failure (POF) and/or fragile X associated tremor/ataxia syndrome (FXTAS). About 20% of the FXS female premutation carriers present POF and around 15% FXTAS. In order to evaluate if these pathologies are associated with skewed XCI patterns, we have studied the X-inactivation pattern in 270 FXS females carriers (41 POF, 2 FXTAS, 3 POF and FXTAS, and 224 no POF no FXTAS). Results showed that FXS premutation female carriers have a normal distribution and that there is no correlation with the CGG repeat number. On the basis of these observations we conclude that FXS female premutation carriers with or without POF and/or FXTAS do not present skewed X-inactivation and therefore, other molecular or environmental factors may predispose to these conditions.

P01.092**High conservation of the 3'UTR of *FMR1* at potential microRNA target sites in patients with fragile X syndrome premutation**

L. Rodriguez-Reventa¹, M. Santos^{2,3}, I. Madrigal¹, C. Berenguer^{2,3}, X. Estivill^{4,5,6}, M. Milà³;

¹CIBERER, Barcelona, Spain, ²Fundació Clínic, Barcelona, Spain, ³Hospital Clínic, Barcelona, Spain, ⁴Center for Genomic Regulation, Barcelona, Spain, ⁵National Genotyping Center, Barcelona, Spain, ⁶Pompeu Fabra University, Barcelona, Spain.

Fragile X syndrome premutation condition consists of an intermediate CGG repeat expansion (55-200 repeats) at the 5'UTR of the *FMR1* gene. In the premutation range, *FMR1* mRNA levels are increased

whereas the amounts of FMRP are slightly reduced compared with the control population, suggesting that posttranscriptional regulation of *FMR1* could be involved in these disorders. MicroRNAs act as regulators of gene expression binding to their target sites located at the 3'UTR in a high number of protein-coding genes inducing cleavage or repression of translation. We have screened the 3'UTR of *FMR1* in 40 Mediterranean premutation carriers and 14 control subjects with no expansion in the *FMR1* gene. Overall, the *FMR1* 3'UTR region appears as a high conserved region, not only in humans, but also in other species. Our study excludes changes in the *FMR1* 3'UTR in the premuted patients, ruling out a possible role of microRNA target sites in *FMR1* regulation in permuted phenotypes. P01.093**Molecular and epigenetic characterization of *FMR1* unmethylated full mutation cell lines**

E. Tabolacci¹, M. Accadia¹, L. Borrelli¹, M. Moscarda¹, F. Zalfa², C. Bagnò², U. Moscato³, P. Chiurazzi¹, G. Neri¹;

¹Institute of Medical Genetics, Rome, Italy, ²Department of Biology, "Tor Vergata" University, Rome, Italy, ³Institute of Hygiene, Catholic University, Rome, Italy.

Fragile X syndrome (FXS) is mostly caused by expansion and subsequent methylation of the CGG repeat at the 5' UTR of the *FMR1* gene (methylated full mutation). Individuals of normal intelligence, carriers of a *FMR1* unmethylated full mutation, represent rare exceptions. We previously performed a molecular and epigenetic analysis of a lymphoblastoid cell line (code 5106), derived from one of these individuals. Recently, two apparently normal individuals with an unmethylated full mutation, belonging to distinct FXS families, were identified. From each subject (named DPM and MA) three independent lymphoblastoid cell lines and a fibroblast culture (from MA) were established. In accordance with our previous findings, these cell lines showed normal transcription and reduced translation of the *FMR1* gene, compared to normal controls. Epigenetic analysis of the *FMR1* locus demonstrated lack of DNA methylation and the methylation pattern of lysines 4 and 27 on histone H3 was also similar to that of a normal control, in accordance with the normal transcription and consistent with an euchromatic configuration. On the other hand, the H3 and H4 acetylation and the methylation of lysine 9 on histone H3 was similar to that of a typical FXS cell line. Comparative analysis of these rare unmethylated full mutation cell lines demonstrates remarkable structural, functional and epigenetic consistency, suggesting a common mechanism of origin, genetically determined. The discovery of such mechanism may be important in view of therapeutic attempts to convert a methylated to unmethylated full mutation, restoring the expression of the *FMR1* gene.

P01.094**Analysis of fragile-X premutation and grey zone in paediatric patients**

INTRODUCTION: The number of CGG repeats defines the state of premutation or full mutation in fragile-X syndrome (FXS). In childhood, full mutation has a characteristic behaviour and physical phenotype. The adult carriers of the premutation can develop a progressive neurodegenerative syndrome (FXTAS). Although the clinical characteristics of the premutation and grey-zone in the childhood are less well-known, clinical experience and case reports suggest that child with premutation and grey-zone alleles may have similar clinical features than those with the full mutation.

PATIENTS AND METHODS: Determination of the number of CGG repeats in samples received in our unit since 2005 for the FXS screening.

Detailed Clinical and cognitive evaluation in a series of 13 children (9 boys and 4 girls), born between 1989 and 2000, with clinical suspect of FXS.

RESULTS: From the 1092 samples analyzed, 7% (77 cases) we detected alleles with 35 to 160 CGG repeats. We haven't detected any alleles in the permuted or grey-zone in the 91 control chromosomes analyzed. The 13 children evaluated clinically have a cognitive-behavioural phenotype suggestive of full mutation and we detected alleles

between 35 to 53 repeats. Clinical findings in this group of patients will be commented.

CONCLUSIONS: We have detected a big number of alleles in the pre-mutation and grey zone in the population analyzed. Large independent samples are required to confirm our impression that the grey-zone and pre-mutation in FXS may be associated with important developmental disabilities and to establish the genotype-phenotype relation in children with this range of repeats.

P01.095

Is FRAXE over-represented among Newfoundland children with cognitive impairment?

A. Dohey¹, M. Crowley², R. Green¹, B. Younghusband¹, B. Fernandez¹; ¹Memorial University of Newfoundland, St. John's, NL, Canada, ²Provincial Medical Genetics Program, St. John's, NL, Canada.

Fragile X syndrome due to mutations in the *FMR1* gene is the commonest cause of inherited mental retardation. In contrast, mutations in *FMR2* (FRAXE) are a much rarer cause of MR. In Newfoundland, only one family segregating an *FMR1* expansion has been identified, but 3 males from 2 families with FRAXE disease have been identified. In this study, I reviewed the charts of all boys seen from 1994-2004 who had negative *FMR1* testing. Participants were recruited using the following criteria - males with developmental delay, between the ages of 2 and 19 and without a specific diagnosis. 139 of 378 individuals met the inclusion criteria, 95 (68%) consented. DNA was collected and amplified using previous published primers. 93 samples were in the normal FRAXE range, 2 failed to amplify. These 2 samples are being further studied as possible FRAXE mutations. FRAXE alleles ranged from 4 to 23 repeats with the most common allele size being 13. A second part of the study describes the previously identified FRAXE families: One proband has an *FMR2* expansion of 620 repeats. He has a FSIQ of 54 and is dysmorphic with facial features reminiscent of FRAXA syndrome. He has a non-dysmorphic first cousin with a learning disability and an expansion of 200 repeats. His mother and maternal aunt carry pre-mutations of 120 and 87 repeats respectively. The second proband is a non-dysmorphic 11-year-old with attention deficit disorder and a FSIQ in the 80's. He has a mosaic *FMR2* expansion of 120-820 repeats.

P01.096

Homozygous R316Q mutation in obesity-associated FTO gene causes a novel polymalformative syndrome

S. Boissel^{1*}, O. Reish^{2*}, F. Molinari¹, H. Etchevers¹, A. Munnich¹, L. Colleaux¹; ¹INSERM U781 and département de Génétique, Université Paris Descartes, Paris, France, ²Department of Medical Genetics, Assaf Harofeh * Equally contributors, Israel.

We report on the analysis of a large inbred family including 8 affected children presenting a newly described syndrome characterized by intra-uterine growth retardation, characteristic facies, cleft palate, cardiac and genital abnormalities, central nervous defects with delayed myelination, severe hypertonicity and premature death. Extensive workup was normal.

Since the pedigree suggested an autosomal recessive mode of inheritance, autozygosity mapping was performed identifying a unique region of shared homozygosity of 6,5 Mb on 16q12 between D16S411 and D16S3140 markers. We identified a homozygous missense mutation within *FTO* gene (c.947G>A, p.R316Q), which altered a highly conserved residue, co-segregated with the disease and was not found in 400 control alleles.

While recent studies have revealed a strong association between intronic variants in *FTO* gene and childhood and adult obesity, the pathophysiological mechanism underlying the phenotype observed in our family remains questionable. Noticeably, *in-situ* hybridization experiments on human embryos showed predominant *FTO* expression in tissues affected in patients (central nervous system, heart and frontonasal prominence).

Interestingly, a recent study showed that *FTO* encodes a 2-oxoglutarate-dependent nucleic acid demethylase likely involved in toxic DNA and/or RNA lesions repair. Moreover, a R316A substitution completely abolishes *Fto* activity *in-vitro*. We consequently propose that the patients' mutation is a null mutation and that their phenotype is the consequence of defective DNA repair. Mass spectrometry assays and cellular sensitivity to methylating agents measurements are underway to

validate this hypothesis.

In conclusion, our data suggest that homozygous *FTO* null mutations are responsible for a hitherto undescribed multiple congenital anomaly syndrome.

P01.097

Studies on *FMR1* gene pre-mutations, causing Fragile X tremor ataxia syndrome (FXTAS) in Polish ataxia patients of unknown etiology and in controls

M. Rajkiewicz, A. Sulek-Piatkowska, E. Zdzienicka, W. Krysa, W. Szirkowicz, E. Fidzińska, J. Zaremba;

Institute of Psychiatry and Neurology, Warsaw, Poland.

Fragile X tremor ataxia syndrome (FXTAS) is a late onset (≥ 50) syndrome, observed generally in male patients, caused by pre-mutation (range 55 - 200 CGG) in *FMR1* gene (Hagerman 2001). The main symptoms are: intention tremor, ataxia, parkinsonism, and cognitive decline. Moreover the MRI shows the presence of white matter lesions of the middle cerebellar peduncles.

The aim of our study was to look for FXTAS in a large group of Polish patients affected with ataxia of unknown origin and in controls.

The studied group comprised 176 male patients with sporadic cerebellar ataxia, with/without other neurological symptoms (age of onset ≥ 50 years), in whom molecular tests carried out previously, excluded SCA1,2,3,6,7,8,12,17 and DRPLA.

The group of controls was composed of 516 healthy subjects. The number of CGG repeats was determined by comparison of PCR product size with size standard after electrophoresis on ABI PRISM377 in 4% denaturing gel.

In the ataxia group we found no pre-mutation alleles, and the largest allele found contained 52 CGG repeats.

The *FMR1* normal allele obtained for the control group ranged from 14 to 56 CGG repeats, with the most frequent 29 CGG alleles.

These results indicate that Polish control group is characterized by similar *FMR1* gene polymorphism as other populations. And since pre-mutation in the patients group was not found, we think that FXTAS among patients with sporadic ataxia is less frequent than we expected; we plan to enlarge the studied group by including patients with other neurological symptoms, such as parkinsonism.

P01.098

Frequency of fragile X tremor ataxia syndrome in fragile X syndrome families

M. Milà^{1,2}, C. Berenguer^{3,1}, I. Madrigal⁴, J. Kulisevsky⁵, J. Pagonabarraga⁵, B. Gomez⁵, L. Rodriguez-Revena⁴;

¹Hospital Clinic, Barcelona, Spain, ²IDIBAPS, Barcelona, Spain, ³Fundació Cínic, Barcelona, Spain, ⁴CIBERER, Barcelona, Spain, ⁵Hospital Sant Pau, Barcelona, Spain.

Fragile X syndrome (FXS), which is caused by a CGG triplet expansion in the first exon of *FMR1* gene, is the leading cause of familial mental retardation. Premutated individuals (55-200 CGG) do not present FXS symptoms, but approximately one third of them can present other manifestations such as a late onset ataxia /tremor syndrome (called FXTAS) or premature ovarian failure (POF). In order to determine the presence of FXTAS among FXS grandparents, we have contacted by telephone with 92 families. We have identified 24 pre-mutated carriers (belonging to 18 FXS families) showing FXTAS symptoms. These results evidence that FXTAS frequency among FXS families is around 20%. The youngest individual is 66 and the oldest 82 y.o. We are now evaluating these patients psychologically, neurological and with magnetic resonance imaging. Molecular studies confirm a slight reduction of FMRP protein and increased levels of mRNA in these patients (x2-x5 folds). The description of associated pathologies (FXTAS and POF) to pre-mutation carriers has modified genetic counseling for FXS, these two disorders and their consequences have to be taken into account by genetic counselor.

P01.099

Deletion of MAOA and MAOB in a male patient causes severe developmental delay, intermittent hypotonia and stereotyped hand movements.

A. Whibley¹, L. Willatt¹, J. Dore², L. Gaunt², P. Tarpey³, M. Stratton³, D. Donna², F. Raymond¹, I. GOLD¹;

¹Cambridge Institute for Medical Research, Cambridge, United Kingdom, ²Regional Genetics Service, St. Mary's Hospital, Manchester, United Kingdom, ³Sanger Institute, Hinxton, Cambridge, United Kingdom.

The monoamine oxidases MAOA and MAOB are isoenzymes which catalyse the oxidative deamination of biogenic amines, with substrates including the neurotransmitters norepinephrine, serotonin and dopamine. A number of behavioural traits, such as aggressive and antisocial behaviour, and psychiatric conditions, such as schizophrenia and bipolar disorder, have been associated with MAOA/B dysfunction and genetic variation at these loci.

The MAOA and MAOB genes occur in tandem but in opposite orientations on Xp11.23. The two genes share 70% identity at the amino acid level and exhibit identical organisation of their 15 exons. Previous reports of MAOA and MAOB deletions have encompassed the adjacent NDP gene. Mutations in NDP cause Norrie disease, a disorder characterised by blindness, progressive sensorineural deafness and, frequently, mental retardation. Genotype-phenotype correlations in Norrie disease suggest that deletions of NDP which also extend to the MAOA/B genes result in a more severe neurological phenotype. However, the phenotypic contribution of MAOA/B gene disruption is difficult to dissect in this context. Here we report an individual with a submicroscopic deletion which encompasses only the MAOA and MAOB genes. The 246kb deletion, which includes exons 2-15 of MAOA and the entire coding region of MAOB, was detected by high-resolution long oligonucleotide X chromosome array comparative genomic hybridisation, and confirmed by fluorescence in situ hybridisation. The phenotype of the affected boy was severe mental retardation with unusual hand posturing. The obligate mother of the affected boy was clinically normal.

P01.100

Raised T3 levels and mutations in MCT8(SLC16A2) cause X-linked cerebral palsy and mental retardation

L. Raymond¹, A. Whibley¹, S. Price², E. Rosser³, N. Rahman⁴, S. Holder⁶, F. Stewart⁶, P. Tarpey⁷, A. Futreal⁷, M. Stratton⁷, I. GOLD¹;

¹Cambridge Institute for Medical Research, Cambridge, United Kingdom, ²Oxford Regional Genetics Service, Oxford, United Kingdom, ³Institute of Child Health, University of London, London, United Kingdom, ⁴Institute for Cancer Research, London, United Kingdom, ⁵Northwick Park Hospital, London, United Kingdom, ⁶Northern Ireland Regional Genetics Centre, Belfast, United Kingdom, ⁷Sanger Institute, Hinxton, Cambridge, United Kingdom.

Mutations or whole gene deletions of MCT8 (SLC16A2) were identified in males with raised serum T3 concentrations and severe psychomotor retardation. The associated phenotype prompted us to screen MCT8(SLC16A2) in males with X-linked mental retardation with spastic quadriplegia and those with XLMR alone. We have identified 3 mutations (1018delC, A224T, R271H) and 2 single exon deletions (exon 1 and exon 6) in families with X-linked spastic quadriplegia and severe mental retardation but did not find any mutations in >300 families where mental retardation alone was the presenting feature.

Prior to identification of the mutation all cases were all described as severe cerebral palsy. Males present with severe hypotonia at birth and develop a severe spastic quadriplegia in all cases within the first year of life that remained static once it had evolved. Brain MRI in one affected individual was normal. None of the affected individuals were able to walk independently or had intelligible speech and all needed full-time care either in institutions or at home. Difficulties with weight gain and difficulty feeding are consistent features. Thyroid hormone profiles were performed in all families once sequence variants in the MCT8(SLC16A2) gene were identified. Carrier females were found to have free T3 levels at the upper limit of normal between 7.0 and 7.5 (3.0-7.5) pmol/l whereas the affected males were found to have raised T3 levels 9.6 - 13.7 (3.0-7.5) pmol/l. Free T4 and TSH levels were within the normal range in all affected males and carrier females.

P01.101

Duplications of the MECP2 gene region and severe mental retardation in males

R. I. Lewis, L. P. Lazarou, S. Morgan, H. L. Archer, S. J. Davies, A. J. Clarke, R. Butler;

Institute of Medical Genetics, Cardiff, United Kingdom.

Mutations in the MECP2 gene are associated with Rett syndrome in females and a spectrum of neurological disorders in males, from mild mental retardation to severe neonatal encephalopathy. More recently, duplications of the MECP2 gene have been described in males with severe mental retardation and a range of other progressive neurological symptoms. Using the multiplex ligation-dependent probe amplification (MLPA) assay, we have screened 20 male patients who have been specifically referred for MECP2 gene duplication analysis, with symptoms including severe mental retardation, epilepsy and an "Angelman like" phenotype. Duplications involving the MECP2 gene were detected in five cases (25%), four of these being in unrelated males and one in a similarly affected brother. Two of the unrelated cases show complex rearrangements of the MECP2 gene. These results and others that have been published recently, show rearrangement of the MECP2 gene to be a relatively common mutation mechanism in males. This redefines the testing criteria for referral for MECP2 analysis. We will attempt to further determine the clinical phenotype for males with MECP2 gene duplications, to help improve service provision.

P01.102

A Study on the Most Common Genes Involvement among Iranian Families Who Have RETT Syndrome

M. Dehghan Manshadi, M. Rostami, T. Majidzadeh, M. SeydHasani, M. Houshmand;

Special Medical Center, Tehran, Islamic Republic of Iran.

MECP2-related disorders include classic Rett syndrome, variant or atypical Rett syndrome, and mild learning disabilities in females and neonatal encephalopathy and mental retardation syndromes in males. Classic Rett syndrome is a progressive neurologic disorder in girls characterized by normal birth and apparently normal psychomotor development during the first six to 18 months of life. The girls then enter a short period of developmental stagnation followed by rapid regression in language and motor skills. Seizures occur in up to 90% of affected females; generalized tonic-clonic seizures and partial complex seizures are the most common. Females with classic Rett syndrome typically survive into adulthood, but the incidence of sudden, unexplained death is significantly higher than in controls of similar age. Atypical Rett syndrome is increasingly observed as MECP2 mutations have been identified in individuals previously diagnosed with autism, mild learning disability, clinically suspected but molecularly unconfirmed Angelman syndrome, or mental retardation with spasticity or tremor.

Rett syndrome is inherited in an X-linked dominant manner. Approximately 99.5% of cases are single occurrences in a family, resulting either from a *de novo* mutation in the child with Rett syndrome or from inheritance of the disease-causing mutation from one parent who has somatic or germ line mosaicism.

PCR amplification and Sequencing of the three exons of MECP2 gene coding region showed that R 407 Stop codon, R 224C and A 72 R were heterozygote mutations in all Iranian female patients.

P01.103

X-linked mental retardation(XLMR) and the MECP2 gene

R. G. Goliath, L. Adonis, G. Carvill, M. Urban, K. Fieggen;

Division of Human Genetics, Cape Town, South Africa.

MECP2 is an X-linked gene encoding a nuclear protein that binds specifically to methylated DNA. Until recently the gene was predicted to function as a general transcriptional repressor. An alternative function however has been recently reported indicating the primary function of MeCP2 not being the silencing of methylated promoters.

Mutations in MECP2 have been reported to be the molecular basis of a broad spectrum of neurological disorders including: Rett syndrome (RTT), unexplained progressive encephalopathy and an Angelman-like phenotype. Also, duplications of MECP2 region are associated with 10% of familial X-linked mental retardation (XLMR). The XLMR phenotypic spectrum often includes hypotonia, spasticity, absent speech and recurrent infections.

To date the Division of Human genetics, University of Cape Town has

DNA banked from 80 XLMR families and 30 male sib-ships that are negative for mutations in the most common XLMR associated genes (*FMR1* CGG expansion and *ARX* mutations). This group of patients was stratified into a smaller cohort of subjects according to the clinical criteria indicated above. Preliminary findings involving qPCR analyses, suggests significant *MECP2* involvement in XLMR patient phenotypes.

This study further assesses the degree of *MECP2* involvement in an XLMR cohort of South African patients using MLPA analysis of the *MECP2* chromosomal region in a larger group of XLMR patients. Determining the proportion of XLMR patients in the Human Genetics bank, due to *MECP2* mutations will assist in the genetic management of XLMR families through definitive diagnostic systems, carrier ascertainment and prenatal diagnoses to carrier females.

P01.104

MECP2 gene mutation analysis in patients with Rett-like features in Latvia

N. Pronina^{1,2}, **O. Sterna**^{1,2}, **D. Bauze**¹, **Z. Krumina**¹, **B. Lace**^{1,2}, **D. Locmele**¹, **Z. Daneberga**^{1,2}, **R. Lugovska**^{1,2};

¹Children's University Hospital; ²Medical Genetics Clinic, Riga, Latvia, ²Riga Stradins University, Riga, Latvia.

Rett syndrome (RTT), an X-linked dominant neurodevelopmental disorder mostly in females, with an incidence of 1 in 10 000-15 000 female births. Gene *MECP2* (methyl-CpG-binding protein) gene has been identified as the disease-causing. RTT is one of the most common causes of mental retardation in females. After a period of normal development usually until 6-18 months of age, affected girls enter a period of regression, losing speech and motor skills, coincident with the onset of hand stereotypies, leading to loss of purposeful hand use, which is the hallmark of the disorder.

MECP2 gene is located on chromosome Xq28 and is subject to X-inactivation. Gene mutations are identifiable in 80% of classic Rett syndrome, but less frequently in atypical RTT.

First 10 unrelated patients (including 2 boys) with developmental delay and autistic features were referred for molecular diagnostic. Genomic DNA was extracted from blood leukocytes. *MECP2* coding exons 2, 3, and partly exon 4, were amplified in 7 overlapping PCR fragments and analyzed by direct sequencing on ABI 310 genetic analyzer. No previously reported mutations were found in analyzed fragments. Studies of remaining part of *MECP2* gene exon 4 for most common mutations in TRD domain are in progress. Additional mutation analysis of exon 1 will be performed after exons 2, 3 and 4 complete investigation. Novel changes found in *MECP2* gene exon 4 should be confirmed by restriction analysis.

P01.105

Analysis of polymorphisms in 5-HTT, HSP 70-1, APOE, and HMOX-1 genes as potential modulation factors of Rett syndrome phenotype

D. Zahorakova¹, **A. Puchmajerova**¹, **L. Kralik**¹, **M. Jachymova**², **A. Baxova**³, **J. Zeman**¹, **P. Martasek**¹;

¹Department of Pediatrics and Center for Applied Genomics, General University Hospital and First School of Medicine Charles University, Prague, Czech Republic, ²Institute of Clinical Biochemistry and Laboratory Diagnostics, General University Hospital and First School of Medicine Charles University, Prague, Czech Republic, ³Institute of Biology and Clinical Genetics, General University Hospital and First School of Medicine Charles University, Prague, Czech Republic.

Background: Rett syndrome is a severe X-linked neurodevelopmental disorder caused primarily by de novo mutations in the *MECP2* gene. It is one of the leading causes of mental retardation in females with prevalence 1:10,000 female births worldwide. The phenotypic spectrum of Rett syndrome is very variable even in females with random X chromosome inactivation. Therefore we hypothesize there might be other genetic factors which modulate the Rett phenotype. In a large case-control study, we performed molecular genetic analysis of functional polymorphisms in several genes involved in neuronal development and metabolism (5-HTT, HSP70-1, APOE, and HMOX-1).

Methods: All patients carried confirmed pathogenic mutation in the *MECP2* gene. Molecular genetic analysis of six polymorphisms was performed using PCR-based methods (PAGE, PCR/RFLP). Results were statistically evaluated by the test of binomical distribution.

Results: Our findings revealed a statistically significant difference between patients and controls for allele and/or genotype distribution of APOE, 5-HTT, and HSP70-1 (-110A>C), but not for associations between Rett syndrome and polymorphisms (GT)_n in the HMOX-1 promoter or +190C>G in HSP70-1.

Conclusion: To our knowledge this is the first such study in Rett syndrome patients and further confirmation in experimental and epidemiological studies is necessary. Understanding the inherited factors that influence patients' susceptibility for developing various Rett phenotypes may lead to the development of better and more comprehensive therapies.

The study was supported by grants GA UK 257927 92707, IGA MZ NR9215, and MSM0021620849.

P01.106

CDKL5 gene mutations in patients with a RTT-like phenotype

N. Puente-Unzueta¹, **C. Martínez-Bouzas**¹, **E. Beristain**¹, **N. Viguera**¹, **J. Prats**¹, **A. García-Rives**¹, **M. T. Calvo**², **M. Salido**³, **M. I. Tejada**¹;

¹Hospital de Cruces, Barakaldo-Bizkaia, Spain, ²Hospital Universitario Miguel Servet, Zaragoza, Spain, ³Hospital del Mar, Barcelona, Spain.

Rett Syndrome (RTT) is a progressive neurodevelopmental disorder showing several phenotypic manifestations. The majority of clinically diagnosed cases have been found to show a mutation in the *MECP2* X-linked gene, a gene that encodes for a transcription suppressor Methyl-CpG-Binding Protein. The cyclin-dependent kinase-like 5 gene (*CDKL5*) is another X-linked gene that belongs to the same molecular pathway of *MECP2* and encodes a phosphorylated protein with protein kinase activity. Mutations in the *CDKL5* gene cause severe mental retardation, early onset epilepsy and drug resistance.

We have screened the 21 exons of the *CDKL5* for mutations in 18 female patients with a RTT-like phenotype and epilepsy who had tested negative for *MECP2* mutations. The aim of this study was to determine whether the condition of these patients is due to mutations in the *CDKL5* gene. Genomic DNA was extracted using standard procedures from the peripheral blood leukocytes of patients. Mutation analyses were performed using CSGE in 24 fragments of the *CDKL5* gene and sequenced in case of anomalous bands.

We have only found 2 cases with variations: three nucleotide exchanges that form a rare conserved haplotype - IVS4+17A>G, c.3003C>T (H1001H) and c.3084G>A (T1028T) (J Tao et al. 2004) - in one patient and a new missense change in the 17th exon - c.2389G>A (D797N) - in another patient without pathologic effect because the father was the carrier.

These results indicate that mutations in the *CDKL5* gene are not an important contribution in the etiology of RTT with epilepsy in our population.

P01.107

Searching for Copy Number Polymorphisms as modifiers in RTT syndrome

R. Artuso¹, **F. Ariani**¹, **A. Spanhol Rosseto**¹, **D. Rondinella**¹, **F. T. Papa**¹, **E. Katzaki**¹, **M. A. Mencarelli**¹, **I. Meloni**¹, **F. Mari**¹, **M. Pollazzon**¹, **M. Zappella**², **G. Hayek**², **A. Renieri**¹;

¹Medical Genetics, Siena, Italy, ²Child Neuropsychiatry, University hospital, Siena, Italy.

MECP2 mutations are associated with a broad spectrum of clinical phenotypes in girls, including the preserved speech variant (PSV) of RTT. In this variant, girls improve language and motor abilities. Previous studies demonstrated that mutation type and/or X chromosome inactivation are not sufficient to explain such variability, suggesting that additional factors are involved. We hypothesized that Copy Number Polymorphisms (CNPs) contribute to RTT clinical variability. We started to search such variations in three familial cases with the same *MECP2* mutation and different phenotype (<http://www.biobank.unisi.it>): two pairs of sisters (one classic and the other PSV) and a mother/daughter pair (mother with mental retardation and daughter with classic RTT). In these cases, we performed whole genome array-CGH and we found a total of 18 CNPs. Three of them (6p21.33, 8p11.23, 14q11) are in common between two familial cases. Interestingly, the 8p11.23 region includes ADAM5. ADAMs are transmembrane proteins that play an important role in the development of the nervous system. They regulate proliferation, migration, differentiation and survival of various cells, as well as axonal growth and myelination. Among the

other CNPs, the 1q42.12 region contains the *ENAH* gene that represents a good candidate as RTT modifier since it is involved in the pathways that control cortical neuronal positioning. Real-time qPCR with specific probes for selected candidate genes in 100 classic and 20 PSV patients is ongoing. The identification of modifier genes will allow to better characterize the pathogenic mechanisms of RTT, giving additional handles for therapy design.

P01.108

Rett syndrome in two years old girl with Xp deletion - case report

A. Todorova¹, T. Todorov¹, R. Tincheva², D. Avdjieva², I. Boneva², V. Mitev¹;
¹Department of Chemistry and Biochemistry, Medical University Sofia, Sofia, Bulgaria, ²Paediatric Hospital, Medical University Sofia, Sofia, Bulgaria.

Rett syndrome (RTT; OMIM#312750) is an early childhood neurodevelopmental disorder. A girl at age of 2 years was referred to our laboratory for DNA analysis of Rett syndrome. She demonstrated some of the symptoms, characteristic for Rett syndrome - arrested mental development, loss of communication skills, speech delay and purposeful hand movements, appearance of autistic features. Under some circumstances the child demonstrates aggressive behavior. The performed cytogenetic analysis showed pathological karyotype - 46,XX,del(X)(p1.22).

About 85% of the cases with Rett syndrome were caused by mutations in the gene encoding methyl-CpG-binding protein 1 (MECP2). In about 10% of the cases the disease causing mutation affects the gene for cyclin dependent kinase like 5 (CDKL5). However, the causative mutation is still unknown in the remaining 5% of the cases.

The complete sequencing of MECP2 and CDKL5 genes revealed no mutations in the affected girl. In addition we sequenced the Aristaless related homeobox (ARX) gene, mutations in which have been shown to cause mental retardation either isolated or associated with a broad spectrum of neurological problems. This gene has been mainly affected in boys. As this gene is localized on the short arm of the X-chromosome (Xp22.13), one of its copies was missing in our Xp deleted girl. For that reason this gene seemed to be a good candidate for screening in our mentally retarded girl. The DNA analysis of ARX showed no pathological changes.

We will appreciate any further comments and suggestions on the reported case.

P01.109

ARX mutations in South African patients with X-Linked mental retardation (XLMR): Research to diagnostics

G. L. Carvill, R. G. Goliath;

Division of Human Genetics, Institute of Infectious Disease and Molecular Medicine, Cape Town, South Africa.

Objectives: Mental retardation (MR) is associated with decreased cognitive function and impaired development of adaptive skills. The genetic heterogeneity of the disorder is exemplified by the number of genes implicated in the pathogenesis of MR. Of these genes, a substantial proportion are located on the X chromosome, giving rise to the term X-linked mental retardation (XLMR). Mutations in the *ARX* gene are the second largest contributor to XLMR, preceded only by CGG expansion mutation in *FMR1*, responsible for Fragile X syndrome.

Methods: DNA sequence alterations in the *ARX* gene were investigated in 119 XLMR patients, 32 patients that form part of a male sib-ship and 183 isolated cases (all individuals are *FMR1* expansion mutation negative). These analyses were conducted using denaturing high-performance liquid chromatography (dHPLC), or PCR amplification and gel electrophoresis of the common c.428_451dup (Dup24) mutation alone.

Results: To date the proportion of *ARX* disease-causing mutations in the XLMR cohort is 2.4% and 3.4% in the sib-ships. While in the isolated group the Dup24 mutation has not been detected.

Conclusion: These findings suggest that c.428_451dup testing is feasible and justified in determining the cause of XLMR in males negative for Fragile X syndrome, in the Western Cape region of South Africa. Incorporating this test into the diagnostic protocol stands to improve the diagnostic yield of patients, which in turn will afford improved genetic management of families. Furthermore, better genetic management will have a valuable impact on the burden of disease in a developing country such as South Africa.

Molecular diagnostic of XLMR in mentally retarded males from Latvia

Z. Daneberga^{1,2}, Z. Krumina¹, B. Lace^{1,2}, D. Bauze¹, N. Pronina¹, R. Lugovska¹;
¹Medical Genetic Clinic, University Children's Hospital, Riga, Latvia, ²Rigas Stradins University, Riga, Latvia.

Mental retardation (MR) is one of the main reasons for referral in paediatric, child neurological and clinical genetic practice. The prevalence of mental retardation is thought to be on the order of 2-3%.

X-linked gene defects have long been considered to be important causes of mental retardation, on the basis of the observation that mental retardation is significantly more common in males than in females. Clinical observations and linkage studies in families revealed that X-linked mental retardation (XLMR) is a highly heterogeneous condition. The most common form of XLMR is the Fragile X mental-retardation syndrome (FXS). Mutations at *FRAXA* locus on distal Xq may cause mental impairment. Most common mutation at *FRAXA* locus is expansion of CGG triplet repeats located in the 5'-untranslated region of the *fragile X mental retardation-1 (FMR1)* gene. The group of 341 unrelated males with MR referred from clinical geneticists was screened for FXS. CGG repeats number was detected by Applied Biosystems protocol on ABI Prism 310. The prevalence of 29, 30 and 31 CGG repeats for normal alleles were found. Six affected patients were detected (1.76%). The final diagnosis of FXS was confirmed by Southern blotting. DNA sequencing for the estimation of AGG inserts structure for gray zone (34-50 repeats) alleles was used.

To analyse undiagnosed XLMR patients we recently introduced the multiplex ligation-dependent probe amplification (MLPA) method to identify deletions and duplications of MRX genes. We use MLPA P106 MRX commercial kit (MRC-Holland) to analyse one or more exons of 14 MRX genes.

P01.111

Novel PCR-based protocol for a rapid molecular testing of Fragile X syndrome

B. López-Posadas¹, E. Velasco², J. A. Garrote^{3,4}, M. Alonso¹, J. J. Tellería¹, A. Blanco¹, I. Fernández-Carvajal¹;

¹Laboratorio de Genética Humana, Unidad de Diagnóstico Genético y Perinatal, Valladolid, Spain, ²Laboratorio de Genética del Cáncer, Unidad de Diagnóstico Genético y Perinatal, Instituto de Biología y Genética Molecular (IBGM), Universidad de Valladolid-CSIC, Valladolid, Spain, ³Unidad de Investigación, Hospital Clínico Universitario de Valladolid, Valladolid, Spain, ⁴Laboratorio de Inmunología, Unidad de Diagnóstico Genético y Perinatal, Instituto de Biología y Genética Molecular (IBGM), Universidad de Valladolid-CSIC, Valladolid, Spain, ⁵Laboratorio de Genética Humana, Unidad de Diagnóstico Genético y Perinatal, Instituto de Biología y Genética Molecular (IBGM), Universidad de Valladolid-CSIC, Valladolid, Spain.

Fragile-X syndrome (FXS) is the most common cause of inherited mental retardation. It is caused by an anomalous expansion of CGG repeats in the 5'UTR of the *FMR1* gene, which are hypermethylated, causing the absence of *FMR1* expression.

Clinical diagnosis of typical FXS is usually difficult to establish before puberty and molecular testing is therefore needed to confirm it.

Several PCR protocols have already been developed to amplify these repeats, but neither of them is able to amplify full-mutated alleles.

With a view to improving the molecular analysis of FXS, we have established a new PCR-based strategy.

We analyzed 68 retrospective samples of known repeat sizes to assess protocol efficiency and 252 prospective samples.

Two PCRs were performed followed by electrophoresis in a DNA sequencer. Finally, a methylation-specific PCR was carried out to test the promoter methylation status.

Results from retrospective samples were reproduced with the new protocol, supporting its capability to test the whole range of *FMR1* alleles. Additionally, its sizing accuracy made allele frequency distribution and transmission studies possible.

Analysis of prospective samples revealed 13 full mutations, two pre-mutation-full mutation mosaicisms, 6 pre-mutations and 10 grey-zone patients.

Moreover, we have amplified and accurately sized a full-mutated allele of 817 repeats, the longest allele amplified by PCR until now.

In conclusion, this PCR approach has improved and speeded up the FXS diagnosis making it less labor-intensive than standard procedures that include Southern blot analysis.

P01.112

Evaluation of a PCR-based method that allows the analysis of fragile X mutations in the complete range of expansions: a multicentric Italian experience

M. Grasso¹, I. Giott², F. Torricelli³, M. Melis³, A. Lo³, A. Ravan⁴, A. Ferlin⁵, E. Bettella⁵, R. Poll⁵, **A. Murgia⁵**;

¹SC Laboratorio Genetica Ospedale Galliera, Genova, Italy, ²SOD Diagnostica Genetica AO Universitaria, Firenze, Italy, ³Laboratorio Genetica Umana, ASL 8, Università di Cagliari, Cagliari, Italy, ⁴Laboratorio Genetica Molecolare AO Universitaria, Ferrara, Italy, ⁵University of Padua Department of Pediatrics, Padua, Italy.

We present the results of a collaborative study aimed at evaluating the performances of the Fragile X PCR Assay (Abbot Molecular, Inc), designed to provide robust amplification and precise sizing of FMR1 dynamic mutations within the entire range of expansions. The goal of the study was to test the following features: 1) accuracy in measuring the number of CGG repeats; 2) capacity to resolve normal FMR1 alleles differing by one triplet unit, 3) capacity to assure efficient co-amplification of different-size fragments; 4) amplification of full mutations. The population studied comprised a total of 378 individuals, 241 females and 137 males, all previously ascertained by Southern blot and other types of PCR-based analysis which found 226 individuals with wt FMR1 alleles, 80 with premutations, 48 with full mutations and 24 with complex mosaicism. A few representative samples were analyzed by all the laboratories involved. The study pointed out the importance of evaluating the whole set of data generated through the analysis for a correct interpretation of the final results. The work confirmed the sensitivity and reliability of the method that allowed to correctly size FMR1 alleles in the different categories of expansions and obtained a robust amplification of full mutations with up to 600 repeats. The Fragile X PCR Assay is a molecular tool that can fill the existing gap between currently used PCR-based methods that do not amplify large CGG expansions and Southern blot analysis which does not allow a precise sizing of FMR1 alleles.

P01.113

Tissue mosaicism of unmethylated expanded FMR1 allele derived from normal number of CGG repeats

C. Catali¹, I. Bagn², A. M. Nardone², G. Fusco¹, M. Frontali², A. Morgante¹, A. Botta¹, G. Novelli^{1,2};

¹Department of biopathology, Tor Vergata University, Roma, Italy, ²Medical genetics, Policlinico Tor Vergata, Roma, Italy.

Fragile-X syndrome (FRAXA, OMIM #300624) is caused by expansion of a [CGG] trinucleotide in the FMR1 gene over 200-230 repeats. This leads to methylation of CpG islands of its promoter region, which in turn causes silencing of FMR1 gene. Length and methylation mosaicism are described, arisen from premutated or mutated maternal alleles, with different and often unpredictable clinical outcome. Here we present the molecular characterization of a clinically normal 33 years old man referred to us for genetic counseling after the identification of a carrier status (61 [CGG]) of her daughter detected during amniocentesis and confirmed at birth. Familial study revealed a maternal transmission of the premutated allele. Surprisingly, a mosaic pattern ranging from normal to 330 unmethylated FMR1 alleles was detected in the father. On clinical re-evaluation, no sign associated with FRAXA were detected, except relative macroorchidia and slightly extroverted ears. Intelligence were above-average. Samples of fibroblasts, sperm and saliva were additionally analyzed and all resulted normal. QF-PCR and chromosome analysis excluded additional chromosome X mosaicism. Blood sample of his mother showed the same normal allele, as resulted from linkage analysis. To our knowledge, even if tissue-confined, this is the first report of expanded FMR1 allele originating from normal allele.

P01.114

Variation in novel exons (RACEfrags) and human genetic disorders; the case of Rett syndrome

P. Makrythanasis¹, P. Kapranov², L. Bartoloni¹, A. Raymond³, S. Deutsch¹, R. Guigo⁴, F. Denoeud⁴, C. Rossier¹, F. Ariani⁵, V. Capra⁶, A. Renier⁶, T. Gingeras², S. E. Antonarakis¹;

¹Medical Genetics and Dev, Medical School, University of Geneva, Geneva, Switzerland, ²Affymetrix, Santa Clara, CA, United States, ³University of Lausanne, Lausanne, Switzerland, ⁴IMIM, Barcelona, Spain, ⁵University of Siena,

Siena, Italy, ⁶Neurochirurgia, Istituto G. Gaslini, Genova, Italy.

The study of transcription using genomic tiling arrays has led to the identification of numerous additional exons. One example is the MECP2 gene on the X-chromosome; using 5'RACE and RT-PCR in human tissues and cell lines, we have found more than 15 novel exons (RACEfrags) connecting to at least one exon of MECP2 gene and map up to 1 Mb telomeric to it. We subsequently asked if variation in the novel exons is causatively associated with Rett syndrome. We sequenced all MECP2-connected exons and flanking sequences in 3 groups: 48 Rett patients without mutations in MECP2 and CDKL5 genes (group_1); 30 Rett patients with mutations in the MECP2 gene (group_2); 100 control individuals from the same geoethnic group (group_3). Approximately 14kb was sequenced per sample, (2.6Mb of DNA resequencing). 75 individuals had new, not yet identified rare variants, but no statistically significant difference was found among the 3 groups. These results suggest that variants in the newly discovered exons studied do not contribute to Rett syndrome, furthermore if some of these variants are related to a phenotype, this must be different from Rett. Interestingly however, the variants in the novel exons are twice as frequent as those found in flanking sequences (50 vs 24 for approximately 1.3 Mb sequenced for each class of sequences). The significance of this result remains to be elucidated; one hypothesis is that novel exons accumulate variants faster than the rest of the genome (positive selection?) that could underscore the functional importance of these sequences.

P01.115

Rett syndrome cases with more than one causative mutation in the MECP2 gene

D. O. Robinson^{1,2}, D. J. Bunyan¹;

¹Wessex Regional Genetics Laboratory, Salisbury, Wilts, United Kingdom,

²Human Genetics Division, Southampton University School of Medicine, Southampton, United Kingdom.

Rett syndrome is an X-linked dominant disease affecting females. It is a progressive neurological disorder characterized by normal birth and psychomotor development for the first six to 18 months of life followed by severe regression in motor and language ability. In 80% of cases mutations in the Methyl-CpG-binding protein 2 (MECP2) gene are identified, usually de novo point mutations, however up to 16% are caused by deletions of one or more exons of the gene. Almost all are single cases in a family resulting from de novo mutations or the inheritance of a mutation from an unaffected parent with somatic or germ line mosaicism.

Point mutation testing and gene dosage analysis of a cohort of 455 cases referred to our laboratory for MECP2 gene analysis identified mutations in 118 cases. However there were four females who each had two different de novo causative mutations, presumed to be on the same chromosome because compound heterozygosity for two causative mutations is likely to be lethal. Two of these cases had a point mutation and a small intraexonic deletion, a third had a whole exon deletion and a separate small intraexonic deletion and a fourth had a small intraexonic deletion and a large duplication. These findings highlight the necessity to perform both point mutation and exon dosage analysis in such cases, particularly because of the possibility of undetected parental mosaicism and the implications for prenatal diagnosis in future pregnancies. These cases also suggest that the MECP2 gene may be particularly prone to mutation.

P01.116

FRAXA Molecular Genetic Diagnosis of the oocyte donor population during 2007 for Assisted Reproduction Treatments.

A. L. Garda-Salas¹, I. Pérez¹, K. Aurrekoetxea², C. Méndez¹, M. C. Martínez¹, P. Albero¹, L. Fernández¹, M. Nicolás¹, J. Landeras¹;

¹IVI-Murcia, Murcia, Spain, ²Abbot Científica, Madrid, Spain.

The Instituto Valenciano de Infertilidad (IVI) has implemented for the oocyte donation program in our clinics, the routine study for molecular analysis of X-FRAGILE Syndrome (FRAXA). FRAXA is one of the greatest genetic prevalence illnesses in general population. In this communication, we present our analysis, using the protocol recently developed by Abbott Molecular, called Fragile X PCR Test. We studied 2278 women from different cities in Spain. All these women as susceptible oocyte donors for processing of assisted reproductive treatments (TRA).

FRAXA is the most common cause associated to mental family inherited and represents among 15 to 20% of the total mental delay related to X cr. This illness has its origin in the deficiency of FMR1 protein synthesis. The expansion of the "dynamic" and repetitive region CGG, 5' to *Fmr-1*, causes its methylation and repression of expression. According repetitions number of the CGG tri-nucleotide, this region is considered normal (<50 CGGn), premutated (55-200 CGGn) or full mutated (>200 CGGn).

In this poster we present the results of this extensive study. In conclusion, we found 21 (0,92 %) premutation carriers; 49 (2,15%) "intermediate" carriers and 1/33 women were excluded from the donation program.

The knowledge of the fragile X premutation carrier condition or full mutation carrier will permit the donor to receive the appropriate genetic counsel for reproductive end. On the other hand, the exclusion from the oocyte donation program of possibly "expanded" trinucleotids of this region, provides greater security to the receptor patients in our processing of Assisted Reproduction.

P01.117

Genotype-phenotype correlation in Rubinstein-Taybi syndrome S. Naudion;

Service de genétique, CHU de Bordeaux, Bordeaux, France.

The Rubinstein-Taybi Syndrome is an autosomal dominant disease. It is characterised by typical facial dysmorphism, abnormalities of the extremities, growth retardation and psychomotor development delay. Mutations have been identified in two genes, *CREBBP* and *EP300*.

We report a series comprising 93 patients with *CREBBP* mutations, and 2 patients with *EP300* mutations. Point mutations were searched for by DHPLC followed by sequencing, and microrearrangements were identified by array-CGH and/or Quantitative Multiplex Fluorescent PCR (QMF-PCR). Among the *CREBBP* mutations, 24% were nonsense, 24% led to a translation reading frame shift, 26% were microrearrangements (24% deletions, 2% duplications), 18% affected a splice site, and 8% were missense. It is noteworthy that no mutation was ever found in exons 7, 9, 11, 18, 22, 23 and 29. Whatever the mutation type and localisation along the gene, the dysmorphic and osseous phenotypes were comparable to the typical RTS phenotype. However, patients carrying a nonsense mutation presented associated anomalies such as cardiopathy (33% vs 26%) or neurological anomalies (hypotonia in 81% vs 60%, hyperreflexia in 37% vs 29%) more frequently than patients with any other type of mutation. Conversely, patients carrying missense mutations presented with less severe phenotypes, since none of them presented any associated malformation or anomaly.

Concerning the 2 patients with an *EP300* mutation, our data were in accordance with those of the literature, since they presented with a typical dysmorphic phenotype with a less severe osseous phenotype. Only one of the two patients had broad thumbs and hallucus, without any associated osseous anomaly.

P01.118

Chromosomal imbalances in Rubinstein-Taybi patients negative to *CREBBP* mutational test

Osp. Rummo, Benevento, Benevento, Italy.

Rubinstein-Taybi syndrome (RSTS, OMIM #180849) is a rare autosomal dominant congenital disorder characterized by postnatal growth retardation and psychomotor developmental delay, skeletal anomalies and specific facial dysmorphisms. RSTS is associated with chromosomal microdeletion or point mutations of *CREBBP* gene in 16p13.3 and

mutations of *EP300* gene in 22q13, observed in 56% and 3% of the tested patients respectively.

Here we report the identification by a-CGH of duplications/deletions in 6 of 25 RSTS patients found negative to point mutations of *CREBBP* and to chromosomal rearrangements affecting *CREBBP* and *EP300* regions. The imbalances are: i) a de novo 9Mb deletion in 2q24.3q31.1 involving the *HOXD* genes, ii) a 5,5 Mb duplication in 2q34q35 inherited by the healthy father, probably representing a private CNV, iii) a 500Kb duplication in 17q11.2 upstream the *NF1* gene in a region delimited by *NF1* REP-P1/P2 iv) a 1,2Mb deletion in 18q21.33q22.1 harbouring one gene, v) a 4,3Mb deletion in 2q22.3q23.1 involving five genes among which *ZFX1B*, the gene mutated in Mowat-Wilson, vi) a 466Kb deletion in 7p21.1 containing *TWIST1*, a proposed candidate for RSTS. The parental origin, gene content and genomic characterization of the last four imbalances is in progress. Although the pathogenetic role is yet unproven in a few cases, this study shows a high fraction of chromosomal rearrangements in regions other than those of *CREBBP/EP300* genes. In addition a-CGH is confirmed to be a suitable approach for diagnostic purposes and to highlight novel positional RSTS candidate genes. Supported by A.S.M. (Associazione Italiana Studio Malformazioni).

P01.119

Two cases of Rubinstein Taybi Syndrome caused by two new mutations that create premature stop codons and truncated *CREBBP* protein

V. I. Guerçi¹, A. Fabretto¹, F. Faletta¹, C. C. G. Gervasin², L. Larizza², P. Gasparini^{3,1};

¹Genetica Medica Dipartimento di Scienze della Riproduzione e Sviluppo, Trieste, Italy, ²Genetica Medica. Università degli Studi di Milano, Ospedale San Paolo, Milano, Italy, ³Genetica Medica, IRCCS Burlo Garofolo, Trieste, Italy.

Rubinstein-Taybi syndrome (RSTS; MIM 180849) is a congenital disorder characterized by growth retardation and psychomotor delay, broad thumbs and hallucus and a wide range of dysmorphic features. RSTS was shown to be associated with microdeletions and point mutations in the gene encoding the CREB-binding protein, located in 16p13.3.

The first case was born from a twin pregnancy. While the sister was normal during pregnancy and postnatal period, the patient had IUGR and typical dysmorphic features since the first weeks of life. Cardiac valvular anomalies were found as well as a bilateral conductive hypoacusia. RSTS was then suspected and was confirmed by molecular analysis. A new mutation was found: c.5838_5857dup20, with the formation of a premature stop codon (p.Pro1953HisfsX30) resulting in a truncated protein of 1982 aminoacids. Second case was an Haitian girl. Pregnancy was terminated at 32 weeks for preeclampsia and IUGR. She was hospitalized because of respiratory distress, feeding difficulties and severe growth retardation. A recurrent infection condition secondary to gastroesophageal reflux was suspected. However, encephalic NMR demonstrated corpus callosum agenesis; oculistic examination revealed severe strabismus and nasolacrimal duct obstruction and bone age was marked delayed. Furthermore, physical examination demonstrated typical RSTS dysmorphisms. Molecular analysis of the *CREBBP* gene revealed a 7 nucleotide deletion: c.3608_3609+5del, eliminating the donor splicing site of exon 18 with the formation of a premature stop codon. This mutation produces a truncated protein (1204 aminoacids). The identification of these two new alleles may increase the knowledge of *CREBBP* function and the prediction of genotype-phenotype correlation.

P01.120

A predominantly sensorial case of CHARGE: towards a refinement of *CHD7* disease spectrum

B. Brasseur¹, N. Revencu¹, P. Clapuyt², M. Maes³, Y. Gillerot¹;

¹Center for Human Genetics, Brussels, Belgium, ²Pediatric Radiology, Brussels, Belgium, ³Pediatric Endocrinology, Brussels, Belgium.

Introduction: We present here a novel *CHD7* mutation in a mildly affected boy. The implications for further delineation of *CHD7* disease spectrum are underlined.

Clinical case: BM was born from unrelated Caucasian parents, with microphallus and bilateral cryptorchidism. Hypogonadotropic hypogonadism was diagnosed in neonatal period. Ophthalmologic examination revealed relative microphthalmia with right chorioretinal coloboma and left retrolental cysts. Psychomotor development and cardiac ul-

trasound were normal. A small isolated notch was noted on the right pinna.

At age 4, right sensorineural deafness was found and cranial imaging revealed bilateral middle and internal ear abnormalities (Mondini defect, bilateral semicircular canal agenesis, large sacculus, ossicular chain ankylosis), and hypoplastic olfactory tractus, without median line defect.

At age 10, anosmia was diagnosed. Growth was conserved, except for delay due to absence of puberty, and he performed well at school.

At age 13, screening of *CHD7* by heteroduplex and sequence analysis detected a c.6290A>G (p.Asp2097Gly) heterozygous mutation. Parents have not yet been tested but different models predict a probable pathogenic effect of this substitution.

Conclusions: This presentation suggests that CHARGE syndrome (MIM 214800) has to be evoked in children with apparently isolated sensorial deficiencies, and certainly in those with unilateral deafness and inner ear radiological abnormalities, in agreement with recent clinical criteria (Verloes). *CHD7* mutation screening would be helpful for better characterization of these "predominantly sensorial" forms, and if confirmed, could allow a more specific work-up and management, with regards to the expanding knowledge on *CHD7* disease spectrum (neurological, mainly rhombencephalic, endocrinological and immunological deficiencies).

P01.121

Clinical and molecular characterisation of a cohort of Portuguese CHARGE patients

A. B. Sousa¹, A. Medeira¹, D. Johnson², A. B. Salgueiro³, H. G. Santos⁴, I. Cordeiro⁵;

¹Serviço de Genética do Hospital de Santa Maria, Lisboa, Portugal, ²Duncan Guthrie Institute, Yorkhill, Glasgow, United Kingdom, ³Serviço de Pediatria do Hospital Fernando da Fonseca, Lisboa, Portugal, ⁴GenoMed, Lisboa, Portugal. CHARGE is an acronym standing for Coloboma, Heart malformation, choanal Atresia, Retardation of growth and/or development, Genital anomalies and Ear anomalies. Since the original description, other clinical features have been added to the CHARGE spectrum of anomalies, namely rhombencephalic dysfunction, hypoplasia of the semicircular canals and arhinencephaly. The diagnostic criteria now stress the importance of the 3C triad (Coloboma, Choanal atresia, abnormal semicircular Canals). Additionally, patients are classified as typical (3 major or 2 major and 2 minor criteria), partial or incomplete (2 major and 1 minor criteria), or atypical (2 major or 1 major and 2 minor criteria). CHARGE was considered an association until recent years, when *CHD7* mutations were identified in approximately 2/3 of patients.

We reviewed the patients with a clinical diagnosis of CHARGE syndrome who visited our Genetics Clinic. 10 patients met the most recent diagnostic criteria. 5 cases could be classified as typical CHARGE and 5 cases were atypical. However, 3/5 of the latter were not checked for hypoplasia of the semicircular canals, which could well alter their status.

CHD7 mutation detection studies were undertaken in all these patients, except for one of the typical CHARGE cases who died in the neonatal period. Highly likely causative mutations were identified in 7 patients overall, 3/4 typical and 4/5 atypical cases. In the remaining atypical CHARGE patient a sequence change of unknown clinical significance was found. This variant was also present in the patient's mother, who has subtle facial asymmetry and anisocoria, complicating result interpretation.

P01.122

A prenatal diagnosis of CHARGE syndrome

W. Courtens¹, P. Clapuyt², C. Barrea³, N. Revencu¹, Y. Gillerot¹, T. Detaille⁴, P. Bernard⁵, J. Biard⁶;

¹Center of Human Genetics UCL, Cliniques Universitaires St-Luc, 1200 Brussels, Belgium, ²Dept of Pediatric Radiology, Cliniques Universitaires St-Luc, 1200 Brussels, Belgium, ³Dept of Cardiology, Cliniques Universitaires St-Luc, 1200 Brussels, Belgium, ⁴Dept of Pediatrics, Cliniques Universitaires St-Luc, 1200 Brussels, Belgium, ⁵Dept of Obstetrics, Cliniques Universitaires St-Luc, 1200 Brussels, Belgium, ⁶Dept of Obstetrics, Cliniques Universitaires St-Luc, 1200 Brussels, Belgium.

We report on a female foetus in whom a CHARGE syndrome was diagnosed at 31 weeks of gestation. A Fallot tetralogy and a cleft lip and palate were observed at a fetal ultrasound examination performed

at ~23 weeks of pregnancy. Amniocentesis, performed in another hospital, revealed a normal female karyotype. A control of the ultrasound examination at 29 weeks' gestation showed, in addition, the presence of dysplastic cup-shaped ears, especially at the right side, evoking the diagnosis of CHARGE syndrome. Fetal brain magnetic resonance was suggestive for the presence of hypoplastic semi-circular canals, a finding that was confirmed by a fetal CT scan of the inner ear.

The parents were young, healthy and non-consanguineous. Family history was unremarkable, except for the presence of miscarriages. The parents were informed about CHARGE syndrome and decided to continue the pregnancy. The child, born at 37 5/7 weeks, had a left-sided cleft lip and palate, a heart murmur 3/6, a facial asymmetry (with right eye being smaller than the left eye) and typical CHARGE ears. She had major cardio-respiratory problems and died soon after birth. The parents refused post-mortem examination, but a cerebral brain MRI could be performed post-mortem and showed a coloboma of the left retina and absent olfactory bulbs. Blood analyses for *CHD7* mutational screening are ongoing.

This case illustrates the use of both fetal brain MRI and CT scan of the inner ear in establishing a prenatal diagnosis of CHARGE syndrome.

P01.123

A novel SOX9 mutation in a case with camptomelic dysplasia

L. Grozdanova¹, M. Krasteva², G. Scherer³, R. Stoeva⁴, E. Bausch³, I. Stoev⁴, T. Krastev⁴, A. Linev⁴, M. Stefanova^{4,5};

¹Department of Medical Genetics, University Hospital, Plovdiv, Bulgaria, ²Department of Obstetrics and Gynaecology, Medical University, Plovdiv, Bulgaria, ³Institute of Human Genetics and Anthropology, University of Freiburg, Freiburg, Germany, ⁴Department of Pediatrics and Medical Genetics, Medical University, Plovdiv, Bulgaria, ⁵Center for Human Genetics, Free Flemish University Hospital, Brussels, Belgium.

Camptomelic dysplasia (CD, MIM 114290) is a rare, often lethal, dominantly inherited, congenital osteochondrodysplasia, associated with male-to-female autosomal sex reversal in two-thirds of the affected karyotypic males. Prominent features are bowing and angulations of long bones, Robin sequence, pelvis, chest and rib abnormalities. De novo mutations of the *SOX9* gene, a tissue-specific transcription factor gene involved both in skeletogenesis and male sexual differentiation, are known to be responsible for both CD and XY sex reversal. Here we present a 4-month-old infant of young non-consanguineous parents out of the Turkish minority group in Bulgaria. Femoral malformations and macrocephaly were detected prenatally. The newborn was delivered at term and presented with an extremely short birth length, below -7 SD, dysmorphic facial features, median cleft palate, remarkably bowed and short limbs, narrow asymmetric thorax, club feet, short deformed toes, and radiographic features characteristic for camptomelic dysplasia. Male pseudohermaphroditism with female external genitalia, enlarged clitoris, and male karyotype was found. DNA analyses revealed a novel de novo mutation of the *SOX9* gene, Q401X. A similar nonsense mutation, Y400X, has been described previously (Hum Mol Genet 6:91, 1997). In both cases, a truncated *SOX9* protein results that completely lacks the C-terminal transactivation domain (residues 402-509). The Q401X mutant *SOX9* protein will still be able to bind to DNA, as it still retains the DNA-binding domain, but will be unable to activate transcription of the genes that are regulated by this transcription factor.

P01.124

Opsismodysplasia with renal agenesis: A case report

M. Mihaescu^{1,2}, G. Olaru², I. Sas², D. Navolan^{1,2}, D. Chiriac^{1,2}, E. Taurescu^{1,2}, D. Citu^{1,2};

¹University of Medicine, Timisoara, Romania, ²Hospital "dr. Dumitru Popescu", Timisoara, Romania.

Opsismodysplasia is a rare chondrodysplasia clinically characterised by micromelia, respiratory distress, and major delay in skeletal ossification.

We present a novel case of opsismodysplasia in a foetus after termination of pregnancy at 30 weeks of gestation. Prenatal was diagnosed during ultrasound in our clinic with shortness of the long bones and short extremities, depressed nasal bridge, narrow thorax. The parent's roms ethnic, delivered no information about the family consanguinity. After termination of pregnancy the female new born lived only 30 minutes. She was at birth: the weight 840g, the length 29 cm, PC 25 cm

and PT 19 cm. Necropsy confirmed dysmorphic features, coarse face, and showed bilateral pulmonary hypoplasia, bilateral renal agenesis (not previously reported in opsismodysplasia) rhizomelic micromelia (handwriting appearance of hands fingers).

She presented: high forehead, horizontals and short palpebral fissures, posterior rotated and low placed prominent ears, small anteverted nose with long philtrum, depressed bridge of nose, micrognathia, thin upper lip), muscle hypotonia, short feet and hands, abnormalities of fingers, dorsolumbar scoliosis. Radiographic findings were hypoplastic vertebral bodies, marked shortness of the long bones of the hands and feet with concave metaphyses.

Karyotype from the peripheral blood lymphocytes and G banding were performed according to standard protocols. The karyotype was 46,XX. In our knowledge were reported only ten cases with termination of pregnancies after the antenatal diagnoses and this is the first case of opsismodysplasia associated with bilateral renal agenesis.

New ocular findings among two sisters with Yunis-Varón syndrome

J. R. Corona-Rivera¹, C. O. Romo-Huerta², S. A. Estrada-Padilla¹, E. López-Marure², M. A. Villafuerte-Bautista²;

¹Instituto de Genética Humana Dr. Enrique Corona-Rivera, Guadalajara, Mexico, ²Hospital Civil de Guadalajara Dr. Juan I. Menchaca, Guadalajara, Mexico.

Introduction. The Yunis-Varón syndrome (YVS) represents a rare autosomal recessive syndrome characterized by cleidocranial dysplasia, absence of thumbs and halluces, distal aphyalangia, ectodermal anomalies, and poor outcome. This report is among two sisters with YVS, which adds ocular findings to the known features of this syndrome.

Clinical reports. The first patient, a 11-month-old female infant was the third child of a healthy consanguineous parents of Mexican descent. She has pre- and post-natal growth retardation, wide sutures and fontanels, sparse hair, telecanthus, short upper lip, high arched palate, abnormal ears, micrognathia, loose skin in neck, sloping shoulders, hypoplastic thumbs, distal aphyalangia, nail hypoplasia, aplasia of great toes, and short pointed toes. Besides, skull dystostosis, hypoplastic clavicles, hypoplasia of proximal phalanges, agenesis of distal phalanges, congenital cardiopathy, central nervous system anomalies, hearing loss and visual impairment were also observed. Ophthalmologic evaluation and fluorescein angiography showed papillo-macular atrophic chorioretinopathy with "salt-and-pepper" appearance. Results of TORCH titers, metabolic screening test, karyotype, and muscle biopsy were normal or negative. The second patient was a female newborn with physical, ophthalmologic, and radiological findings similar to her sister. Absence of thumbs and first toes were observed on ultrasound examination at 22 weeks.

Conclusions. This appears to be the first cases of YVS associated with chorioretinopathy that could not be attributed to environmental causes. Other anomalies such as sclerocornea, cataracts, corneal opacity and microphthalmos make mandatory the ophthalmologic evaluation for patients with YVS.

COL2A1 mutations and related phenotypes in Italian patients with presumptive type II collagenopathy

E. Andreucci¹, I. Carboni², E. Lap³, M. F. Bedeschi⁴, F. Lalatta⁴, M. Di Rocco⁵, M. G. Patricelli⁶, C. Auriti⁷, G. Seganti⁷, F. Papadia⁸, L. Giunti⁹, M. Genuardi¹, S. Giglio¹;

¹Dept. of Clinical Pathophysiology, University of Florence and Medical Genetics Unit, Meyer Children's University Hospital, Florence, Italy, ²Dept. of Clinical Pathophysiology, University of Florence and Medical Genetics Unit, Meyer Children's University Hospital, Florence, Italy, ³Medical Genetics Unit, Meyer Children's University Hospital, Florence, Italy, ⁴Medical Genetics Unit, Policlinico Mangiagalli Hospital, Milan, Italy, ⁵Rare Disease Unit, Department of Paediatrics, Gaslini Institute, Genoa, Italy, ⁶Laboraf, "San Raffaele" Hospital, Milan, Italy, ⁷Neonatal Pathology Unit, Children's Hospital "Bambino Gesù", Rome, Italy, ⁸Metabolic Disease-Medical Genetics Division, Children's Hospital "Giovanni XXIII", Bari, Italy.

COL2A1 mutations are associated with a wide spectrum of phenotypic manifestations. At present little is known about the distribution of COL2A1 defects and related phenotypes in Italian patients. We investigated a series of 13 unrelated Italian probands with a presumptive diagnosis of type II collagenopathy. The 54 exons of the COL2A1 gene

were screened by dHPLC, followed by sequencing of amplicons with an abnormal profile. Overall, eight distinct mutations were detected. Five of these had been previously described in the literature, and three have never been reported to our knowledge. Previously described genotype-phenotype correlations for the already reported mutations were confirmed in this series.

Among the newly reported mutations, the IVS7+1G>A variant was found in a female proband with typical type 1 Stickler syndrome with a positive family history and wide intrafamilial phenotypic variability. A nonsense mutation, K1447X, in the C-terminal region of the protein was found in a family, mother and child, studied for a suspicion of Kniest Dysplasia. Finally, a G891C missense variant, affecting the triple helical domain of the protein, was associated with a clinical picture of spondyloepimetaphyseal dysplasia, Strudwick type.

Further cases will need to be examined in order to obtain a better definition of genotype-phenotype correlations for COL2A1 mutations in the Italian population.

P01.127

Genetic diagnosis of the craniosynostosis in Spain

D. Arroyo, D. Corella, M. Edo;

Progenie molecular, Valencia, Spain.

The craniosynostosis consist in an anomalous fusion of cranial bones that originates problems in the normal growth of the cranium and involves dramatic alterations in the shape of the head and the face, and in some cases severe mental delay. The craniosynostosis is classified under several syndromes: Apert, Crouzon, Pfeiffer, Beare-Stevenson, Saethre-Chotzen, Muenke and Jackson-Weiss. Each one has a particular pattern of inheritance and a few clinical specific characteristics, but in some cases they are difficult to distinguish by the external aspect, specially when prenatal diagnosis is done by means of the ultrasound scans. The genetic diagnosis allows to detect the craniosynostosis in the first stages of the pregnancy and to confirm the clinical observations.

The most important genes associated to these disorders are FGFR1, FGFR 2, FGFR3 and TWIST. The genetic study of the craniosynostosis is complex, and may includes the four genes involved in the pathology. In this communication we show the results obtained in the study of these syndromes in Spain. We analysed 38 genes from 19 people, including affected people and their families. We found 5 mutations that have been reported as the genetic basis of the disease. We also done a prenatal genetic diagnosis that confirms a Pfeiffer syndrome, previously diagnosed by ultrasound scan. Our results suggest that most of mutation associated to craniosynostosis are located in a few regions of these genes, in opposition to what happens with other genetic diseases, in which the mutations could be found along the entire gene.

P01.128

Czech dysplasia: clinical and molecular delineation of a novel COL2A1 disorder

A. Tzschach¹, S. Tinscher², E. Kaminsky³, E. Lusga³, S. Mundlos⁴, L. M. Gaul-Neumann⁴;

¹Max Planck Institute for Molecular Genetics, Berlin, Germany, ²Institute of Clinical Genetics, Technical University, Dresden, Germany, ³Practice of Human Genetics, Schomburgstrasse 120, Hamburg, Germany, ⁴Institute of Medical Genetics, Charité-Universitätsmedizin Berlin, Berlin, Germany.

Czech dysplasia (OMIM 609162) is a novel type II collagen disorder which is phenotypically distinct from other COL2A1-related diseases. Czech dysplasia is characterized by early-onset progressive pseudo-rheumatoid arthritis, short third and fourth metatarsals, mild platyspondyly, normal height, and the absence of ophthalmological problems or cleft palate. The disorder is caused by a specific missense mutation (R275C, c.823C>T) in the triple helical domain of the COL2A1 gene. We report a large German family consisting of 11 patients who not only suffered from the typical features mentioned above, but who also had sensorineural hearing loss, a problem that has hitherto not been considered as a major feature of Czech dysplasia. Mutation analysis revealed the COL2A1 c.823C>T (R275C) mutation in all patients. This finding provides further evidence that Czech dysplasia is caused exclusively by the R275C mutation, which is a unique situation among the COL2A1 disorders, and indicates that this amino acid exchange leads to specific structural changes of type II collagen. The clinical and radiological data of this family and previously reported patients with

the R275C mutation demonstrate a remarkably uniform manifestation of the pathological features and add hearing loss to the list of major problems of Czech dysplasia.

P01.129

Clinical and molecular characterization of Diastrophic Dysplasia in the Portuguese population

M. Barbosa¹, E. Almeida², A. Oliveira³, N. Alegrete⁴, C. Alves⁵, A. Sousa⁶, A. Medeira⁶, J. Saraiva⁷, J. Pinto-Basto⁸, G. Soares¹, A. Fortuna¹, A. Superti-Furga⁹, L. Mitzaz¹⁰, L. Bonafé¹⁰, M. Reis-Lima¹;

¹Centro de Genética Médica Jacinto Magalhães, Oporto, Portugal, ²Serviço de Ortopedia, Hospital de Crianças Maria Pia, Oporto, Portugal, ³Serviço de Ortopedia, Hospital Geral de Santo António, Oporto, Portugal, ⁴Serviço de Ortopedia, Hospital de São João, Oporto, Portugal, ⁵Serviço de Ortopedia, Centro Hospitalar do Funchal, Funchal, Portugal, ⁶Serviço de Genética Médica, Hospital de Santa Maria, Lisboa, Portugal, ⁷Serviço de Genética Médica, Hospital Pediátrico, Coimbra, Portugal, ⁸Centro de Genética Preditiva e Preventiva, Instituto de Biologia Molecular e Celular, Oporto, Portugal, ⁹Department of Pediatrics, Centre for Pediatrics and Adolescent Medicine, Freiburg University Hospital, Freiburg, Germany, ¹⁰Division of Molecular Pediatrics, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland.

Diastrophic dysplasia (DTD; MIM #222600) is an autosomal recessive chondrodysplasia, characterized by limb shortening, hitchhiker thumbs, spinal deformities and contractures. Diagnosis is confirmed by molecular testing of the sulphate transporter *SLC26A2* gene. *SLC26A2*-related dysplasias encompasses a range of disease: from lethal achondrogenesis type 1B and atelosteogenesis type 2 (AO2) to classical DTD and mild recessive multiple epiphyseal dysplasia (rMED). Genotype-phenotype correlations have been described. This study aimed at characterizing clinically, radiologically and molecularly, 14 patients and 3 fetuses affected by *SLC26A2*-related dysplasias and to evaluate genotype-phenotype correlation. The main Portuguese Departments of Genetics and Orthopaedics were contacted in order to recruit patients from all the country.

Phenotypically, 8 patients were classified as classical DTD, 3 patients as rMED, and 3 patients had an intermediate phenotype (mild DTD). Foetuses had a homogenous presentation of severe DTD/AO2. Molecular analysis showed that the R279W mutation is present in all living patients, in homozygosity in rMED and in compound heterozygosity with the known severe allele R178X in classical DTD.

This report shows the clinical and molecular spectrum of *SLC26A2*-related skeletal dysplasias in the Portuguese population. R279W mutation in homozygosity causes rMED and the association of this mild allele with a null mutation causes classical DTD. The "Finnish mutation", was not found and is probably very rare in the Portuguese population. The data of this series indicate that screening for common *SLC26A2* mutations allows to confirm the diagnosis in the majority of Portuguese patients or at least to identify one pathogenic allele.

P01.130

Compound heterozygosity for GDF5 in Du Pan type chondrodysplasia

S. Douzou^{1,2}, K. Lehmann³, R. Mingarelli¹, S. Mundlos³, B. Dallapiccola^{1,2};

¹IRCCS-C.S.S. San Giovanni Rotondo and C.S.S. Mendel Institute, Rome, Italy, ²Department of Experimental Medicine, Sapienza University, Rome, Italy, ³Institut für Medizinische Genetik, Universitätsmedizin Berlin Charité, Berlin, Germany.

Du Pan type Chondrodysplasia (DPC) represents the milder end of the Growth Differentiation Factor 5 (GDF5) morphopathies which, according to an increasing gradient of clinical severity, include also the Hunter-Thompson type and the Grebe type acromesomelic chondrodysplasias. DPC is characterised by mild short stature, complex brachydactyly, and fibular aplasia. Affected individuals are homozygotes for loss-of-function mutations in the highly conserved mature domain of GDF5 that result in an impaired GDF5 signaling through the Bone Morphogenetic Protein Receptor 1B (BMPR1B). We investigated a 20 month-old child with complex brachydactyly and mild proximal fibular hypoplasia, consistent with DPC, in the absence of short stature and other long bones' and joints' anomalies. Mutational analysis disclosed compound heterozygosity for two novel GDF5 mutations, the P436T mutation in the mature domain, that most likely results in reduced binding to BMPR1B and the R378Q mutation at the end of the prodomain. The mutation R378Q is located within the recognition motif at the processing site

of GDF5 where the precursor protein is cleaved and probably results in at least a partial loss of protein function. Metacarpophalangeal profile (MCP) analysis on radiographs of the parents disclosed unremarkable results for the P436T mutation, transmitted from the mother, while the father's R378Q mutation was associated with a MCP showing overlap with BDA1, including brachymesophalangy of all digits and mild shortening of the entire first digit. This observation connects DPC with the BDA1 phenotype and further expands the clinical variability of GDF5 associated phenotypes.

P01.131

Early recognition of Ellis van Creveld syndrome: report of a new case

V. Plaiaşu, G. Motei, F. Nedelea, E. Neagu, M. Iordachescu; IOMC Prof.dr.Alfred Rusescu, Bucharest, Romania.

Ellis van Creveld is a rare chondro-ectodermal dysplasia characterized by short ribs, polydactyly, growth retardation and ectodermal defects. Significant findings in the general survey of our male case were narrow thorax, postaxial polydactyly of the hands, bones deformities with extremities markedly shortened, dysplastic fingernails, neonatal teeth, respiratory distress due to narrow chest.

Aspects of the ribs and dystrophic nails are the major criteria in establishing the diagnosis. It may be differentiated from other chondrodysplasias or syndromes associated with polydactyly.

Early recognition is important in order to identify the real diagnosis, to know evolution and prognosis and to offer proper genetic counselling. Prognosis of our case is linked to the respiratory difficulties.

New molecular findings in Hypochondroplasia: clinical, radiological and molecular review of a cohort of 15 Portuguese patients

M. Gonçalves-Rocha¹, G. Soares¹, J. Pinto-Basto¹, M. Martins¹, F. Macedo², M. Almeida³, B. Campos-Xavier^{3,4}, H. G. Santos³, M. Reis-Lima¹;

¹Centro de Genética Médica, Porto, Portugal, ²SMIC - Serviço Médico de Imagem Computorizada, Porto, Portugal, ³GenoMed, Diagnósticos de Medicina Molecular SA, Lisboa, Portugal, ⁴Division of Molecular Pediatrics, Centre Hospitalier Universitaire Vaudois (currently affiliation), Lausanne, Switzerland.

Short stature in childhood is a frequent clinical presentation, being 1% of these cases due to bone dysplasias. Achondroplasia (Ach;MIM#100800)/ Hypochondroplasia (Hch;MIM#146000) are the two most common autosomal dominant skeletal dysplasias. FGFR3 gene is the only currently known gene to be implicated.

In Hch, p.N540K mutation in tyrosine-kinase domain 1 accounts for up to 65% of cases.

These two conditions have overlapping phenotypes characterized by disproportionate short stature with rhizomelic limb shortening, Ach being more severe.

We reviewed 13 probands and their first relatives (16 patients) followed at our Genetics Clinic with diagnosis of Hch. Clinical and radiological findings were assessed independently by two clinical geneticists. Differential diagnosis were considered and systematically excluded whenever indicated.

Molecular study of FGFR3 gene was performed in all cases.

Seven mutations were identified in 16 patients: three N540K, one rare mutation R200C (described once) and a new mutation p.E360K in a pair of sibs and their mother.

When there is a high (clinical/radiological) suspicion of hypochondroplasia, and after negative mutation scanning, full sequencing FGFR3 coding region is indicated.

This allows a higher detection rate uncovering rare/new mutations. In our series one new mutation and another rare one were identified by this method.

Sequencing of FGFR3 coding region was negative in 7 patients. These patients also have clinical and radiological features within the spectrum of Hch. In these patients hypochondroplasia is most probably not FGFR3 related, raising attention to the role of other unknown (at the moment) genes may play in this condition.

P01.133**White matter abnormalities in siblings with Goldberg Shprintzen syndrome**

J. Pilch¹, J. D. H. Jongbloed², E. Kluczevska³, P. M. Grootsholter², E. Emich-Widera¹, E. Marszał¹;

¹Department of Child Neurology, Medical University of Silesia, Katowice, Poland, ²Departments of Genetics, UMCG, University of Groningen, Groningen, The Netherlands, ³Department of Radiology Zabrze, Medical University of Silesia, Katowice, Poland.

Goldberg Shprintzen syndrome (OMIM 609460, GOLDBERG-SHPRINTZEN MEGACOLON SYNDROME - GOSHS) is rare syndrome of congenital malformations with autosomal recessive pattern of inheritance. The most frequent manifestations are: mental retardation, microcephaly with accompanying dysmorphic features, and Hirschsprung disease. The syndrome is a result of mutations in KIAA1279 gene, which function is still poorly understood. It is possible that incorrect function of the gene product is a cause of abnormal migration of neurons, thus in addition to Hirschsprung disease, a brain developmental defects e.g. polymicrogyria, pachygyria or agenesis of corpus callosum is observed. There is just few reports in the literature describing GOSHS, including one reporting an abnormal intensity of white matter signals. Here we report two brothers with GOSHS symptoms and mutation found in KIAA1279 gene. The MRI revealed in one patient evidence of cranio-facial dysmorphism, asymmetry and dilatation of the ventricular system, and partial agenesis of corpus callosum. Additionally, in both patients discrete stranded regions of high intensity signals along the Roland's sulci, in the both internal capsules and lateral parts of the thalamus were found. Also, in both patients abnormal values of evoked potentials were observed. The clinical symptoms were variable in GOSHS, similarly like in most such syndromes. In one patient the features of Hirschsprung's disease did not occur but in the other one they were of mild intensity. Changes in the MRI pattern of the brain not seen in this syndrome until now and systematic description of clinical features are valuable additions to clinical characterization of GOSHS.

P01.134**Two new cases of Hajdu-Cheney Syndrome and further syndrome delineation**

R. Posmyk¹, K. Kozłowski², E. Huber³, A. T. Midro¹;

¹Department of Clinical Genetics, Medical University, Białystok, Poland, ²Royal Alexandra Hospital for Children, Sydney, Australia, ³Maxillo-Facial Surgery Clinic, Medical University, Białystok, Poland.

Hajdu-Cheney syndrome (HCS) (102500#OMIM) is a rare disorder characterised clinically by small stature and distinctive face. Diagnostic radiographic features consist of acro-osteolysis and unique dysplastic skull changes. We report on two new HCS cases a 9 and 16-year-old boys full filing inclusion criteria by Brennan and Pauli (2001). A detailed phenotype description of each boy is given and evaluated together with 23 other published case reports with the aim to delineate the spectrum of clinical and anthropological features. A catalogue of nearly 900 well-defined traits according to Stengel-Rutkowski *et al* (1996) with own modification was used. Sixty dysmorphological, clinical and radiographic features were put into the quantitative phenotype definition of HCS syndrome. Additionally, a variety of clinical (hearing loss, vocal scale limited to lower tones, delayed fontanel closure, delayed dental eruption, open bite, depressed sternum) and radiological findings (Wormian bones, acro-osteolysis, generalized osteoporosis) were taken into account. As molecular basis of this entity remains unknown, we believe that quantitative phenotype definition of HCS can be helpful for early diagnosis, before acro-osteolysis, the decisive diagnostic sign, develops.

P01.135**Familial Hanhart Syndrome in a Newfoundland Kindred**

C. Li;

McMaster University Medical Center, Hamilton, ON, Canada.

Hanhart syndrome, also known as oligodactyly-hypoglossia, adactyloglossia or oromandibulo limb hypoplasia syndrome because of the cardinal signs of limb and tongue anomalies associated with abnormal mandibular development, is a rare genetic condition that usually happens sporadically and is assumed to be the consequences of either a vascular disruption event or a new dominant mutation. A Newfound-

land kindred spanning 4 generations is believed to have this condition where affected members manifest ulnar ray defects, oligodactyly and ankyloglossia with highly variable expressivity amongst the affected. Development, intelligence, stature and overall health are normal for these individuals. To my knowledge, this is the first report of familial cases of this genetic condition. Its presence confirms autosomal dominant inheritance as one underlying etiology.

P01.136**Holt-Oram syndrome - case report**

M. C. Panzaru, C. Rusu, M. Volosciuc, M. Covic;

Medical Genetics Centre, Iasi, Romania.

Holt-Oram syndrome (HOS) is an autosomal dominant condition with variable expressivity characterized by the association of congenital heart defects and preaxial radial ray upper limb defects. We present a new case in order to illustrate this rare entity and to discuss the variable expression and the management. Our proband is a 13,5 old male, the only child of an unrelated couple. Father presents absence of the left thumb, short left limb, cardiac failure. No fetal ultrasound scan was performed. The proband was born naturally at 37 weeks gestation (Wt-2450g, Ht-46,5cm, HC-36 cm, Apgar score 7). Postnatal development was relatively normal. Physical examination (13y old) revealed: Wt - 2,52 SD, short limbs with absence of forearms, bilateral absence of thumbs, absence of left forefinger. Radiological examination showed bilateral absence of radius and ulna. Echocardiography: ASD ostium secundum; ECG: first-degree atrioventricular block. We have established the diagnosis of HOS based on the characteristic association of congenital heart defects and upper limbs defects. Differential diagnosis was done with other heart-hand syndrome. The plan for the management and the genetic counseling will be presented. In conclusion, we present a case of HOS in order to illustrate this rare genetic disorder but also to discuss the variable expression, the management and the genetic counseling.

P01.137**Spinal abnormalities, Klippel-Feil syndrome and the Mayer-Rokitansky-Küster-Hauser syndrome: four case reports**

T. Rebai, R. Badraoui, F. Kallebi, R. Louati, N. B. Abdelmoula;

Medical University, Sfax, Tunisia.

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome is characterized by congenital aplasia of the uterus and the upper part (2/3) of the vagina and is regarded as an inhibitory malformation of the Müllerian ducts. MRKH may be isolated but it is more frequently associated with renal, vertebral, and, to a lesser extent, auditory and cardiac defects (MURCS association). The molecular basis for the MRKH syndrome is currently unknown.

We describe four female patients in whom diagnosis of MRKH syndrome was confirmed. All complained of primary amenorrhea associated with cyclic pelvic pain and presented normal sexual development, normal levels of FSH, LH and 17beta estradiol, 46,XX karyotype and congenital absence of the uterus and upper vagina.

The first patient presented short neck, low-set posterior hairline, limited neck motion and fusion of cervical vertebrae associated with unilateral elevated scapula. The second patient presented low-set posterior hairline, short neck with very limited neck motion and fusion of cervical vertebrae associated with unilateral elevated scapula, cyphoscoliosis, asymmetrical breast development, dental abnormalities and flat feet. A familial history with a Sister complaining of secondary amenorrhea with low-set posterior hairline, minor scoliosis and flatfeet, was recorded. The described skeletal deformity in these 2 females, were consistent with Klippel-Feil syndrome.

The third patient presented low-set posterior hairline, short neck, shield-like chest and scoliosis. She presented also dental deformities, *cafe-au-lait spots* and many nevus spilus and vascularis. An history of two azoospermic maternal uncles was recorded. The fourth patient presented a minor scoliosis and asymmetrical hips.

P01.138**Clinical and molecular diagnosis of ADULT syndrome in a pregnant woman**

A. Wischmeijer¹, C. Graziano¹, M. Gnoli¹, R. Bocciardi², R. Ravazzolo², M. Serì¹;

¹U.O. Genetica Medica, Bologna, Italy, ²U.O. Genetica Molecolare e Citogenetica, Genova, Italy.

A 29 year old woman affected by ectodermal dysplasia came to our attention during her 1st pregnancy, asking about the risk of recurrence in her children and the possibility of diagnostic prenatal testing.

No relatives were reported to be affected and the patient's parents were not consanguineous. Ectodermal dysplasia was suspected in childhood because of hypodontia, corneal dystrophy, sparse hair, thin skin and dystrophic nails, but a specific diagnosis had never been formulated.

Upon clinical examination we noticed, besides classical signs, mild dysmorphic features: deep-set eyes with upward-slanted and short palpebral fissures, high forehead, low nasal bridge. Moreover, we noticed bifid uvula, freckling and absence of nipples, which led us to hypothesize involvement of the p63 gene. In fact, molecular analysis of p63 identified the presence of a Gly134Val mutation, previously described in a patient with ADULT syndrome. p63 mutations can give rise to a spectrum of partially overlapping phenotypes, from ADULT syndrome to limb-mammary and EEC syndrome, all transmitted with an autosomal dominant pattern.

Absence of the mutation in the parents proved its de novo origin. Our patient underwent CVS for fetal molecular analysis and, fortunately, the mutation was not transmitted to the fetus.

Due to limited time availability, it is seldom possible to successfully resolve a molecular diagnosis during pregnancy without pre-conceptual analysis. Thanks to careful clinical examination, the availability of an efficient laboratory and prompt familial involvement, our proband received the result of prenatal testing in less than one month from the 1st counselling session.

P01.139**Variable expression in a familial case of Pfeiffer Syndrome with FGFR1 P252R mutation**

K. Ludwig¹, C. Daolio¹, L. Salvati¹, M. Bald², I. Mura², M. Clementi¹, R. Tenconi¹;

¹Servizio di Genetica Clinica, Padova, Italy, ²Laboratorio di Genetica, E.O. Ospedali Galliera, Genova, Italy.

A 4 year and six month old boy was diagnosed with Pfeiffer syndrome on the basis of bilateral coronal craniosynostosis, skin syndactyly of toes, brachydactyly, broad thumbs and big toes and characteristic facial dysmorphisms.

Close examination of the patient's family revealed flattening, bilateral soft tissue hypertrophy, foreshortening and medial deviation of the great toes as well as mild bilateral proptosis in the mother and in the older brother. The brother also had partial skin syndactyly of toes, broad thumbs and camptodactyly of the left fifth finger. Neither the mother, nor the brother showed any signs of craniosynostosis.

Molecular analysis of the FGFR1 gene revealed the P252R mutation in all three family members.

Several articles have documented the high clinical variability and genetic heterogeneity in individuals affected by Pfeiffer syndrome.

As far as we know this is the first case of an affected family with the common FGFR1 P252R mutation in which just the proband has the full-blown syndrome, whereas the other two affected persons show characteristic feet anomalies without skull involvement, underlining the broad intrafamilial variability of expression.

P01.140**Molecular analysis of a Case of Pfeiffer Syndrome**

M. Nateghi, M. Rostami, T. Majidzadeh, M. Dehghan Manshdi, M. Houshmand;

Special Medical Center, Tehran, Islamic Republic of Iran.

Pfeiffer syndrome is a rare autosomal dominantly inherited osteochondrodysplasia with craniosynostosis conditions that is genetically heterogeneous that can be caused by mutations in the fibroblast growth factor receptor 2 (FGFR2) gene. The FGFR2 gene provides instructions for making a protein called fibroblast growth factor receptor 2. More than 20 FGFR2 mutations that cause Pfeiffer syndrome have

been identified. Several of these mutations change the number of cysteine amino acids in a critical region of the FGFR2 protein known as the IgIII domain.

Sporadic cases of Pfeiffer syndrome have previously been associated with advanced paternal age.

The patient in our study was a 2 years old male baby. His parents were healthy both under 25 years and they were not consanguineous. Labor began spontaneously and the infant was delivered vaginally at term with a birth weight of 2,975 g with the Apgar score of 8-9. The proband had a cloverleaf skull, severe exorbitism, choanal atresia, low-set and posteriorly-rotated ears, broad and medially-deviated halluces and partial cutaneous syndactyly of the second and third toes. The ocular globes and eyelids were intact with shallow orbits that would have prevented the replacement of the eye. The ocular anterior structures were preserved, without iris or lens abnormalities. The baby developed respiratory distress.

Molecular analysis of the patient revealed a heterozygous C342R mutation in exon 10 and a missense T → C in mRNA further studies on such sporadic cases recommended enhancing the molecular information.

P01.141**Combination of Saethre-Chotzen and Greig syndromes in one family: the phenotype of a proband**

S. Holubeva¹, N. Rummyantseva²;

¹Vitebsk Regional Diagnostic Center, Vitebsk, Belarus, ²Belarusian Medical Academy of Postgraduate Education, Minsk, Belarus.

We present a female child (5-year-old), from a family with the features of cephalopolysyndactyly (Greig syndrome) in her mother (30-year-old), and acrocephalosyndactyly (Saethre-Chotzen syndrome) in her father (28-year-old) and paternal grandfather (61-year-old). Both syndromes are autosomal dominant, minimal diagnostic criteria for the first are syndactyly, polydactyly and cranial anomalies, for the second - cranial synostosis with skull asymmetry, 2-3 toes syndactyly. The mother's phenotype consisted of cranial anomalies (protrudent frontal tubers, hypertelorism, wide bridge of the nose), anomalies of extremities (postaxial polydactyly of the right hand; moderately wide nail bones of the first fingers of both hands; preaxial polydactyly and full 1-2-3 toes syndactyly of the right foot; preaxial polydactyly with total toes hypoplasia and full 1-2-3 toes syndactyly of the left foot). Clinical features of both the father and the grandfather included macrocephalia, facial asymmetry, nasal septum deviation, partial 2-3 toes syndactyly. The child showed a combination of cranial anomalies (macrocephalia, facial asymmetry, nasal septum deviation, antimongoloid slant, wide bridge of the nose), epicanthus of both eyes, low-set ears, anomalies of extremities (postaxial polydactyly, preaxial polydactyly with full syndactyly and common nail plate of both hands; postaxial polydactyly, partial 2-3 and 4-5 toes syndactyly, full 3-4 toes syndactyly of the right foot; postaxial polydactyly and full 2-3-4 toes syndactyly of the left foot). Thus, the proband has inherited the signs of both syndromes, this means realization of their 50% of probabilities. The fact significantly increases the risk for further generations, which should be taken into account during genetic counseling.

P01.142**Short rib-polydactyly syndrome on three consecutive pregnancies**

N. B. Abdelmoula¹, M. Trifa², H. Amouri¹, H. Amouri³, R. Badraoui¹, R. Louati¹, F. Kallebi¹, T. Rebai¹;

¹Medical University, Sfax, Tunisia, ²Urology of Private Sector, Sfax, Tunisia,

³Department of Gynecology, Sfax, Tunisia.

Short rib polydactyly syndromes are lethal skeletal dysplasias with an autosomal recessive inheritance pattern that can be distinguished on radiological and histological grounds. We report on three consecutive pregnancies complicated by a short rib-polydactyly syndrome that was difficult to categorize. Parents from North of Africa were consanguineous (second degree). The third fetus aborted at 22 weeks' gestation because of abnormalities visualized on sonography, has been radiologically and histologically explored.

He presented shortened ribs with thoracic hypoplasia, short limbs with postaxial polydactyly of hands and feet, cystic hygroma and facial dysmorphism.

The skeletal changes observed included shortened ribs and shortened

curved radii, ulnae, tibiae and fibulae

In autopsy, multiple visceral abnormalities of major organs such as bilateral polycystic kidney and intestinal malrotations were detected. Based on radiological criteria and the pattern of associated abnormalities, short rib-polydactyly syndrome type IV or Beemer-Langer type was retained as diagnosis. The differential diagnosis of this entity is discussed.

P01.143

Ellis-Van Creveld syndrome, with bilateral sensory-neural hearing loss: report of a case and literature review

B. Bozorgmehr, F. Afroozan, V. Hadavi, M. H. Kariminejad;

Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Islamic Republic of Iran.

Ellis-Van Creveld syndrome is a constellation of chondral, ectodermal and cardiac defects. It is a rare autosomal recessive syndrome with variable expression. This syndrome is also known as chondroectodermal dysplasia and mesoectodermal dysplasia. The main features are short stature, short ribs, polydactyly, dysplastic fingernails and teeth, accompanied by heart defects. We are reporting a 2-year-old girl referred to our genetics center with dwarfism, mesomelic short limbs, narrow thorax, funnel chest, short ribs, oligodontia, oral frenula, post-axial polydactyly of fingers and deafness. Her clinical findings are compatible with Ellis-Van Creveld Syndrome. We believe that this is the first Ellis-Van Creveld Syndrome with sensory-neural hearing loss.

P01.144

Skeletal dysplasia with amelogenesis imperfecta- report of a third family

O. Caluseriu^{1,2}, M. Cholette¹, M. A. Copete³, U. Amendy^{1,2}, J. J. Howard^{1,2}, R. D. McLeod^{1,2};

¹Alberta Children's Hospital, Calgary, AB, Canada, ²University of Calgary, Calgary, AB, Canada, ³Royal University Hospital, Saskatoon, AB, Canada.

Platyspondyly is a frequent feature in skeletal dysplasias, but an association with amelogenesis imperfecta has only been reported twice. Verloes and colleagues (1996) described two siblings of Moroccan origin with consanguineous parents, who had mild growth retardation, platyspondyly, dysplastic femoral necks, amelogenesis imperfecta and oligodontia. They proposed their case to be a new subtype of brachyolmia with amelogenesis imperfecta. A third case was described in a separate paper (Houlston et al, 1994). We present three additional cases from a sibship of five. The affected children, two girls and a boy of 16, 9, and 12 years of age are non-dysmorphic and of normal intelligence. They have short trunk short stature (-5SD, 3-10 centile and respectively -3SD) with platyspondyly and oligodontia. The oldest girl has an S shape scoliosis mid-thoracic to lumbar spine that required surgery and bilateral coxa valga. The other two siblings have osteopenic bones and lower thoracic-lumbar scoliosis. Recurrent dental abscesses were noted and a subsequent diagnosis of amelogenesis imperfecta was confirmed by dental pathology. The parents first cousins of Pakistani origin are healthy and of normal stature. We provide further evidence for a new AR previously proposed condition. Known genes involved in amelogenesis imperfecta (including AR forms) do not explain concurrent skeletal abnormalities.

P01.145

From a multimalformed baby to a new skeletal dysplasia

C. O. Barbosa¹, D. P. Cavalcanti²;

¹UNICAMP, Campinas, Brazil, ²UNICAMP, Campinas - SP, Brazil.

In a number of cases skeletal dysplasias (SD) can be associated with other malformations not related to the bone system, but usually the diagnosis of SD is early after birth. In this presentation we report a case of a multimalformed boy, firstly thought representing a VACTER association, which afterward revealed an unusual skeletal dysplasia. The infant was born at term by caesarean section weighting 2.130 g, 46 cm height, and HC of 34 cm. Prenatal ultrasonography evaluation showed oligohydramnios and absence of right kidney. Soon after birth additional minor dysmorphisms and major anomalies were detected: prominent metopic suture, up-slanting palpebral fissures, bilateral epicanthal folds, ulnar deviation of 4th-5th fingers, syndactyly of the 2nd-3rd toes, prominent calcaneus, esophageal atresia with distal fistula, mild ventricular dilatation with tricuspid insufficiency and pulmonary hypertension, dilated bile ducts, and moderate ventricular dilatation sugges-

tive of cerebral atrophy. No skeletal anomalies were observed at this time. Karyotype was normal - 46,XY. Mental retardation was evident in the follow up. At age of 6 years old short stature was evident. Bone age was normal, but the skeletal findings showed findings of SD with spondylo-epi-metaphyseal involvement and also some dyaphyseal lesions. At this time the mother reported two maternal uncles with short stature. As the skeletal lesions were suggestive of spondyloenchondrodysplasia, hydroxyglutaric aciduria investigation was performed, but results were normal. In conclusion, the patient here reported seems to represent a new pattern of SD associated with mental retardation and other no related skeletal anomalies.

Further evidence for a recessive form of SEMD resembling pseudoachondroplasia in a consanguineous family of Maghrebian origin

D. R. Amrom^{1,2}, N. Van Regemoorter³, Y. Sznajer⁴, G. Jackson⁵, M. Briggs⁵, G. Mortier⁶;

¹Hôpital Français, Brussels, Belgium, ²Center La famille, Brussels, Belgium,

³Department of Medical Genetics, Hôpital Erasme - ULB, Brussels, Belgium,

⁴Clinical Genetics, Hôpital Universitaire des Enfants Reine Fabiola - ULB,

Brussels, Belgium, ⁵Wellcome Trust Centre for Cell-Matrix Research, Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom, ⁶Department of Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Pseudoachondroplasia is an autosomal dominant disorder caused by mutations of the COMP gene. In 2005, Spranger et al. described two sibs with a spondyloepimetaphyseal dysplasia (SEMD) resembling pseudoachondroplasia but without a COMP mutation. We have identified a similar skeletal dysplasia in a dizygotic twin and maternal first cousin, born to consanguineous parents of Maghrebian origin. They presented around the age of 1 year with growth failure.

The proband is a 8-year-old girl with short-limb dwarfism (height at -7sd). She is of normal intelligence and has a normal head and face. Clinical features include mild obesity, lumbar hyperlordosis, hyperlaxity of finger and knee joints, metatarsus adductus and waddling gait. Radiographic evaluation reveals mild anterior protrusion of the central aspects of the vertebrae, abnormal pelvis with absent ossification of the femoral epiphyses, shortened tubular bones with small epiphyses and marked metaphyseal changes, and delayed carpal ossification. Similar radiographic changes are observed in her twin brother who in addition to short stature (height at -9sd) has microcephaly and tetraspasticity of unknown origin. A maternal first cousin was referred at the age of 7 years because of short stature (height at -3.5sd) and suspicion of pseudoachondroplasia. Sequence analysis of the COMP gene did not reveal any mutation in this boy.

We believe that the three children in this consanguineous family have the same skeletal dysplasia that resembles pseudoachondroplasia but shows autosomal recessive inheritance. No mutation in the COMP gene was identified suggesting a genetic defect in another gene important in bone growth and development.

P01.147

Omani type spondyloepiphyseal dysplasia with cardiac involvement caused by a new missense mutation in CHST3

B. Tüysüz¹, S. Turkmen², P. Nürnberg², K. Sugahara², A. Çelebi¹, S. Mundlos²;

¹Istanbul University, Cerrahpaşa Medical Faculty Department of Pediatric Ge-

netics, Istanbul, Turkey, ²Universitätsklinikum Berlin, Charité Virchow-Klinik, Berlin, Germany.

We present three patients with a spondyloepiphyseal dysplasia, brachydactyly and cardiac involvement in a large inbred Turkish family. A genome wide scan using the 250K Affymetrix SNP chip revealed a locus for homozygosity on chromosome 10q23. This interval includes an obvious candidate, Chondroitin 6-O-sulfotransferase-1 (C6ST-1) gene (CHST3), previously shown to be mutated in Spondyloepiphyseal Dysplasia (SED) Omani type. Focusing on CHST3, we amplified the coding region of the CHST3 and identified a homozygous missense mutation (T141M) in the exon 3 of the CHST3 gene in all three of the affected members of the family. Using recombinant C6ST-1, it could be shown that the identified missense mutation reduced the activity of C6ST-1 to 24-29%. This is the second description of SED Omani type further supporting this skeletal dysplasia as a distinct clinical entity. Our patients shared the following features: short trunk stature, progressive spinal involvement, brachydactyly, camptodactyly, irregular-

ity of the endplates of the vertebral bodies, narrowed intervertebral space and small and irregular epiphyses as described by Rajab et al. (Am J Med Genet 2004;126:413) in Omani family. When compared phenotypically to Omani's family, all our patients had also minor facial changes and most importantly they all had a cardiac involvement like mitral, tricuspid and aortal regurgitations, which were not described. The differences in clinical outcome are likely to be due to differences in the nature of the mutation. The original SED Omani mutation resulted in a complete loss of function whereas T141M appears to have residual function.

P01.148

Tibial Developmental Field Defect is the most Common Lower Limb Malformation Pattern in VACTERL Association

M. Castori¹, R. Rinaldi¹, S. Cappellacci¹, P. Grammatico^{1,2};

¹San Camillo-Forlanini Hospital, Rome, Italy, ²La Sapienza University of Rome, Rome, Italy.

VACTERL association is one of the most common recognizable patterns of human malformation and has been recently defined as a multiple polytopic developmental field defect. Limb anomalies are a key component of this condition and characteristically reflect perturbation of radial ray development. However, the pattern of appendicular malformations in VACTERL association is wider and includes a broad spectrum of additional and apparently unspecific anomalies. We report on the sporadic case of a 4-10/12-year-old boy presenting with multiple costo-vertebral defects, dextrocardia, bilateral radial ray hypo/aplasia, unilateral kidney agenesis and anal atresia. Homolaterally to the more severe radial ray defect and kidney aplasia, he also has a complex lower limb malformation, consisting of distal tibial aplasia, clubfoot, hallucal deficiency and preaxial polydactyly. Literature review identifies 24 additional patients with VACTERL manifestations and lower limb malformations (excluding cases with isolated secondary deformations). Tibial hypo/aplasia with or without additional tibial field defects, reported in about 2/3 (68%) of the patients, represents the most common finding, while involvement of the fibular ray is rare (20%) and very often accompanies tibial anomalies. The relatively high frequency of tibial ray anomalies in VACTERL patients could easily be explained by the principle of homology of the developmental field theory. Careful search of lower limb anomalies of the "tibial type" is, therefore, indicated in all patients with multiple polytopic developmental field defects.

P01.149

Hypoplasia of tibia with polysyndactyly (Werner syndrome) is allelic to preaxial polydactyly II (PPD2) and caused by a point mutation in the distant Sonic Hedgehog (SHH) cis-regulator (ZRS)

D. Wiczorek¹, B. Pawlik², N. A. Akarsu³, G. Gillissen-Kaesbach^{1,4}, Y. Hellenbroich^{1,4}, S. Lyonnet⁵, F. R. Vargas⁶, B. Wollnik²;

¹Institut für Humangenetik, Essen, Germany, ²Institut für Humangenetik, Köln, Germany, ³Hacettepe University Pediatric Hematology Gene Mapping Laboratory, Ankara, Turkey, ⁴Institut für Humangenetik, Lübeck, Germany, ⁵Département de Génétique et Unité INSERM, Paris, France, ⁶Centro de Genética Médica, Rio de Janeiro, Brazil.

Tibial hypoplasia, preaxial polydactyly of hands and feet and/or a five-fingered hand with absence of thumbs was first described by Werner in 1915 (MIM 188770). This autosomal dominant condition is variable and no causative mutations have been described so far.

Here we describe an adult Turkish patient with short stature, shortening of forearms, and preaxial polydactyly of hands. His femora are mildly and his lower legs are severely shortened. He had preaxial polydactyly of feet, the supernumerary toe was surgically removed. The clinical diagnosis hypoplasia of tibia with polysyndactyly was established. The patient's father has a preaxial polydactyly of his right hand. We performed mutational analysis in the *Sonic Hedgehog* (*SHH*) gene and *SHH* regulatory region (ZRS) located in intron 5 of the *LMBR1* gene. A transition (G>A) at position 404 of the ZRS, which was previously reported as the Cuban mutation of the preaxial polydactyly type II (PPD2)-phenotype (Zguricas et al., 1999; Lettice et al., 2003) was identified in the patient and his father. Single nucleotide substitutions in the ZRS regulatory region, also described in the Hemingway's Cats, operate as gain-of-function mutations that activate *Shh* expression at an ectopic embryonic site (Lettice et al., 2007). Currently, molecular

studies including copy number analysis of the ZRS and *SHH* regions are done in additional families with Werner syndrome, triphalangeal thumb-polysyndactyly syndrome and polysyndactyly type Haas.

In summary, we identified the molecular cause of Werner syndrome in our patient and confirmed the previously suggested hypothesis that Werner syndrome is allelic to PPD2.

P01.150

Fetal phenotype of three cases of campomelic dysplasia harbouring novel mutations of SOX9 gene

B. Gentilin¹, F. Forzano², F. Faravelli³, M. Bedeschi¹, M. Baffico², M. Lituanja³, P. Ficarazzi⁴, T. Rizzuti⁵, P. Bianchi⁶, F. Lalatta¹;

¹UOS Dipartimentale di Genetica Medica, Fondazione IRCSS Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milano, Italy, ²Medical Genetics Unit; E.O. Ospedali Galliera, Genova, Italy, ³Fetal Medicine Unit; E.O. Ospedali Galliera, Genova, Italy, ⁴Obstetric and Gynaecologic Unit; Fondazione IRCSS Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milano, Italy, ⁵Pathological Unit, Fondazione IRCSS Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milano, Italy, ⁶Neonatal Intensive Care Unit, Ospedali Riuniti di Bergamo, Bergamo, Italy.

Campomelic dysplasia (CD) is a rare congenital skeletal disorder characterized by bowing of the long bones and a variable association of other skeletal and extraskeletal defects, with or without XY sex reversal.

CD is caused by mutations in the SRY-box 9 gene (*SOX9*), a dosage-sensitive gene expressed in chondrocytes and other tissues and located at 17q24. The correlation between the campomelic dysplasia genotype and phenotype is still unclear.

In the prenatal period the most characteristic sign of campomelic dysplasia is the shortening and marked anterior bowing of long bones, particularly of femur and tibia. Narrow chest, scoliosis, talipes equinovarus, and flat facial profile are other sonographic features commonly present. Increased nuchal translucency, polyhydramnios, and anomalies of the central nervous, cardiac, and renal systems have also been described.

We report three cases of campomelic dysplasia suspected in the first or second trimester of pregnancy by prenatal ultrasound. The pregnancies were all terminated and the diagnosis of campomelic dysplasia has been confirmed on clinical and radiographic examination of the fetuses.

In the three cases molecular analysis detected three novel mutations in the *SOX9* gene which occurred de novo.

The protocol which allowed the specific diagnosis of this rare condition will be presented.

P01.151

Prenatal diagnosis and management of a patient affected by Kniest dysplasia.

M. F. Bedeschi¹, V. Bianchi¹, L. Colombo², F. Natacci¹, S. Giglio³, E. Andreucci³, L. Trespidi⁴, B. Acaia⁴, G. Canepa¹, F. Lalatta¹;

¹Clinical Genetics Unit, Fondazione IRCCS, Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milano, Italy, ²Neonatal Intensive Care Unit, Fondazione IRCCS, Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milano, Italy, ³Department of Clinical Pathophysiology and Medical Genetics Unit, AOU Meyer, University of Florence, Firenze, Italy, ⁴Obstetrics and Gynecology Clinic I, Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milano, Italy.

Patients affected by rare skeletal dysplasias may remain undiagnosed for a long time, until adulthood. In these cases a pregnancy might disclose several unexpected problems and special needs. We present the case of a 28 year old primigravida who was referred to our centre at 17 weeks of gestation with an undiagnosed skeletal dysplasia. Her clinical and radiological examination showed severe dwarfism characterized by spinal curvature anomalies including dorsal scoliosis, lumbar lordosis, platyspondyly, bell-shaped chest, pectus carinatum, drooping ribs, suggesting the diagnosis of Kniest dysplasia (MIM 156550) which is a rare, severe, chondrodysplasia characterized by short trunk and limbs, kyphoscoliosis, midface hypoplasia, severe myopia and hearing loss. The woman was then informed about the recurrence risk and offered ultrasound prenatal diagnosis. Ultrasound examination at 17-18-20 weeks revealed fetal macrocephaly, narrow thorax, shortening and bowing of long bones. Parents decided to continue the pregnancy informed about the clinical features of the fetus. The baby was deliv-

ered at the 33rd gestational week for maternal reasons He experienced severe respiratory distress for four weeks. Diagnosis was confirmed clinically and radiologically. Genomic DNA analysis revealed a new missense mutation in exon 54 (c4339 A>T) of the *COL2A1* gene. This case demonstrates the relevance of correct diagnosis even in the adult age, when people have the right to know: recurrence risk, risk of pregnancy and delivery and possible neonatal problems of the affected newborn.

P01.152

More surprises in *FGFR2*: atypical mutations in Apert syndrome

E. G. Bochkova¹, T. Rosciol², D. J. Hedges³, I. B. Taylor¹, A. Colley⁴, G. Elakis⁵, M. Buckley⁶, D. Johnson¹, D. J. David⁷, P. L. Deininger⁸, A. O. M. Wilkie¹;
¹Weatherall Institute of Molecular Medicine, Oxford, United Kingdom, ²Sydney South West Integrated Genetics Service, Royal Prince Alfred hospital, University of Sydney, Sydney, Australia, ³Tulane Cancer Center and Department of Epidemiology, Tulane University Health Sciences Center, New Orleans, LA, United States, ⁴Department of Clinical Genetics, Liverpool Health Service, New South Wales, Australia, ⁵Australian Craniofacial Unit, Women's and Children's Hospital, Adelaide, Australia.

Apert syndrome (AS) is one of the most severe craniosynostosis syndromes, characterized by premature fusion of multiple craniofacial sutures and complex syndactyly of the hands and feet. Two heterozygous gain-of-function mutations (Ser252Trp and Pro253Arg) in fibroblast growth factor receptor 2 (*FGFR2*) are responsible for >98% of AS cases. Here, we have identified different novel mutations in the *FGFR2* gene in the last two outstanding Apert patients with unidentified mutation from a cohort of 227 patients. One is a 1.9 kb deletion, removing the entire exon IIIc of the gene and substantial portions of the flanking introns. This is the first large *FGFR2* deletion described in any patient with craniosynostosis. The other mutation is a *de novo* *Alu* insertion into the IIIc exon of *FGFR2*. This is the third identified AS-related *Alu* insertion within 105 bp of sequence, a remarkable enrichment considering that only ~30 new *Alu* insertions have been described in all human diseases. Computational analysis revealed that the inserted *Alu* element belongs to a new subfamily, not previously known to be mobile, which we characterize and term *Alu* Yk. Previous analysis of an AS patient with *Alu* insertion, and a mouse model with an engineered exon IIIc deletion, indicate that both types of mutation are likely to cause AS by driving ectopic expression of an *FGFR2* isoform containing the alternatively spliced IIIb exon in mesenchymal tissues. We speculate that the *Alu* insertions, all of which have arisen on the paternal allele, are enriched because of positive selection during spermatogenesis.

P01.153

Mutations in aggrecan (*AGC1*) cause Dexter cattle chondrodysplasia

R. Savarirayan¹, J. Cavanagh², I. Tammen³, P. Windsor³, J. F. Bateman¹, F. Nicholas³, H. Raadsma³;

¹Murdoch Childrens Research Institute, Melbourne, Australia, ²University of Sydney, Camden, Australia, ³University of Sydney, Camden, Australia.

Lethal "bulldog" chondrodysplasia in Dexter cattle is one of the earliest Mendelian traits described in animals. Affected (homozygous) fetuses display extreme disproportionate dwarfism, a short vertebral column, marked micromelia, short ribs, large head with a retruded muzzle, cleft palate, protruding tongue, and abdominal hernia. Carriers (heterozygotes) show a milder phenotype, having rhizomelic limb shortening in addition to radiographic spinal abnormalities.

Homozygosity mapping in an Australian Dexter cattle pedigree identified the gene *AGC1* as a positional candidate. Homozygous *AGC1* mutations have been shown to cause the lethal chondrodysplasia, cartilage matrix deficiency (*cmd*) in mice and nanomelia in chicks. Heterozygous *AGC1* mutations cause dwarfism and shortened skeletal elements in mouse and chick, and a spondylo-epiphyseal dysplasia (Kimberley type) associated with severe premature joint and spinal arthritis in humans.

AGC1 mutation screening revealed a common 4bp insertion in exon 11 (2266_2267insGGCA) (BD1) and a second, rarer transition in exon 1 (-198C>T) (BD2) that co-segregated with the disorder. We performed allele-specific primer extension analysis of mRNA isolated from chondrocytes of cattle heterozygous for the common insertion (BD1) mutation. This demonstrated that mutant mRNA was subjected to non-

sense-mediated decay, showing only 7% of normal expression, suggesting haploinsufficiency for aggrecan as the pathogenetic basis for the carrier phenotype. Genotyping in Dexter cattle families worldwide has shown that these two mutations account for all cases and segregate fully with the heterozygous or homozygous phenotype. We anticipate that these Dexter cattle will prove extremely useful as a model for investigating and understanding corresponding human chondrodysplasias and arthritis phenotypes.

P01.154

Analysis of the Q289P mutation in the *FGFR2* gene: populational and computational studies

B. L. N. Passarinho, E. C. Freitas, V. L. Gil-da-Silva-Lopes;
 FCM, Campinas, Brazil.

The Q289P mutation in the *FGFR2* gene was identified in some individuals of a family with clinical features of a Saethre-Chotzen Syndrome (SCS). Considering the variable expressivity of this condition and in this specific family as well, some hypotheses were suggested. The aims of this study were to verify the prevalence of this mutation in different populations and to simulate the effects of this mutation by computational analyses. Three different populations were investigated: 40 individuals with syndromic craniosynostosis and 200 normal controls and all members clinically evaluated from mentioned family. This investigation also includes the search for mutations in hot spots for all individuals with craniosynostosis. Computational approaches were applied to simulate the effects of the mutation in the protein and predict its deleterious potential. Except by the patients in whom the Q289P mutation was previously detected, no more cases were identified. Simulated computational approaches indicated a deleterious potential. We suggested that the Q289P mutation is deleterious, rare and associated to the craniosynostosis phenotype only and not strongly related to the facial and neurological phenotype.

Key words: Craniosynostosis; Saethre-Chotzen; *FGFR2*; Mutation; SIFT; PolyPhen; Grantham

P01.155

Characterization of two translocation-associated ectrodactyly related loci in distal 2q14.1 and proximal 2q14.2 and the corresponding candidate genes

D. David¹, B. Marques¹, C. Pires¹, P. Vieira¹, C. Reis¹, S. Malveira¹, A. Corona-Rivera², J. C. Ferreira³, H. van Bokhoven⁴;

¹Centre of Human Genetics, National Institute of Health "Dr. Ricardo Jorge", Lisboa, Portugal, ²Department of Physiology, University of Guadalajara, Guadalajara, Mexico, ³Garcia de Orta Hospital, Almada, Portugal, ⁴Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Split hand-split foot malformation (SHFM) or ectrodactyly, is a heterozygous congenital defect of digit formation. The aim of this study is the mapping of the breakpoints and detailed molecular characterization of the candidate genes for an isolated form of bilateral split foot malformation (SFM) and for a syndromic form (holoprosencephaly, hypertelorism, and ectrodactyly syndrome (HHES)) both associated with *de novo* apparently balanced chromosome translocations involving the same chromosome 2q14.2 subband, [t(2;11)(q14.2;q14.2)] and [t(2;4)(q14.2;q35)], respectively. Breakpoints were mapped by fluorescence in situ hybridisation (FISH) using BAC clones. Where possible, these breakpoints were further delimited using PCR fragments as FISH probes. The identified candidate genes were screened for pathogenic mutations by direct sequencing. The SFM associated chromosome 2 breakpoint was localised at 120.9 Mb, between the two main candidate genes, GLI-Kruppel family member GLI2 (*GLI2*) and inhibin beta B (*INHBB*). No clear pathogenic mutation was identified in these. The second breakpoint associated with HHES was mapped 2.5 Mb proximal at 118.4 Mb and the candidate genes identified from this region were the insulin induced protein 2 (*INSG2*) and the homeobox protein engrailed-1 (*EN1*). In conclusion we have confirmed the presence of a new SHFM7 locus in the intergenic region between *INHBB* and *GLI2*. Furthermore, a locus for HHES is proposed 2.5 Mb proximal to the previous one. The molecular mechanism proposed for these congenital anomalies is a sequence of alterations induced by the positional effects introduced by the translocations leading to spatiotemporal misregulated expression of the candidate genes.

P01.156

FGFR2 mutations in Turkish patients with craniosynostosis syndrome by DHPLCS. Pehlivanoglu¹, E. Mihçip, H. Kayserilip, M. O. Caliskan¹, S. Tacoy², G. Luleci¹, O. M. Alper¹;¹Akdeniz University, Faculty of Medicine, Department of Medical Biology and Genetics, Antalya, Turkey, ²Department of Clinical Genetics, Antalya, Turkey, ³Istanbul University, Institute of Children's Health, Department of Medical Genetics, Istanbul, Turkey.

Fibroblast growth factor receptor 2 (FGFR2) gene mutations have been associated with the craniosynostotic conditions of Apert, Crouzon, Pfeiffer, Jackson-Weiss, Saethre-Chotzen, Beare-Stevenson Cutis Gyrate, and Antley-Bixler syndromes in various ethnic groups. Thirty seven unrelated Turkish patients with Apert syndrome (n=8), Crouzon syndrome (n=10), Pfeiffer syndrome (n=3), Saethre-Chotzen syndrome (n=3), and unclassified craniosynostosis (n=13) were screened for mutations in exons IIIa and IIIc of the FGFR2 gene by polymerase chain reaction, DHPLC and direct sequencing. We established the optimal denaturing High Performance Liquid Chromatography (DHPLC) parameters of each exons using the WAVE Maker Software version 1.6.2. Each anomalous elution peak was then subjected to direct sequencing. Our DHPLC based protocol enabled us to identify the causative mutations in most of the patients, as following, seven of 8 patients with Apert syndrome (S252W,P253R) and six out of 10 patients with Crouzon syndrome (C278F,Q289P,W290R,C342Y), two out of 3 patients with Pfeiffer syndrome (P253R,C342R). We did not detect any FGFR2 gene mutations in patients with Saethre-Chotzen syndrome or unclassified craniosynostosis patients. The DHPLC based protocol can be used for an efficient, cost effective and reliable mutational analysis of the FGFR2 gene. In addition, the present study provides a preliminary data in Turkish population, elucidation of the FGFR2 mutations in patients with clinical features suggestive of especially Apert, Crouzon and Pfeiffer syndrome offers a significant benefit to those families in terms of genetic counseling and prenatal diagnosis.

P01.157

Prenatal analysis of dwarfism due to mutations in FGFR3 gene in Spanish populationM. Fenollar-Cortés¹, M. Martínez-García^{2,3}, M. Rodríguez de Alba^{2,3}, D. Díezgo-Álvarez^{2,3}, I. Lorda-Sánchez^{2,3}, R. Cardero^{2,3}, C. Ramos^{2,3}, C. Ayuso^{2,3}, M. Trujillo-Tiebas^{2,3};¹Hospital Clínico San Carlos, Madrid, Spain, ²Fundación Jiménez Díaz, Madrid, Spain, ³Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Madrid, Spain.

INTRODUCTION: Thanatophoric dysplasia (TD), achondroplasia (ACH) and hypochondroplasia (HCH) are skeletal dysplasias with an autosomal dominant pattern. We present the results of FJD skeletal dysplasias cases over eight years in prenatal and miscarriage samples studying mutations in the fibroblast growth factor receptor 3 (FGFR3) gene.

MATERIAL AND METHODS: Fetal DNA was isolated from amniotic fluids (AF, 15-35 weeks of gestation), villi chorionic samples (CVS, 9-20 weeks) and tissue of abortion (TA, 15-35 weeks). All samples were karyotyped. 5 different PCRs that comprises the more relevant condons (248, 249, 250, 253, 370, 371, 373, 375, 380, 538, 540, 650 and 807) were analysed by automated sequencing analyser. 30 prenatal cases were referred to FJD Laboratory: 18 CVS (60%) and 12 AF (40%).

RESULTS: Of the 18 CVS only 2 were positives, and in both cases the pregnant women were also affected of ACH. Of the 12 AF, we obtained 10 negative cases and 2 TD-I+. Main referral (75%) was short limbs and other skeletal anomaly in the present pregnancy. We received 19 TA but only 16 studies because of DNA degraded, with the following results: 1 TD-I; 3 TD-II, 2 aneuploides.

CONCLUSIONS: Molecular analysis of CVS in first trimester is useful when one of the parents is affected due to the 50% of risk. Only severe forms (TD) are detected by ultrasound in second trimester. For miscarriages, is obligatory the fetal karyotype fetal and molecular analysis by sequencing of FGFR3 gene.

P01.158

Postnatal analysis of dwarfism due to mutations in FGFR3 gene in Spanish populationM. Trujillo-Tiebas^{1,2}, M. Fenollar-Cortés³, M. Martínez-García^{1,2}, C. Ramos^{1,2}, J. Gallego-Merlo^{1,2}, F. Infantes^{1,2}, M. Rodríguez de Alba^{1,2}, I. Lorda-Sánchez^{1,2}, C. Ayuso^{1,2};¹Fundación Jiménez Díaz, Madrid, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Madrid, Spain, ³Hospital Clínico San Carlos, Madrid, Spain.

Introduction: Achondroplasia (ACH), the most common form of human dwarfism (1/10.000-30.000 births), and hypochondroplasia (HCH), a less severe and less frequent condition (1/50.000 births), are inherited in an autosomal dominant manner as other lethal skeletal dysplasias (Thanatophoric dysplasia (TD) type I and II). Mutations in the gene of fibroblast growth factor receptor 3 (FGFR3) are known responsible for them.

We present the results about this disorders gather in eight years in our hospital from different geographical origins of Spain.

Material and Methods: Patients were all postnatal (neonatal, child and adult people) with a wide range of age. DNA was isolated from blood leucocytes or mouth epithelial cells. 5 different PCRs that comprise the more relevant codons (248, 249, 250, 370, 371, 373, 375, 380, 540, 650 and 807) were analysed by automated sequencing analyser. We also detected the most frequent mutation R380G in ACH phenotype by SNAPSHOT technology.

Results: From 77 cases, we obtained 26 ACH+ (33.8%); 7 HCH+ (9.1%) and 1 TD type I+ (1.3%). We found 5 cases with a polymorphic allele (F384L) and 3 cases with a polymorphic allele (G549G) very close to the splice site.

Conclusions: Our strategy for studying all samples is always the same independently the clinical suspicion. Sequencing FGFR3 is a good practice to detect known and new mutations in individuals affected with different skeletal dysplasias, especially when few clinical findings are added to the application.

P01.159

Functional analysis of osteoporosis pseudoglioma associated missense mutations in LRP5A. Saarinen^{1,2}, U. Lahtinen^{1,3}, A. Lehesjoki^{1,3}, O. Mäkitie^{1,4};¹Folkhälsan Institute of Genetics, Biomedicum Helsinki, Helsinki, Finland, ²Department of Medical Genetics, University of Helsinki, Helsinki, Finland, ³Neuroscience Center, University of Helsinki, Helsinki, Finland, ⁴Metabolic Bone Clinic, Hospital for Children and Adolescents, Helsinki University Hospital, Helsinki, Finland.

Background: Mutations in the low density lipoprotein receptor-related protein 5 gene (LRP5) have been associated with high and low bone mass. While homozygous LRP5 mutations cause osteoporosis-pseudoglioma syndrome (OPPG), characterized by severe osteoporosis and blindness, heterozygous mutations have been associated with reduced bone mass. LRP5 functions as a plasma membrane receptor in the Wnt signaling pathway. We previously described LRP5 mutations in patients with OPPG and/or severe osteoporosis. In this study we further analyzed the role of these mutations in Wnt signal transduction and cellular localization.

Methods: Mutations were introduced to full length human LRP5-pcDNA3.1 expression vector using site-directed mutagenesis. Wnt signal transduction assays were performed in 293HEK cells using a previously published Wnt-induced canonical signaling assay (Ai et al. 2005). Localization studies were performed in COS-1 cells using immunofluorescence staining.

Results: Three different missense mutations were identified and selected for further studies. Wnt signaling assays indicated that one of the mutations, R570W in exon 8, completely disrupted Wnt signal transduction. The second mutation, R1036Q in exon 14, resulted in partial disruption of Wnt signaling while the third mutation, R925C in exon 12, did not show any alteration in the signaling assays. Localization studies revealed that the R1036Q and R925C mutant proteins were able to reach plasma membrane where as the R570W could not be detected, suggesting that it might be post-translationally degraded.

Conclusions: We were able to show that some LRP5 mutations directly impair Wnt signal transduction and cellular transportation while other pathogenetic mechanisms are associated with some mutations.

P01.160**Characterization of the Exostosin-1 (EXT1) promoter**I. Jennes¹, W. Wuyts^{1,2};¹University of Antwerp, Antwerp, Belgium, ²University Hospital of Antwerp, Antwerp, Belgium.

Introduction

Multiple osteochondromas (MO) is an autosomal dominant skeletal disorder characterized by the formation of multiple cartilage-capped protuberances.

MO is genetically heterogeneous and is associated with a mutation in the *EXT1* or *EXT2* tumour suppressor genes. Both genes are ubiquitously expressed and encode proteins that function as glycosyltransferases in the biosynthesis of heparan sulphate.

At present, very little is known about the transcriptional regulation of the EXT genes. To elucidate transcriptional regulation of EXT1, we isolated and characterized the EXT1 promoter.

Methods and results

Theoretical analysis of the 10 kb upstream of the EXT1 start codon was performed with promoter prediction programs TSSG, TSSW, FPRO, BDGP, Promoter 2.0 Prediction Server and Web Promoter Scan. This showed presence of a CpG island containing CG and CAAT boxes but no TATA box which, characteristic for a housekeeping gene. Two potential functional promoter regions were identified located respectively ~2.650 bp and ~900 bp upstream of the start codon.

Overlapping PCR fragments of the 10 kb putative EXT1 promoter region were generated and cloned in the pGL4.72 Luciferase Reporter Vector. Promoter activity was determined by luciferase assays after transfection in Human Embryonic Kidney (HEK) cells. This situated the actual core promoter within the fragment containing the predicted sequence ~900 bp upstream of the start codon. Further fine mapping of the core promoter and potential regulatory sites was achieved by generating additional subclones, which were subsequently analyzed for promoter activity and analyzed for protein binding capacities. This allowed identification of EXT1 promoter binding proteins.

P01.161**Mutation screening for autosomal recessive malignant osteopetrosis**S. Akbaroghli¹, T. Majidzadeh¹, M. Dehghan Manshadi¹, M. Rostami¹, M. Natoghi¹, M. Sanati², M. Houshamd^{2,1};¹Special Medical Center, Tehran, Islamic Republic of Iran, ²National Institute of Genetic Engineering & Biotechnology, Tehran, Islamic Republic of Iran.

Osteopetrosis is a congenital disorder characterized by defective or absent osteoclasts, the cells that break down bone. In healthy bone, a balance is achieved between the production of bone by osteoblasts, and the break down of bone by osteoclasts. In osteopetrosis, osteoclasts don't function normally, and the production of bone by osteoblasts leads to bones that are abnormally dense and brittle. Osteopetrosis may result from conditions which interfere with the production of osteoclasts and their ability to remove bone.

Several forms of osteopetrosis exist. The most common form is autosomal dominant. The most severe form of osteopetrosis is termed infantile osteopetrosis, as affected individuals usually have difficulties soon after birth, inherited in an autosomal recessive pattern. The disease is very rare, with about 1/300,000 children having severe osteopetrosis. The candidate genes for Osteopetrosis are TCIRG1, CLCN7 genes. The spectrum of CLCN7-related osteopetrosis includes infantile malignant CLCN7-related autosomal recessive osteopetrosis, intermediate autosomal and autosomal dominant osteopetrosis type II. Mutations of the TCIRG1 gene are the most frequent cause of AR osteopetrosis. TCIRG1 encoding the α 3 subunit of the vacuolar proton pump is located on chromosome 11q13 consists of 20 exons.

In present study DNA was received from a consanguineous couple who had 1 affected child from who no sample was available and they were referred us for screening the problem if any, in the fetus. For each sample we performed genetic analysis of hot spot axons of TCIRG1 by direct sequence analysis. We reported a new mutation in TCIRG1 gene.

P01.162**A novel homozygous COL11A2 deletion causes a C-terminal protein truncation without mRNA decay in a Turkish patient**O. Z. Uyguner¹, H. Kayserili¹, G. Guven¹, M. U. Emiroglu¹, N. Baserer¹, B. Wollnik²;¹Istanbul University, Istanbul, Turkey, ²University of Cologne, Cologne, Germany.

Otospondylomegapiphyseal dysplasia (OSMED, OMIM 215150) is a rare autosomal recessive disorder of bone growth and development that results in disproportionate shortness of the limbs with abnormally large knees and elbows, severe hearing loss, and distinctive facial features presenting mid-face hypoplasia, depressed nasal bridge with anteverted nares. Cleft palate and micrognathia are also the common findings. The phenotype is very similar to non-ophthalmic Stickler or Stickler Type III (OMIM 184840), which displays more subtle signs. Recessive mutations on collagen peptide coding gene, *COL11A2*, are responsible for OSMED while dominant mutations are associated with Stickler Type III. Furthermore, mutations in the *COL11A2* gene have been also found in patients with isolated cleft palate, Robin sequences, micrognathia, and non-ophthalmic Stickler syndrome. In this study, two cousins with OSMED were clinically assessed and mutations testing on patient's cDNA identified the novel homozygous c.2763delT in exon 38 of the *COL11A2* gene. The deletion which causes a frame shift after position 425 and a premature stop after additional 62 amino acids (p.P425PfsX62) was confirmed on genomic level in both patients and was not found in 200 ethnically matched control chromosomes.

P01.163**Mutations of the Sequestosome 1 gene associated with Paget's disease in patients from Salamanca, Spain**E. Corral Moro¹, L. Corral Gudino², J. García Aparicio², S. Ciria Abad¹, N. Alonso López¹, J. del Pino Montes², R. González Sarmiento¹;¹Unidad de Medicina Molecular-Departamento de Medicina, Universidad de Salamanca, Salamanca, Spain, ²Servicio de Reumatología, Hospital Universitario de Salamanca, Salamanca, Spain.

Paget's disease of bone (PDB) is a common condition characterized by focal abnormalities of increased bone turnover.

Mutations in the sequestosome 1/p62 gene (SQSTM1) are associated with Paget linked to the 5q35.

Mutations described to date cluster within the C-terminal ubiquitin-associated (UBA) domain of p62 and patients with truncating mutations of p62 in or close to the UBA domain generally suffer more severe disease than those with missense mutations.

We investigated a cohort of 20 familial PDB patients for sequestosome mutations.

We identified three mutations within exon 8: P392L, M404T, previously reported by other groups, and A426V, a novel missense mutation. All three of these mutations affect the ubiquitin-associated (UBA) domain of the protein which is involved in the ubiquitin binding.

Moreover, analysis of exon 6 detected a G to C substitution at position +822, resulting in a glutamic acid to aspartic acid substitution at codon 426. This mutation affects the PEST sequence, important for the span life to the protein. Actually, more studies are under way to examine the effect of his mutation.

P01.164**Mutations, duplications and deletions, upstream, downstream and overlapping the SHOX gene in Leri-Weill dyschondrosteosis or short stature patients of the Balearic islands**J. Rosell¹, J. Ferragué¹, M. Caimar², N. Govea¹, M. Bernues¹, A. Perez-Grañero¹, D. Heine-Suñer¹;¹Genetics Hospital Universitari Son Dureta, Palma de Mallorca, Spain, ²Paediatrics Hospital Universitari Son Dureta, Palma de Mallorca, Spain.

The *SHOX* gene is located on the pseudoautosomal regions (PAR1) of the X and Y chromosomes. Mutations and deletions of *SHOX* have been shown to be associated with Leri-Weill dyschondrosteosis (LWD) and idiopathic short stature (ISS). Recently, it has been shown that deletions downstream within in the PAR1 region and that do not include the *SHOX* gene can be also associated with LWD. We have studied a total of 120 ISS and LWD patients and their families from the Balearic islands population. The presence of deletions has been determined using microsatellites that are located upstream and/or MLPA (SALSA 18C) which can detect downstream deletions. Mutations have been

analysed by sequencing exons 1 to 6A. We have found deletions, duplications or mutations in a total of 10 families. Three of these families harbour mutations in exon 4, four families had downstream deletions, and three carry deletions overlapping the *SHOX* gene. The remaining family had a duplication upstream of the *SHOX* gene as the sole trait. Interestingly, one of the families with a downstream deletion had also a 5' duplication of *SHOX* up to exon 3 that segregated independently. Deletions and duplications show different breakpoints in each family supporting the idea that there is no main deletion breakpoint hotspot. This work has been supported by the grant FIS 05-1585 from the Instituto de Salud Carlos III from the Spanish ministry of Health.

P01.165

Detection and characterisation of partial *SHOX* deletions in patients with Léri-Weill dyschondrosteosis (LWD), Langer mesomelic dysplasia (LMD) and idiopathic short stature (ISS)

S. Benito-Sanz¹, P. Lapunzina^{2,3}, N. S. Thomas⁴, Á. Campos-Barros⁵, J. L. Ross⁶, A. R. Zinn⁷, K. E. Heath¹;

¹Hospital Infantil Universitario Niño Jesús, Universidad Autónoma de Madrid, Madrid, Spain, ²Hospital Universitario La Paz, Madrid, Spain, ³CIBERER, Instituto de Salud Carlos III, Madrid, Spain, ⁴Wessex Regional Genetics Service, Salisbury, United Kingdom, ⁵Hospital Infantil Universitario Niño Jesús, Madrid, Spain, ⁶Thomas Jefferson University, Philadelphia, PA, United States, ⁷University of Texas Southwestern Medical School, Dallas, TX, United States.

SHOX is located in the pseudoautosomal region 1 (PAR1) of the X and Y chromosomes. Mutations in *SHOX* or in the downstream PAR1 have been shown to be the cause of Léri-Weill dyschondrosteosis (LWD), Langer mesomelic dysplasia (LMD) and idiopathic short stature (ISS). We routinely perform deletion screening of *SHOX* and the downstream PAR1 in LWD, LMD and ISS patients using MLPA. Microsatellite markers and SNPs are then utilized for further characterisation in specific cases.

During our screening, we identified nine partial *SHOX* deletions (five LWD, one LMD and three ISS). The deletions were all of variable size, ranging from the deletion of a single exon to multiple exons. Polymorphisms in the ligation sites were excluded in cases where deletions only included one exon. A common 5' breakpoint region in intron 3 was observed in five patients. Three patients also share the 3' limit in intron 2 and two more in the 3'UTR. Deletion breakpoints are currently being further delimited by fine-tiling CGH arrays and subsequently amplification across the breakpoints.

MLPA is an accurate, rapid and economic technique to detect complete and partial *SHOX* deletions as well as downstream PAR1 deletions. FISH and microsatellite analysis cannot accurately detect or delimit this class of deletions. Our results show that, although the partial deletions of *SHOX* are variable in size, intron 2 and 3 appear to be hotspots for breakages.

P01.166

Mosaicism of the *SHOX* gene in a serie of Spanish patients with short stature

L. Magano Casero¹, K. Heath², P. Lapunzina³, P. Arias⁴, I. Incera⁵, S. Benito Sanz⁶, A. Delicado⁷, R. Gracia Bouthellier⁸;

¹Hospital Universitario La Paz, Hospital Infantil Universitario Niño Jesús, Madrid, Spain, ²Hospital Infantil Universitario Niño Jesús, Madrid, Spain, ³Hospital Universitario La Paz., Madrid, Spain.

The *SHOX* gene, located at the pseudo-autosomal region (PAR1) of the X (Xp22) and Y (Yp11) chromosomes codifies for a transcription factor implicated in the regulation of skeletal growth. Deletions or mutations in *SHOX* may lead to haploinsufficiency of this gene and sometimes is associated with Turner syndrome, Leri-Weill dyschondrosteosis (LWD), Langer type mesomelic displasia (LMD) and idiopathic short stature (ISS).

PATIENTS AND METHODS: Using STRs (microsatellites, repeated sequences in tandems distributed in the DNA) we evaluated the copy number of *SHOX* and/or their different alleles in 340 patients with short stature. The peak areas of both alleles were evaluated by means of the ratio between both alleles and then compared and normalized with normal controls. Calculation was expressed as a percentage of each allele.

RESULTS: We detected mosaicism for *SHOX* in 5 out of 340 patients. Normalization showed a percentage of deletion of 46, 33, 26, 26 and 11% respectively. Karyotypes (100 cells were evaluated for each pa-

tient) were normal in all patients.

CONCLUSION: Though classical haploinsufficiency of the *SHOX* gene shows a heterogeneous phenotypic expression in patients with short stature, patients with mosaicism of this gene should be recognized as a special group of children since the genetic dose of the gene is variable and the final height and evolution is unpredictable.

P01.167

Microduplication of the long range SHH limb regulator (ZRS) is associated with triphalangeal thumb-polysyndactyly syndrome

E. Klopocki¹, C. E. Ott¹, N. Benatar², R. Ullmann³, S. Mundlos^{1,3}, K. Lehmann¹;

¹Charite Universitätsmedizin Berlin, Institute of Medical Genetics, Berlin, Germany, ²Klinik für Handchirurgie, Krankenhaus Marienstift, Braunschweig, Germany, ³Max Planck Institute of Molecular Genetics, Berlin, Germany.

An important player in establishing the anterior-posterior patterning of the limb is the developmental regulator gene *sonic hedgehog* (*SHH*). Previous studies have identified a long range regulator for *SHH* expression in the limb bud residing in a highly conserved non-coding sequence about 1 Mb upstream from the *SHH* gene itself. As shown in mice point mutations within this non-coding regulatory region designated ZRS lead to ectopic expression of *Shh* in the anterior margin of the limb bud and thus to preaxial extra digits. In humans ZRS point mutations are associated with the triphalangeal thumb and polysyndactyly (TPT-PS, OMIM #174500) phenotype.

In this study we investigated a large pedigree with a variable phenotype of TPT-PS. Although linkage to the *SHH* locus was confirmed sequencing of the ZRS did not reveal point mutations. A subsequent screening by array-CGH detected a microduplication in 7q36.3 comprising the ZRS in an affected individual. The microduplication was confirmed by qPCR in all affected family members. By using a direct sequencing strategy we showed that the duplicated segment is in direct tandem orientation.

In summary we demonstrated that microduplication of the ZRS region in 7q36.3 results in a similar phenotype as caused by point mutation in the limb specific *SHH* regulatory element. Thus, genomic duplications have to be considered as a possible mechanism which leads to disturbance of long-range transcriptional control. The discovery of novel mechanisms of gene regulation, i.e. distant enhancers/repressors and their relevance to human disease if disrupted is a challenging task in the future.

P01.168

The transcription factor TRPS1 interacts with the RINGfinger ubiquitin ligase ARKADIA

C. Will¹, M. Albrecht¹, S. Gkalympoudis², R. Depping³, G. Gillissen-Kaesbach¹, H. Lüdecke², F. J. Kaiser¹;

¹Institut für Humangenetik, Lübeck, Germany, ²Institut für Humangenetik, Essen, Germany, ³Institut für Physiologie, Lübeck, Germany.

Mutations or deletions of the TRPS1 gene on human chromosome 8q24.1 cause the tricho-rhino-phalangeal syndromes (TRPS), which are characterized by craniofacial and skeletal abnormalities. The gene encodes a transcription factor that functions as a repressor for GATA-mediated transcription. The activity of transcription factors is often controlled by post-translational modifications. And in fact, we have recently found that SUMOylation of specific sites within the repression domain (RD) of TRPS1 regulates its function.

In a yeast-two-hybrid screen we identified two clones encoding amino acids (aa) 352-505 of the 986 aa protein ARKADIA. ARKADIA is a RINGfinger ubiquitin ligase. In mice, Arakdia is known as a key regulator in the TGF-beta pathway by inducing the ubiquitin-dependent degradation of Smad7, SnoN and c-Ski. By using a variety of truncated TRPS1 and ARKADIA constructs we could narrow down the ARKADIA-binding region within TRPS1 to the last 100 aa, which includes the RD. ARKADIA appears to interact with TRPS1 via two different regions, which were also described to enable the interaction of ARKADIA with SMAD7. TRPS1 is known to be localized within the nucleus. Selective inhibition of the proteasome complex with lactacystin results in cytoplasmic accumulation of TRPS1 in cells co-transfected with ARKADIA. Furthermore, in luciferase reporter gene assays we could show that ARKADIA decreases the repressional activity of TRPS1. Our results strongly indicate an ARKADIA-mediated ubiquitination which induces a cytoplasmic degradation of TRPS1.

P01.169

A variant in the ZRS sonic hedgehog regulatory sequence is associated with triphalangeal thumb and deregulates expression in the developing limb

D. Furniss^{1,2}, L. A. Lettice³, I. B. Taylor¹, P. S. Critchley², H. Giele², R. E. Hill², A. O. M. Wilkie¹;

¹Weatherall Institute of Molecular Medicine, Oxford, United Kingdom, ²Department of Plastic and Reconstructive Surgery, Oxford, United Kingdom, ³MRC Human Genetics Unit, Edinburgh, United Kingdom.

A locus for triphalangeal thumb, variably associated with preaxial polydactyly, was previously identified in the Zone of Polarizing Activity Regulatory Sequence (ZRS), a long range limb-specific enhancer of the Sonic Hedgehog gene (*SHH*) at human chromosome 7q36.3. Here, we demonstrate that a 295T>C variant in the ZRS, previously thought to represent a neutral polymorphism, acts as a dominant mutation with reduced penetrance. We found this variant in 3 independently ascertained probands from southern England with triphalangeal thumb, demonstrated significant linkage of the phenotype to the variant (LOD = 4.1), and identified a shared microsatellite haplotype around the ZRS, suggesting that the probands share a common ancestor. An individual homozygous for the 295C allele presented with isolated bilateral triphalangeal thumb resembling the heterozygous phenotype, suggesting that the variant is largely dominant to the wild type allele. As a functional test of the pathogenicity of the 295C allele, we utilised a mutated ZRS construct to demonstrate that it can drive ectopic anterior expression of a reporter gene in the developing mouse forelimb. We conclude that the 295T>C variant is in fact pathogenic and appears to be the most common cause of triphalangeal thumb in southern England. Depending on the dispersal of the founding mutation, it may play a wider role on the aetiology of this disorder.

P01.170

Fetal Alcohol Syndrome a phenocopy of Spondylocarpotarsal synostosis syndrome?

R. Ruppis¹, D. Krakow², N. Puvanachandra³, J. Gardiner³, C. F. Boerkoel¹;

¹Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada, ²Skeletal Dysplasia Registry, Cedars-Sinai Medical Center, Los Angeles, CA, United States, ³Department of Ophthalmology and Visual Sciences, University of British Columbia, Vancouver, BC, Canada.

Spondylocarpotarsal synostosis syndrome is characterized by disproportionate short stature with fusion of vertebrae, carpal and tarsal bones, thoracic scoliosis and pes planus. Other features often described include delayed bone age, epiphyseal ossification delay, cleft palate, dental enamel hypoplasia and renal anomalies. Skeletal manifestations of fetal alcohol syndrome (FAS) include poor growth, delayed bone age, congenital fusion of cervical vertebrae, coalition of the capitate and hamate carpal bones and transverse limb defects. We report a 6-year-old girl born to a 32-year-old mother and a 62 year old father after a pregnancy complicated by alcohol abuse. She presented with short stature, hypotonia, dysmorphic facial features, generalized joint laxity and hyperextensibility and hearing loss. She also had poor visual acuity, extremely high bilateral myopia, pale optic nerves, thin retinal vessels and tigroid retinae. Subsequently, she developed an asymptomatic complete funnel retinal detachment of the right eye. Her skeletal survey revealed normal bone age, fusion of vertebral facet joints of C2-4 and C5-6 with narrowing of these disc spaces but widening of the C4-5 and C6-7 disc spaces, flared ilii, longer proximal than distal long bones, fused capitate and hamate ossification centres and bilateral coxa valga. We postulate that prenatal alcohol exposure can phenocopy spondylocarpotarsal synostosis syndrome. Alternately, this patient's features could represent an overlap of fetal alcohol spectrum disorder with spondylocarpotarsal synostosis syndrome, an extension of the spondylocarpotarsal synostosis syndrome or an undescribed syndrome.

P01.171

Variable phenotype of Hennekam syndrome

P. Blanchet, L. Pinson, C. Coubes, G. Lefort, P. Sarda;

Hôpital Arnaud de Villeneuve, Service de Génétique, Montpellier, France.

Hennekam syndrome is a rare autosomal recessive anomaly characterized by lymphedema, lymphangiectasia, facial dysmorphism and developmental delay. Heart, renal, skeletal anomalies and growth retardation may also be a part of the spectrum. Severity of the syndrome

is due to lymphangiectasia, preferentially intestinal, and mental retardation.

We describe two new unrelated cases of Hennekam syndrome.

The first patient, a 3-year-old girl, is the only infant born of non-consanguineous parents. At birth, she presented facial edema. Lymphedema rapidly extended to legs and feet. Enteropathy appeared during the first year. At 3 years, she presented the facial dysmorphism of Hennekam syndrome and psychomotor development was normal.

The second case, a 36-year-old woman, is the only child of non-consanguineous parents.

At birth, syndactyly of toes was present associated with particular facial features. Later, she developed psychomotor delay with mental retardation and seizures. Lymphedema appeared on the right leg at 3 years and on the left leg at 15 years. Recurrent episodes of diarrhoea were present without enteropathy.

Abdominal cystic lymphangioma were surgically corrected at 30 years. At 36 years, facial dysmorphism resembled that of Hennekam syndrome. She had short hands, hypoplastic thumbs, short feet with bilateral syndactylies. These two observations confirm the variable expressivity of Hennekam syndrome. Lymphedema of the limbs and facial dysmorphism are the only constant features. All other traits, in particular intestinal lymphangiectasia, may be absent.

P01.172

Novel VEGFR3 missense mutation in a Spanish family with Milroy disease

M. Ballesta-Martínez¹, E. Guillén-Navarro¹, V. López-González¹, S. Jeffery²;

¹Hospital Universitario Virgen de la Arrixaca, Murcia, Spain, ²St. George's University of London, London, United Kingdom.

Introduction: Milroy disease, or hereditary lymphedema type 1 (MIM153100), is characterized by lower limb lymphedema usually present at birth. Variability in expression has been reported both within and among families. Mutations in VEGFR3 with resultant dysgenesis of microlymphatic vessels cause this disease. It is inherited in an autosomal dominant manner with incomplete penetrance (85-90%).

Objective: We describe phenotype of Milroy disease in two-generation Spanish family. Molecular analysis of VEGFR3 gene has been performed.

Clinical description: A girl was referred at 2 years of age because of bilateral swelling of feet since birth, more evident on the right foot, which partially decreased during the first year of life. She had dysplastic 2-4th toenails. She was the first child of a young and non-consanguineous couple. Her father referred swelling of feet at birth which disappeared progressively during childhood. He had dysplastic toenails. Soon after a sister was born with swelling of feet and distal part of limbs as well. She is now 4 years old and the lymphedema is stable; dysplastic nails are not present. The son of a father's asymptomatic sister has also been born with bilateral swelling of feet. Analysis of VEGFR3 gene revealed a heterozygote mutation c.3056T>C in exon 22 in the two girls and their father.

Conclusions: 1- We describe a novel VEGFR3 mutation in exon 22 causing Milroy disease. 2- Clinical variability and incomplete penetrance is present in this family.

P01.173

VEGFR3 mutation frequency in Milroy disease and other primary lymphoedema

F. C. Connell, P. Ostergaard, G. Brice, C. Carver, N. Williams, S. Mansour, P.

S. Mortimer, S. Jeffery;

St George's University of London, London, United Kingdom.

Milroy disease (Hereditary Lymphoedema type I) is a congenital onset primary lymphoedema with autosomal dominant inheritance. Mutations in the gene, vasculo-endothelial growth factor receptor, VEGFR3 (*FLT4*), are known to cause Milroy disease, but there is uncertainty about the prevalence of VEGFR3 mutations in patients with primary lymphoedema and more specifically in those with a phenotype that resembles Milroy disease. This study addresses this issue and thereby delineates the Milroy disease phenotype. Fifty-four patients with primary lymphoedema were analysed for mutations in VEGFR3. Patients were divided into four groups: Typical Milroy disease with family history (group I), typical Milroy disease with no family history (group II), atypical Milroy disease (group III), and complex primary lymphoedema (group IV). Results demonstrated that with rigorous phenotyping

the likelihood of detecting *VEGFR3* mutations is optimised. Mutation prevalence is 72% in typical Milroy patients with a family history (group I) and 64% if positive family history is not a diagnostic criterion. A positive family history is not essential in Milroy disease. The likelihood of detecting *VEGFR3* mutations in patients who have a phenotype which is not typical of Milroy disease is very small (<5%). For the 22 mutation positive patients, 14 novel *VEGFR3* mutations were identified, two of which were in exon 22 and one in exon 17, confirming that these exons should be included in *VEGFR3* analysis.

P01.174

Microcephaly, lymphedema, chorioretinal dysplasia syndrome (MLCRD) and atrial septal defect (ASD) further delineation of a rare syndrome

A. Singer¹, S. Eventov-Friedman², C. Vinkler³;

¹Genetic Institute, Barzilai Medical Center, Ashkelon, Israel, ²Department of Neonatology, Kaplan Medical center, Rehovot, Israel, ³Institute of Clinical Genetics, Wolfson Medical Center, Holon, Israel.

Combinations of microcephaly and lymphoedema, as well as microcephaly and chorioretinopathy, have been well described in the past. It has been later suggested these two entities represent a single entity: lymphoedema, microcephaly, chorioretinopathy syndrome (MLCRD OMIM 152950). To date, less than 30 patients have been reported in the literature. This entity is characterized by microcephaly, lymphoedema of the limbs, chorioretinal dysplasia, and normal or near-normal intelligence. The inheritance can be autosomal dominant, or recessive. A few sporadic instances have also been reported. Although this condition is thought to be a single genetic entity with variable expression, only three cases were previously described in the literature with cardiac anomaly.

We describe here another case of MLCRD with a cardiac anomaly.

A six months male infant has been first referred to our clinic because of microcephaly and lymphedema. Further evaluation revealed chorioretinal changes, severe myopia and atrial septal defect (ASD). Brain MRI was normal. He is the first child of healthy and unrelated couple with unremarkable medical history, except for nonsyndromic familial microcephaly in the mother's family.

At the age of one year he came for a regular follow up to our clinic. The infant developed normally and achieved the expected motor, mental and social milestone for his age.

This case further emphasizes the inter- and intra-familial variable expressivity of MLCRD.

P01.175

Neurofibromatosis-Noonan like Syndrome/Watson Syndrome- the syndromes of the same mitogen-activated protein kinase (MAPK) pathway.

E. Jamroz¹, A. Pyrkosz², J. Surmiki¹, E. Marszał¹;

¹Department of Child Neurology, Medical University of Silesia, Katowice, Poland, ²Department of Molecular Biology and Genetics, Medical University of Silesia, Katowice, Poland.

Since 1967, when G.H. Watson described first three families with a condition characterized by café au lait spots, pulmonary valvular stenosis, short stature and dull intelligence-there have been only few more patients diagnosed with this disease. The authors report a 11-month-old child manifesting the symptoms, which are in the picture of Neurofibromatosis-Noonan like /Watson syndrome: café au lait spots, pectus abnormality, pulmonary stenosis. Additionally, magnetic resonance imaging of the head demonstrated the lesion, diameter about 4mm change, situated in the capsula interna on the border with the posterior part of thalamus which is possibly hamartoma. Significant is, as well, the family history- the father of the child has phenotype of Neurofibromatosis-Noonan like /Watson Syndrome, although, his condition was diagnosed as neurofibromatosis type I in childhood. The authors analyse the clinical phenotype, overlapping characteristic features of above mentioned syndromes and discuss the molecular basis of this phenomenon.

P01.176

Noonan syndrome and marfanoid habitus in a patient with *SOS1* mutation

G. Morin¹, E. Gailly¹, M. Mathieu¹, H. Cavé², C. Boileau³, J. Lebrun⁴, A. Verloes²;

¹Unité de Génétique Clinique, Amiens, France, ²Département de Génétique - Hôpital Robert Debré, Paris, France, ³Laboratoire de Génétique Moléculaire - Hôpital Ambroise Paré, Boulogne, France, ⁴Service de Pédiatrie, Soissons, France.

We report the observation of a 24-year-old male patient exhibiting features suggesting Noonan syndrome (mild mental retardation, low-set hair, hypertelorism, bilateral ptosis, dysplastic low-set ears, and webbed neck), and others compatible with Marfan disease (height at 1m83, joint hyperlaxity, arachnodactyly, pectus carinatum, severe scoliosis, myopia). Cardiac ultrasound examination was normal. Familial stature was tall (mother 1m73, father 1m83, and brothers 1m95 and 2m). Blood standard karyotype was normal. Noonan syndrome was confirmed by molecular analysis of *SOS1* gene (heterozygous mutation 1654 A>C (R552G)). However Marfan disease was not documented with a negative screening of *FBN1* gene. We discuss the hypothesis of a pleiotropic effect of the *SOS1* mutation, the influence of the familial stature, and the eventuality of two concomitant independent diseases.

P01.177

SOS1 and *PTPN11* mutations in five cases of Noonan syndrome with multiple giant cell lesions

C. Beneteau^{1,2}, H. Cavé³, A. Moncla⁴, N. Dorison⁵, A. Munnich⁶, A. Verloes³, B. Leheup^{1,2};

¹Service de Médecine Infantile III et Génétique Clinique, Hôpital d'Enfants CHU de Nancy, Vandoeuvre les Nancy, France, ²Faculté de médecine Nancy Université Henri Poincaré, Vandoeuvre les Nancy, France, ³Département de Génétique clinique, Hôpital Robert Debré, Paris, France, ⁴Département de Génétique Médicale, Hôpital d'enfants de la Timone, Marseille, France, ⁵Neuropédiatrie pathologie du développement, Hôpital Armand Trousseau, Paris, France, ⁶Service de Génétique Médicale, Hôpital Necker Enfants Malades, Paris, France.

We report five cases of multiple giant cell lesions in patients with typical Noonan syndrome. Such association has been frequently referred to as Noonan like-Multiple Giant Cell syndrome before the molecular definition of Noonan syndrome. Three patients carry mutations in *SOS1* (p.Arg552Ser and p.Arg552Thr) and two in *PTPN11* (p.Tyr62Asp and p.Asn308Asp) and are the first *SOS1* mutations in Noonan like-Multiple Giant Cell syndrome.

The five patients have typical features for Noonan syndrome. Congenital heart diseases were diagnosed during gestation or after birth. Radiograph and CT scan showed unilateral or bilateral mandibular radiolucencies characteristic of cherubism for five patients with cherubic appearance or incidentally discovered at systematic radiographic examination. The other patient presented typical imaging and histopathological signs of a left ankle pigmented villonodular synovitis. Three of the five patients had short stature and three had learning disabilities.

They show two distinct phenotypes: Noonan with cherubism and Noonan with pigmented villonodular synovitis, demonstrating that both clinical phenotypes are not *PTPN11*-specific anomalies and represents a rare complication of overexpression of the RAS/MAPK signaling pathway. We discuss the clinical overlap between Noonan syndrome, Noonan like-Multiple Giant Cell syndrome, "true" cherubism and pigmented villonodular synovitis. The two latter terms should be used only when multiple giant cell lesions occur without any other evidence of Noonan syndrome. Noonan like-Multiple Giant Cell syndrome previously regarded as an entity distinct from Noonan syndrome is more likely as a phenotypic variation within the Noonan spectrum.

P01.178

Clinical study of a family with Noonan Syndrome (NS) transmitted from mother to daughter

L. I. Butnariu¹, E. Gorduza¹, D. Anton², M. Covic¹;

¹*University of Medicine and Pharmacy "Gr. T. Popa", Department of Human Genetics, Iasi, Romania, ²*University of Medicine and Pharmacy "Gr. T. Popa", "Saint Mary" Hospital, Iasi, Romania.

Noonan Syndrome (NS) is an autosomal dominant disease, with mutation inherited especially from mother, characterized by typical facial dysmorphism, short stature, heart defect, mental retardation and he-

matological anomalies. Almost 50% of patients with NS (sporadic or familial) carry an missense mutation of PTPN11 gene (12q24), while other genes (KRAS and SOS1) play a minor role in the molecular pathogenesis of the disease.

We present a familial case, mother and daughter, with NS diagnosed by used a scoring system based by clinical signs.

The diagnosis was performed first in daughter, which was identified at birth. She presented polihidramnios, nuchal oedema and premature born. The patient was reevaluated of two months age. Clinical and paraclinical evaluation revealed the major features of NS: feeding difficulties with failure to thrive, short stature, typical facial dysmorphism (microcephaly, broad and high forehead, down-slanting palpebral fissures, hypertelorism, epicanthic folds, micrognathia, low-set posteriorly rotated ears), short neck with excess nuchal skin, pectus excavatum, Hypertrophic Obstructive Cardiomyopathy (HOMC) with asymmetrical septum hypertrophy and neuromotor retardation. Other feature was umbilical hernia. She had anemia, but no thrombocytopenia or other coagulation defect. Clinical genetic examination of mother (N.C.M.), 31 years old, after delivery revealed the phenotype of NS (facial typical dysmorphism, pterygium colli, pectus carinatum superior and excavatum inferior), pulmonary stenosis and mental retardation. The analysis of pedigree showed the absence of other cases in family. In conclusion, we emphasize, the importance of the clinical features for diagnosis, leading further to an appropriate management and for according genetic counseling

P01.179

Noonan and Cardio-facio-cutaneous syndromes: Two Clinically and Genetically Overlapping Disorders

A. M. Nyström¹, S. Ekvall¹, E. Berglund², M. Björkqvist³, G. Braathen⁴, K. Duchon⁵, H. Enell⁶, E. Holmberg⁷, U. Holmlund⁸, M. Olsson-Engman⁹, G. Annerén¹, M. L. Bondeson¹;

¹Uppsala University, Uppsala, Sweden, ²Central Hospital, Skellefteå, Sweden, ³University Hospital, Örebro, Sweden, ⁴Sahlgrenska University Hospital, Gothenburg, Sweden, ⁵University Hospital, Linköping, Sweden, ⁶Regional Hospital of Halmstad, Halmstad, Sweden, ⁷Central Hospital, Västerås, Sweden, ⁸Regional Hospital of Karlskrona, Karlskrona, Sweden.

Noonan and Cardio-facio-cutaneous (CFC) syndromes are related disorders associated with dysregulated RAS-MAPK signalling. Noonan syndrome (NS) is associated with mutations in the genes PTPN11, SOS1, KRAS and RAF1. The genetic aetiology of the clinically overlapping CFC syndrome was recently assigned to four genes, BRAF, KRAS, MEK1 and MEK2. Here, we present a comprehensive mutation analysis of BRAF, KRAS, MEK1, MEK2 and SOS1 in 31 unrelated NS/CFC patients without mutations in PTPN11. Mutations were identified in 8 patients, in whom we also present a detailed clinical investigation. Seven of the mutations were identified in patients with CFC diagnoses (2 in BRAF, 1 in KRAS, 1 in MEK1, 2 in MEK2 and 1 in SOS1). Two mutations were novel: MEK1 E203Q and MEK2 F57L. The SOS1 E433K mutation, identified in a patient diagnosed as CFC, has previously been reported in patients with NS. In one NS patient, we also identified a BRAF K499E mutation, previously reported in patients with CFC. We thus suggest involvement also of BRAF in the pathogenesis of NS.

Taken together, our results indicate that the molecular and clinical overlap between CFC and NS is more complex than previously suggested and that the syndromes might even present as allelic disorders. Furthermore, we suggest that the diagnosis should be refined to, e.g., NS-PTPN11-associated or CFC- BRAF-associated after the genetic defect has been established since this may have an impact on prognosis and treatment of the patients.

P01.180

Clinical and molecular studies in 95 Polish patients with Noonan syndrome

E. Obersztyn, J. Klapecki, M. Łaniewski-Wołk, A. Szpecht - Potocka, J. Bal, T. Mazurczak;

Institute of Mother and Child, Warsaw, Poland.

Noonan syndrome (NS, OMIM 163950) is genetically heterogeneous disorder characterized by facial dysmorphism, short stature, variety of heart defects (particularly pulmonary stenosis), chest deformations, pterygium colli, lymphatic dysplasia, cryptorchidism and psychomotor retardation. Heterogeneous mutations in PTPN11 gene are respon-

sible for 29-60% of NS cases. The aim of our study was to estimate the frequency of PTPN11 gene mutations in Polish patients with NS. Results of clinical and molecular studies the group of 95 probands are reported. Detailed clinical evaluation, including family pedigree, dysmorphic features, pre- and postnatal development and congenital malformations is presented. Direct sequencing analysis of the 15 exons of PTPN11 gene was performed and mutation was found in 32 (35%) of the probands. The most frequent among 15 identified missense mutations were: 1510A>G and 922A>G. In 9(28%) patients mutation was familial and in 77% of cases was maternal in origin.

All patients with PTPN11 mutation demonstrated typical NS phenotype. Pulmonary valve stenosis, atrial septum defect, coagulation abnormalities, mild mental retardation, short triangular face with pointed chin were statistically the most frequent in patients with PTPN11 mutation. Statistically significant correlation of pulmonary stenosis with 922A>G and 1510A>G mutation was found. Heart defect was present in all probands with PTPN11 mutation, but only in 66% of their parents.

We concluded that probably another mutations within SOS1, KRAS and BRAF genes involved in the RAS-MAPK pathway may be responsible for NS in subset of presented patients without PTPN11 mutation. Further investigations are planned to explain NS phenotype in these patients.

P01.181

SOS1 mutation as a cause for Noonan syndrome type 4: A report of two patients

G. Yesil¹, B. Tuysuz¹, M. Zenker²;

¹Istanbul University, Cerrahpasa Faculty of Medicine, Istanbul, Turkey, ²Universitätsklinikum Erlangen, Humangenetisches Institut, Erlangen, Germany.

Noonan syndrome (NS) is an autosomal dominantly inherited disease characterized by mental retardation (25%), short stature, pterygium colli, congenital heart defect and hypogonadism. Approximately 50% of cases are caused by mutations in the PTPN11 gene on chromosome 12q24.1. Recently, Roberts and Tartaglia (2007) found mutation in the SOS1 gene on chromosome 2p22 to be responsible from 20% of NS who had ectodermal abnormalities but normal development. This subtype called NS4 which share many clinical features with a group of developmental disorders including Costello and CFC (Cardiofaciocutaneous) syndrome. Our first patient was a 7 month old male and the second was 45 days old girl who had coarse face, sparse hair and eyebrows and skin loss. Valvular pulmonary stenosis was shown in echocardiography at the first patient and atrioventricular channel defect and pulmonary hypertension at the second. One of our patients had signs of hyperkeratotic skin too. SOS 1 mutation were detected on exon 6; c.797C->A heterozygous, p.T266K and on exon16 c.2536G>A heterozygous p.E846K in patient 1 and patient 2 respectively. Pulmonary stenosis was found more frequently in patients with SOS1 mutations than PTPN11 mutations and atrial septal defect was relatively rare in affected individuals with SOS1 mutations. Thus clinical examination can be indeterminate. It is important to remember to identify SOS1 gene on patients who are free of BRAF, KRAS, MEK 1, 2 mutations that are responsible from the etiology of CFC syndrome.

P01.182

Prenatal images and evolution to cutis verticis gyrata in a newborn with Noonan syndrome

A. Moresco¹, J. van der Velde², M. Ingilde², G. Chernovetzky², S. Naddeo², S. Spinelli², M. Rittler²;

¹Centro Nacional de Genética Médica, Buenos Aires, Argentina, ²Grupo de Diagnóstico Prenatal. Hospital Materno Infantil Ramón Sardá, Buenos Aires, Argentina.

Cutis verticis gyrata (CVG) is a rare defect, characterized by skin ridges and

furrows forming cerebriform folds. Its primary form is associated with neuropsychiatric disorders or genetic syndromes, such as Turner and, more rarely, Noonan. Secondarily, CVG may be due to a local process or a systemic illness.

Objective: To show the prenatal images of CVG in a fetus, and its evolution until birth, when Noonan syndrome was diagnosed.

Case report: The propositus was the third child of a young and healthy couple. Pregnancy was uneventful until 18 gestational weeks, when an ultrasound (US) scan revealed a cystic hygroma, hydrothorax and a fluid collection at the cephalic pole, which first suggested an underlying

skull defect, until bony tissue between the intracranial structures and the overlying lesion could be identified. At 22 gestational weeks, the mentioned fluid collection had disappeared, leaving a residual scalp thickening and an enlarged nuchal fold. Fetal karyotype by amniocentesis was normal (46,XY). At birth, the infant showed a Noonan syndrome phenotype and a CVG.

Discussion: CVG is possibly due to an initial scalp lymphedema and its further resolution, and should be distinguished from a cephalocele. This is the third description of a patient with Noonan syndrome and CVG, and the second describing a fluid collection at the cephalic pole that progressed to CVG. The observed images and their evolution are of clinical importance, because they can strengthen the suspicion of Noonan syndrome prenatally.

P01.183

Gain-of-function *RAF1* mutations cause Noonan and LEOPARD syndromes with hypertrophic cardiomyopathy

B. Pandit¹, A. Sarkozy², L. Pennacchio³, C. Carta⁴, K. Oishi¹, S. Martinelli⁴, W. Schackwitz³, A. Ustaszewska³, S. R. Ommer⁵, F. Lepr⁶, C. Faul¹, P. Mundel¹, J. P. López Siguero⁶, R. Tenconi⁷, A. Noonan and LEOPARD syndromes (NS and LS) are developmental disorders with overlapping features including cardiac abnormalities, short stature and facial dysmorphisms. Increased RAS signaling due to *PTPN11*, *KRAS* and *SOS1* mutations cause approximately 60% of NS cases, while *PTPN11* mutations cause approximately 90% of LS cases. Here, we report that 18 of 231 NS and two of six LS patients without mutations in known genes have missense mutations in *RAF1*, which encodes a serine/threonine protein kinase that activates MEK1 and MEK2. Most mutations altered a motif flanking Ser259, a residue critical for *RAF1*'s autoinhibition through 14-3-3 binding. *RAF1* mutations in two hotspots were strongly associated with hypertrophic cardiomyopathy (HCM; 95% vs. 18% of all NS). Ectopically expressed *RAF1* mutants from HCM clusters had increased kinase activity and enhanced ERK activation, while non-HCM-associated-cluster mutants were kinase impaired. Our findings further implicate increased RAS signaling in pathological cardiomyocyte hypertrophy.

P01.184

SOS1 mutation in a CFC patient

M. Somer¹, M. L. Väisänen², M. Lähde³, J. Ignatius²;

¹Dept Medical Genetics, The Family Federation of Finland, Helsinki, Finland, ²Oulu University Hospital, Oulu, Finland, ³North Carelian Central Hospital, Joensuu, Finland.

After the CFC syndrome was originally published in 1986 it was continuously debated whether it can be separated from the Noonan syndrome. Molecular genetic studies have shown that at least one gene in the RAS pathway, *KRAS* can cause both syndromes. When *SOS1* was described to be the second most common gene in Noonan it was emphasized that it usually does not cause the CFC syndrome. We describe a 4-y-o boy with *SOS1* exon 6 missense mutation c.797C>A (p.T266K), earlier reported by Roberts et al in 2007 in a Noonan patient. Parental studies were normal. He was born at after 37 weeks of pregnancy complicated by fetal hydronephrosis and polyhydramnios with birth weight 4000g, length 51 cm and OFC 36,5 cm. There was oedema, opisthotonus, poor feeding, cryptorchidism, and umbilical hernia. He has pulmonary and mild aortic stenosis, ASD secundum, and hypertrophy of the ventricular septum. His growth is on the -1.2 SD curve and OFC +1.5 SD. He started to walk at 18 months but is not yet able to run. He spoke the first words at 3,5 years and mainly uses sign language. He has melatonin treatment for poor sleeping patterns. Dysmorphic features are compatible with the CFC syndrome with bi-temporal constrictions, sparse hair, absent eyebrows, dystrophic nails

and hyperkeratotic eczema on face and legs. *SOS1* mutation found in this patient with CFC phenotype further emphasizes the need of phenotype-genotype correlation studies in *SOS1* mutation patients.

P01.185

Improved Mutation Detection in the Polygenic Disorders Noonan Syndrome and LEOPARD Syndrome

S. Ramos¹, J. Short¹, N. Elanko¹, K. Kalidas², S. Cottrell¹, R. Poh¹, R. Taylor¹;

¹South West Thames Molecular Genetics Laboratory, St George's Hospital, London, United Kingdom, ²Clinical Developmental Sciences, St George's University of London, London, United Kingdom.

Noonan syndrome (NS) is a common autosomal dominant multiple congenital anomaly syndrome exhibiting short stature, heart defects and facial dysmorphism. LEOPARD syndrome (LS) is a rare autosomal dominant multiple congenital abnormality syndrome. The acronym LEOPARD defines the common features: multiple Lentiginosis, ECG conduction abnormalities, Ocular hypertelorism, Pulmonary stenosis, Abnormal genitalia, Retardation of growth and sensorineural Deafness. Defects in the RAS-MAPK pathway have been implicated in both syndromes.

Since 2001 missense mutations in the *PTPN11* gene have been recognised as causative in approximately half of NS cases and the majority of LS cases. We established a service in 2002 to analyse exons 3 and 8 of this gene which contain ~80% of known NS mutations. Since 2005 we have screened all exons in which mutations had been identified and thus allowed molecular confirmation of LS.

Mutations in the *SOS1*, *RAF1* and *KRAS* genes, which also encode proteins in the RAS-MAPK pathway, have been identified in 10-20% of *PTPN11* negative NS cases. *RAF1* mutations have also been identified in a proportion of *PTPN11* negative LS cases. We have set up a diagnostic service to analyse the known mutation-containing exons of *SOS1* and *RAF1* and all exons of *KRAS*. Testing involves a dHPLC pre-screen followed by bidirectional sequencing of any variants. We have identified 12 pathogenic mutations in *SOS1* and *RAF1* in our initial cohort of 110 *PTPN11* negative cases referred for NS/LS. This analysis is now integrated with the *PTPN11* screen to facilitate a comprehensive molecular investigation of NS and LS referrals.

P01.186

Molecular analysis of the *PTPN11* (protein-tyrosine phosphatase, nonreceptor-type 11) gene in Estonian patients with Noonan syndrome

I. Kalev¹, K. Muru², M. Zimmermann³, T. Reimand⁴, R. Teek⁴, S. Virro⁵, M. Sõnajalg⁶, K. Õunap⁶;

¹Department of Human Biology and Genetics, Institute of General and Molecular Pathology, University of Tartu, Tartu, Estonia, ²Department of Human Biology and Genetics, Institute of General and Molecular Pathology, University of Tartu; Department of Genetics, United Laboratories, Tartu University, Tartu, Estonia, ³Department of Human Biology and Genetics, Institute of General and Molecular Pathology, University of Tartu; Department of Cell Biology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia, ⁴Department of Genetics, United Laboratories, Tartu University Hospital, Tartu, Estonia, ⁵Children's Clinic, Tartu University Hospital, Tartu, Estonia, ⁶Department of Genetics, United Laboratories, Tartu University Hospital; Department of Pediatrics, University of Tartu, Tartu, Estonia.

Noonan syndrome (NS; OMIM# 163950) is a relatively common (1:1000-2500) autosomal dominant disorder characterized by proportional short stature, facial dysmorphisms and cardiac anomalies. Missense mutations of *PTPN11* gene have been documented in about 50% of NS cases, while molecular lesions of other genes of the RAS pathway (*KRAS*, *SOS1*, *RAS1*) play a minor role in the molecular pathogenesis of the disease.

Study group consisted of 10 probands (age 1-36 y; 5 males/5 females), 4 of which were familial cases. All patients had the typical face and inclusion diagnostic criteria of NS proposed by van der Burgt (1994). All of the patients had a normal karyotype. Sequence analysis was performed for five coding *PTPN11* exons 3, 4, 7, 8, 13 and their flanking regions. Mutation analysis of the *PTPN11* hot spot coding exons revealed two different heterozygous missense mutations in two unrelated families. A transition A1510G in exon13 for family NS-VI, which predicts the Met504Val substitution, was described previously (Tartaglia, 2001), resided in the PTP domain of SHP-2 protein. A172G tran-

sition was identified in the exon3. This change predicts the Asn58Asp substitution in family NS-X, and affects the N-SH2 domain of SHP-2. Patients with *PTPN11* disease related mutations had characteristic phenotypes: a proband from NS-VI family presented short stature, dysmorphic facial features and atrial septal defect; a proband from NS-X family had short stature, pulmonary valve stenosis and dysmorphic facial features. Future studies involving clinical and genetic investigations are necessary to correlate genotype-phenotype expression. Supported by Estonian Science Foundation grant GARM6573.

P01.187

PTPN11 gene analysis in a sample of Mexican patients with Noonan syndrome

C. N. Gonzalez-Huerta¹, L. M. Gonzalez-Huerta², S. Cuevas-Covarrubias³;

¹Instituto Nacional de Rehabilitacion, Mexico DF, Mexico, ²Hospital General de Mexico, Mexico DF, Mexico, ³Hospital General de Mexico, Facultad de Medicina, UNAM, Mexico DF, Mexico.

Noonan syndrome (NS) is a dysmorphic syndrome characterized by hypertelorism, low-set posteriorly rotated ears, short stature, a short neck with webbing or redundancy of skin, cardiac anomalies, epicanthic folds and motor delay. NS may occur on a sporadic basis, with a predominance of paternal origin, or in an autosomal dominant inheritance with a predominance of maternal transmission. NS is clinically similar to the Turner syndrome. More than 50% of patients with NS have mutations in the *PTPN11* gene. Most of the mutations are recurrent and cluster in exons 3, 8 and 13. All the *PTPN11* missense mutations are present in the interacting regions of the amino N-SH2 domain and the phosphotyrosine phosphatase (PTP) domains. It seems that gain-of-function changes are responsible of the phenotype observed in NS. In the present study we analyzed the *PTPN11* gene in a group of 10 patients with diagnosis of NS. DNA genomic from leukocytes was extracted with conventional methods. All exons of the *PTPN11* were amplified and sequenced through polymerase chain reaction and DNA sequencing analyzes. We detected a low frequency of mutations in the *PTPN11* gene in the patients; most patients showed a normal sequence of the *PTPN11* gene. These data indicate that probably *PTPN11* gene mutations are not the most frequent cause of NS in Mexican population.

P01.188

Diverse driving forces underlie the occurrence of invariant PTPN11 mutations in Noonan and LEOPARD syndromes

S. Martinelli¹, P. Torrieri¹, M. Tinti², L. Stella², G. Bocchinfuso², E. Flex¹, A. Grottes³, S. Delle Vigne¹, M. Ceccarini¹, A. Palleschi², G. Cesaren², L. Castagnoli⁴, T. C. Petrucci¹, B. D. Gelb⁴, M. Tartaglia¹;

¹Istituto Superiore di Sanità, Rome, Italy, ²Università "Tor Vergata", Rome, Italy, ³Consorzio for the Application of Super-Computing for Universities and Research, Rome, Italy, ⁴Mount Sinai School of Medicine, New York, NY, United States.

Missense *PTPN11* mutations cause Noonan and LEOPARD syndromes (NS and LS), two developmental disorders with pleiomorphic phenotypes. *PTPN11* encodes SHP2, an SH2 domain-containing protein tyrosine phosphatase functioning as a signal transducer. Generally, different substitutions of a particular amino acid residue are observed in these diseases, indicating that the crucial factor is the residue being replaced. For a few codons, only one substitution is observed, suggesting the possibility of specific roles for the residue introduced. We analyzed the biochemical behavior and ligand-binding properties of all possible substitutions arising from single-base changes affecting codons 42, 139, 279, 282 and 468 to investigate the mechanisms underlying the invariant occurrence of the T42A, E139D and I282V substitutions in NS and the Y279C and T468M changes in LS. Our data demonstrate that the isoleucine-to-valine change at codon 282 is the only substitution at that position perturbing the stability of SHP2's closed conformation without impairing catalysis, while the threonine-to-alanine change at codon 42, but not other substitutions of that residue, promotes increased phosphopeptide binding affinity. The recognition specificity of the C-SH2 domain bearing the E139D substitution differed substantially from its wild type counterpart acquiring binding properties similar to those observed for the N-SH2 domain, revealing a novel mechanism of SHP2's functional dysregulation. Finally, while functional selection does not seem to occur for the substitutions at codons 279 and 468, we point to deamination of the methylated

cytosine at nucleotide 1403 as the driving factor leading to the high prevalence of the T468M change in LS.

P01.189

Diagnostic tests for Costello syndrome and cardio-facio-cutaneous syndrome - two years service experience.

J. A. Shorto¹, B. Kerr², B. Tang³, R. Elles¹;

¹Regional Molecular Genetics Service, Manchester, United Kingdom, ²Clinical Genetics Service, Manchester, United Kingdom, ³Academic Unit of Medical Genetics and Regional Genetics Service, Manchester, United Kingdom.

Costello and Cardio-Facio-Cutaneous (CFC) syndromes are autosomal dominant multiple congenital abnormalities with phenotypic overlaps to Noonan syndrome. The main difference with respect to their management is an increased tumour risk in Costello syndrome (approximately 17%).

Costello syndrome is associated with mutations in *HRAS* (82-92%), the majority of the mutations identified to date are in codons 12 and 13. No other disease causing genes have been identified. All five coding exons of *HRAS* are screened by bi-directional fluorescent sequencing.

So far four genes have been identified in CFC syndrome; *BRAF* (37-78% patients), *KRAS*, *MEK1* and *MEK2*. We use bi-directional fluorescent sequencing to screen *BRAF* (exons 6, 11, 12, 13, 14, 15 and 16), *KRAS* (all five coding exons), *MEK1* (exons 2 and 3) and *MEK2* (exons 2 and 3).

We have been offering a diagnostic service for both Costello syndrome and CFC syndrome for 2 years, since June 2006. So far 125 patients with a likely diagnosis of either Costello or CFC syndrome have been referred to us. We detected 26 pathogenic mutations in 101 patients tested for *HRAS* mutations. In the cohort of 71 patients tested for CFC syndrome we detected 19 pathogenic mutations (*BRAF*=14, *KRAS*=2, *MEK1*=3) and a further seven that are likely to be pathogenic (*BRAF*=4, *KRAS*=2, *MEK2*=1). We tested both parents of 14 patients with a known pathogenic mutation and 2 patients with a likely pathogenic mutation, in all cases the mutation was shown to be de novo.

Complex Approach to Diagnostics and Data Analysis for Neurofibromatosis type 1

T. Marikova¹, A. Krepelova¹, S. Bendova¹, B. Petrak¹, M. Kaluzova¹, M. Zalkova², L. Novakova², O. Stepankova²;

¹2nd Medical School, Prague 5 - Motol, Czech Republic, ²Czech Technical University, Prague, Czech Republic.

The Neurofibromatosis type 1 (NF1) is one of the most common single gene diseases (the expected incidence is 1:3000).

There was implemented a database of 300 records of patients suffering from NF1 in the Institute of Biology and Medical Genetics 2nd Medical School, Charles University in Prague.

The complex investigation methodology in the patients with a NF1 has been verified. The DNA bank for these patients was created containing 150 DNA samples. We have implemented reliable molecular genetic diagnostics of the NF1 gene using MLPA and DHPLC methods. We have investigated 39 families and detected causal mutation of the NF1 gene in 26 patients, from which 13 mutations were not been previously detected. Last year, we have implemented high resolution melt analysis (HRM) as an effective tool for the mutation scanning of the NF1 gene with sensitivity comparable with the DHPLC method.

The clinical, neurological, neurophysiological, and biochemical data of patients have been analyzed in detail by support of artificial intelligence methods.

The patient records are stored in the form of text files. Their content has to be converted into a database format to analyze them by available machine learning techniques. The pilot data analysis will be summarized.

San Paolo, University of Milan, Milano, Italy.

Neurofibromatosis type 1 (NF1), a genetic disease, with an estimate incidence of 1/3000. It is a neurocutaneous disorder characterized by multisystemic involvement. NF1 has a wide clinical variability even between family members, with the possibility of mild forms and age specific complications.

Although childhood clinical spectrum and possible complications are well known, few data are available on adult patients, concerning the evolution of the disease, the applicability of a follow up program, the indications for genetic testing, the social and health needs typical of this age.

We describe a clinical cohort of 80 adult NF1 patients, referred to Clinical Genetics Unit at Ospedale Maggiore Policlinico Mangiagalli e Regina Elena. The cohort is composed by 46 females and 34 males patients, age range: 19-69 years. NF1 was inherited from an affected parent in 24 cases (30%). The diagnosis was segmental NF1 in 5 cases, while the other 75 patients have a classical form of the disease. Clinical features and detected complications of this cohort are compared with the available literature data. Specific attention will be given to the typical and specific needs of adulthood, related to the reproductive life: demand for genetic counselling, recurrence risk, procreative option discussion, prenatal diagnosis request, pregnancy follow up in affected women.

P01.192

Prenatal diagnosis of neurofibromatosis type 1: Importance of genetic counseling

Y. Terzi¹, S. Oguzkan Balçık², B. Anlar³, S. Aysun³, S. Ayter¹;

¹Hacettepe University, Department of Medical Biology, Ankara, Turkey, ²University of Gaziantep, Department of Medical Biology, Gaziantep, Turkey, ³Hacettepe University, Department of Pediatric Neurology, Ankara, Turkey.

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder with an incidence of about 1 in 3500 live births. Because of the large size and complexity of the NF1 gene, the variety of mutations and the need to identify the specific mutation in each family, indirect diagnosis using linked markers has an important part in genetic counseling. In this study, thirty-seven families have been characterized and two prenatal diagnoses have been performed by using indirect analyses. Two family were informative for NF1 markers. One of fetuses was under NF1 risk. Now, she is 15 month old, has NF1 features. The variability of the phenotypic expression of the NF1 gene makes reproductive decisions in NF1 families very difficult. Even mutation detection can not help for decision because molecular diagnosis can not predict the severity of the disease. Therefore good genetic counseling is very important for the couples with the NF1 risk.

P01.193

Detection of a *de novo* germline deletion and somatic NF1 mutation in a 2 year-old boy with JMML and multiple café au lait spots

Y. J. Sznajder^{1,2}, A. Klein³, P. Heimann⁴, M. Hortala⁵, K. Claes⁶;

¹Hopital Universitaire des Enfants Reine Fabiola, Brussels, Belgium, ²Center for Human Genetics, U.L.B, Brussels, Belgium, ³Haematology-Oncology, Hopital Universitaire des Enfants Reine Fabiola, Brussels, Belgium, ⁴Genetic Oncology, Center for Genetics, ULB Hopital Erasme, Brussels, Belgium, ⁵Dermatology, Hopital Universitaire des Enfants Reine Fabiola, Brussels, Belgium, ⁶Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

We describe the history of a child from healthy unrelated parents diagnosed having juvenile myelomonocytic leukemia (JMML) at the age

of 10 months. Since 10% to 14% of patients with JMML have NF1; the present patient had multiple café-au-lait spots allowing to consider for Neurofibromatosis Type I (1,2). The standard karyotype on lymphocytes was 46,XY normal male. Bone marrow karyotype showed monosomy 7. By cDNA sequencing a frameshift mutation in *NF1* gene was characterized, c.2033dupC. With MLPA, total *NF1* gene deletion was observed. These mutations were confirmed on a second independent sample. On fibroblasts, we confirmed the total gene deletion providing evidence for a germline mutation while the c.2033dupC was absent (most likely representing a second hit mutation). Investigation on bone marrow is planned. This is the first report on a *NF1* microdeletion patient with JMML. The finding of a second hit point mutation in a patient with *NF1* microdeletion represents another example of that the type of germline mutation influences the type of second hit in the tumors (3). Loss of heterozygosity (LOH) in the *NF1* region is not an usual mechanism for somatic *NF1* inactivation from tumors in patients with a microdeletion. It is postulated that LOH of *NF1* microdeletion region in these patients would *de facto* lead to a nullizygous state of the genes and might be lethal.

Germline and somatic NF1 mutations and copy number alterations of chromosome 17 in sporadic and NF1-associated malignant peripheral nerve sheath tumors

I. Bottillo¹, I. Torrente¹, T. Ahlquist², H. Brekke², S. A. Danielsen², E. van den Berg³, F. Mertens⁴, R. A. Lothe², B. Dallapiccola^{1,5};

¹CSS-Mendel Institute, Rome, Italy, ²Department of Cancer Prevention, Institute for Cancer Research, Rikshospitalet Medical Centre, Oslo, Norway, ³Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands, ⁴Department of Clinical Genetics, Lund University Hospital, Lund SE-221 85, Sweden, ⁵Department of Experimental Medicine, Sapienza University, Rome, Italy.

Malignant peripheral nerve sheath tumor (MPNST) is a rare malignancy occurring with increased frequency in patients with neurofibromatosis type 1 (NF1). In contrast to the well known spectrum of germline *NF1* mutations, the information on somatic mutations in MPNSTs are limited. In this study we evaluated the presence of *NF1* mutations in 47 MPNSTs from patients with (n=25) or without (n=22) NF1; from 7 of the NF1-patients neurofibromas were also analyzed. The mutation status was assessed for two other genes, *KRAS* and *BRAF*. Mutation profiles were compared with copy number changes for chromosome 17 and *TP53* mutation status. Germline *NF1* mutations were detected in 17 NF1-patients: 6 frameshift, 5 truncating, 3 missense mutations, 2 large deletions, and 1 chromosome 17 imbalance. Somatic *NF1* mutations were found in 17/25 NF1-associated MPNSTs, in 3/7 neurofibromas and in 9/22 sporadic MPNSTs. Large chromosomal imbalances accounted for 13/17 and 7/9 somatic mutations in NF1-associated and sporadic MPNSTs, respectively. In the present cohort, 20 NF1-associated and 11 sporadic tumors harbored distal 17q gain. Two NF1-associated and 13 sporadic MPNSTs did not show any *NF1* mutation, arguing for a contribution of other genes. However, a major role of the *KRAS* or *BRAF* gene was excluded. Loss of the 17p13 region including the *TP53* gene appeared to be implicated both in NF1-associated and sporadic MPNSTs. The present results suggest that somatic and germline *NF1* mutations involved in MPNST development develop by two distinct mechanisms, the former being the same in sporadic and NF1-associated cases.

P01.195

Early-onset breast cancer in Neurofibromatosis type I

C. D. Delozier^{1,2}, W. J. Podalsky³, C. J. Curry^{1,2};

¹Genetic Medicine Central California, Fresno, CA, United States, ²UCSF-Fresno, Fresno, CA, United States, ³Radiation Oncology, Saint Agnes Medical Center, Fresno, CA, United States.

Neurofibromatosis type 1 (NF1), with an incidence of approximately 1/3500, is one of the most common hereditary disorders. Breast cancer, usually due to somatic rather than inherited gene mutations, is one of the most common malignancies; the lifetime risk for breast cancer in

women ranges by population from 8-12%.

Individuals with NF1 have a well-documented increase in the relative risk of several rare malignancies, including malignant nerve sheath tumors, childhood myeloid malignancies, neurogenic sarcomas, malignant CNS tumors, rhabdomyosarcomas, pheochromocytomas and carcinoid tumors. There has not, however, been a well-documented increase in the incidence of common adult-onset malignancies such as colon, breast and prostate, in individuals with NF1.

Over the past six months in our familial cancer clinic we have encountered two women with a classical presentation of NF1 who developed pre-menopausal invasive ductal carcinoma. A literature and database review initially revealed only anecdotal case reports of breast cancer in NF1, but a recent publication (Sharif et al., J MED GENET 44:481-484, 2007) concluded that women with NF1 under age 50 have an approximately 5-fold increased risk of breast cancer. We next proceeded to a more complete review of publications dealing with mortality and morbidity in NF1 and now agree with the above authors that women with NF1 should be offered earlier mammographic screening because of a moderately-increased risk of pre-menopausal breast cancer. Although a genotype-phenotype correlation might be suspected, such correlations have been difficult in NF1 in general and have not been identified in relation to breast cancer.

P01.196

Neurofibroma by numbers: mutational mechanisms, models and modifier genes

C. Garcia Linares¹, B. Canef², J. Fernandez², L. Benito², I. Blanco², C. Lázaro², E. Serra Arenas¹;

¹IDIBELL, L'Hospitalet de Llobregat (Barcelona), Spain, ²Institut Català d'Oncologia, L'Hospitalet de Llobregat (Barcelona), Spain.

The number of dermal neurofibromas (dNFs) in Neurofibromatosis type 1 patients is highly variable. It has been shown that there is an important genetic component in the variation of neurofibroma number that seems to be consistent with a polygenic effect. Neurofibroma initiates due to the double inactivation of the *NF1* gene. Most (if not all) somatic *NF1* inactivations in dNFs are due to mutation, thus genes important for DNA repair mechanisms are good candidates as modifier genes of neurofibroma number variability. We have chosen to study genes responsible for mitotic recombination as candidate modifiers, since mitotic recombination is an important mechanism leading to LOH that accounts for the 20-30% of somatic *NF1* inactivations in dNFs. We are employing different strategies, either directly in humans or using *Saccharomyces cerevisiae* as a model, for identifying candidate genes that will be used in association studies in a well-characterized cohort of NF1 patients.

P01.197

Mosaic neurofibromatosis type 1 (NF1) in Finland

M. Pöyhönen^{1,2}, J. Ruohonen¹, J. Peltonen³, S. Peltonen⁴;

¹Dept of Medical Genetics, University of Helsinki, Helsinki, Finland, ²Dept of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland, ³Institute of Biomedicine, Department of Anatomy, University of Turku, Turku, Finland, ⁴Department of Dermatology, University of Turku, Turku, Finland.

Background Neurofibromatoses are hereditary diseases that belong to the group of phakomatoses. NF1 has distinctive cutaneous features and NF2 has mainly intracranial lesions. In the segmental or mosaic type (NF5) the disease features of NF1 are distributed regionally on the body. There is no previous data on mosaic NF1 in Finland.

Methods Patients' disease features were collected from hospital files. A large literature search was made and the cases were compared with the Finnish patients. The objective was to study the incidence of mosaic NF1 in Finland and the disease features in Finnish patients.

Results Classification of patients unequivocally according to existing criteria for mosaic NF1 proved difficult. The incidence of mosaic NF1 in Finland (0,0005%) was lower than that found in other countries (0,0014%-0,002%), but in areas where the material was the most comprehensive (Turku and Oulu University Hospital districts) the incidences (0,0013% and 0,0011% respectively) were very similar to the other studies. The most common disease feature was the neurofibroma, which was found in 81% of the Finnish patients and in 76% of the cases in the literature. The frequency of café-au-lait-spots was respectively 39% and 35% and that of freckles 26% and 38%. Lisch nodules, mainly unilateral, presented in 15% of the Finnish patients

and in 8% of the literature cases.

Conclusions There is a need for more unified criteria for classifying mosaic NF1. The incidence and disease features of mosaic NF1 in Finland are similar to those found in other countries and in the literature.

P01.198

Analysis of the *NF1* gene in a cohort of 118 unselected NF1 patients using direct cDNA sequencing complemented with MLPA analysis

B. Campos¹, J. Gardenyes¹, O. Abad¹, P. Fábregas¹, S. Bernaf², V. Volpini¹;
¹IDIBELL, L'Hospitalet de Llobregat, Spain, ²Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Neurofibromatosis type 1 (NF1) [MIM 162200] is a common dominant autosomal disorder, affecting 1 in 3500 individuals. The disease is caused by mutations in the *NF1* gene at 17q11.2, in which has been identified a wide range of molecular abnormalities. In the last years it has made clear the need for a reliable and sensitive genetic test for the *NF1* gene to help resolve diagnostic dilemmas in patients not fulfilling clinical criteria as those defined by The National Institutes of Health (NIH).

We screened for mutations a panel of 118 unrelated patients suspected of having NF1, using direct cDNA sequencing complemented with multiplex ligation-dependent probe amplification (MLPA) analysis. Possible disease causing mutations were identified in 82 (69%) cases. These comprised 74 different sequence alterations, of which 46 were novel. Among the 82 changes identified, we observed 26 (32%) frame-shift mutations, 21 (26%) nonsense mutations, 15 (18%) splice errors and 6 (7%) missense mutations. Furthermore, using MLPA approach we found 14 mutations (17%): 8 total gene deletions, 4 multiexon deletions and 2 multiexon duplications.

Out of the 118 cases referred, there were 84 patients with reliable clinical data, of whom 53 satisfied the NIH diagnostic criteria. Within this better defined cohort of NF1 patients, mutations were identified in 47 individuals (89%). Interestingly, 10 out of 24 (42%) patients who satisfied only one NIH criteria carried a mutation.

Our results show that direct cDNA sequencing together with MLPA analysis provide a sensitive and specific method for the rapid identification of *NF1* mutations.

P01.199

Genetic diagnosis of Neurofibromatosis 1 in 62 Spanish patients and determination of the mutational spectrum of the *NF1* gene in our population

J. Garcia-Planells^{1,2}, M. Molero¹, M. Bellón¹, M. Torres-Puente¹, M. Perez-Alonso^{1,2};

¹Sistemas Genómicos, Valencia, Spain, ²Instituto Valenciano de Genética, IVGEN, Valencia, Spain.

Neurofibromatosis 1 (NF1) is a multisystemic disease characterized by the presence of multiple café au lait spots, freckling, neurofibromas and iris Lisch nodules. NF1 is caused by mutations in the *NF1* gene, more than 500 different mutations been identified and many of them are private. A half of mutations are *de novo* and the mutational heterogeneity of *NF1* gene is high: point mutations (27%), splicing mutations (20%), small deletion or insertion (47%) and large deletions or rearrangements (8%). The aims of this work are: i) to achieve a genetic diagnosis in patients with clinical criteria of NF1, ii) to evaluate the RNA sequencing of the *NF1* gene as a diagnostic methodology for Neurofibromatosis 1, iii) to determinate the mutational spectrum of the *NF1* gene in our series. Here we report our three years results and experience with genetic diagnosis of NF1. We have achieved a genetic diagnosis in 75 patients and 42 mutations not reported previously have been identified. RNA sequencing of the *NF1* gene is the methodology gold standard for the genetic diagnosis of Neurofibromatosis 1, because it allows to identify point mutations, splicing mutations and duplications or deletions, including these affecting to one or a only a few exons. The mutational spectrum of the *NF1* gene obtained in our population provides an interesting epidemiologic and pathogenic information. A high expertise and experience must be required for the interpretation of nucleotide changes identified in the sequencing of genes with a high rate of *de novo* mutations

UMD-DMD France is a national locus-specific database (LSDB) dedicated to dystrophinopathies. It has been developed through a multi-center academic effort to provide an up-to-date resource of curated information covering all identified and fully validated mutations in patients with dystrophinopathies in France. Whenever necessary, mutations have been reevaluated at the light of the currently available techniques. The database includes 2270 entries corresponding to 2070 independent mutational events identified in either male patients (2034) or symptomatic female carriers (36). These mutations consist in 1420 deletions, 261 duplications, and 449 small rearrangements of which 39.1% are nonsense. Most of them are unpublished. Experts in the DMD gene and related diseases are responsible for data quality and accuracy. In addition to gather mutations, the UMD-DMD France includes available data on dystrophin and RNA analysis, phenotypic groups, and transmission. The database aims to include extensive description of phenotypes associated with the reported mutations to better delineate the clinical spectrum of dystrophinopathies and to allow genotype/phenotype correlations. In addition to the existing routines in the UMD software, new tools have been specifically developed to facilitate large-scale mutation analyses of the DMD gene. UMD-DMD is a searchable anonymous database which will benefit to all the scientific community interested in dystrophinopathies including geneticists, clinicians, and researchers involved in the design of therapeutic strategies. It will prove useful also to implement forthcoming global registries of patients for clinical trials as ultimate goal within the European network of excellence for treatment of neuromuscular disorders (TREAT-NMD).

P01.201

Analysis of duplications within the DMD gene

B. Dworniczak, E. Minor, S. Hamer, B. Hitschfeld, P. Pennenkamp; University of Muenster, Muenster, Germany.

The DMD gene is one of the largest human genes identified, spanning more than 2000 kb of genomic DNA encoding a 14-kb transcript. It is known that 60 to 65% of the mutations causing DMD/BMD are large deletions in the dystrophin gene. The deletions are nonrandomly distributed and occur primarily in the center (80%) and less frequently near the 5' end (20%) of the gene. The large size of the gene may account for part of the high deletion rate. However because of the nonrandom distribution of the deletions, in addition to target size, other factors must be involved like variation in chromosomal stability. Although partial gene duplications in the DMD gene were reported to be relatively frequent (5% - 10%), only recently - with the development of MLPA - detection of duplications in male patients and deletions and duplication in female carriers became feasible in a routine setting and first data concerning frequency and distribution of duplications within the DMD gene became available.

These data show that unlike the deletion distribution, the majority of the duplications (80%) are found at the 5' end of the gene and only 20% in the central region suggesting that deletions and duplication originate by different mechanism.

To investigate the mechanism causing duplications in more detail and to compare this mechanism with mechanism causing deletions in the same region of the gene we precisely mapped duplication breakpoints

and sequenced six of them. First data of these comparisons will be presented.

P01.202

Congenital Muscular Dystrophy with heterozygous mutations in LAMA2 and FKRP

Y. Nevo¹, M. Becker-Cohen¹, Y. Yaron², E. Pras³, H. Resnik-Wolf³, M. Rachmiel¹, **S. Mitrani-Rosenbaum¹**;

¹Hadassah Hebrew University Medical Center, Jerusalem, Israel, ²Tel Aviv Souraski Medical Center, Tel Aviv, Israel, ³Sheba Medical Center, Tel Aviv University, Tel Hashomer, Israel.

A child presenting with hypotonia and muscle weakness since infancy, ambulation until twelve years of age, seizures and normal cognitive function is described. CK was elevated (650-1420 IU/L). Brain MRI showed a few abnormal T2 white matter changes. Muscle biopsy showed dystrophic features and skin biopsy demonstrated absence of merosin immunostaining (300 kd antibodies, Novocastra Laboratories). Molecular genetic studies detected heterozygote mutations in both the LAMA2 (Val1754X) and FKRP (A114G) genes, which were traced to the father and to the mother respectively. Two subsequent sibling fetuses carried the LAMA2 mutation. In one of them the FKRP mutation was also detected in one allele and in the other the FKRP gene was normal at both alleles. Even though the genotype of the two aborted fetuses and the patient were identical at the LAMA2 locus, the fetuses had normal merosin staining in chorionic villus sampling, whereas the patient was merosin-negative. Our findings suggest an additional potential interactive mechanism to LAMA2, possibly of the FKRP protein which is essential for preserving the sarcolemma integrity. These findings suggest that merosin-deficiency could be the result of di-genic inheritance.

P01.203

Genetic testing and counseling for Facioscapulohumeral Muscular Dystrophy (FSHD) in Israel, 2000-6

M. Yanoov-Sharav¹, E. Leshinsky-Silver¹, C. Vinkler¹, M. Michelson-Kerman¹, S. Cohen¹, T. Lerman-Sagie^{1,2}, M. Ginzberg¹, M. Sadeh^{1,2}, **D. Levi^{1,2}**;

¹Wolfson Medical Center, Holon, Israel, ²Tel-Aviv University, Tel-Aviv, Israel.

In the last few years our laboratory at Wolfson Medical Center has been the only lab in Israel to perform genetic testing for FSHD, a common, dominantly inherited, late onset, progressive, but relatively mild type of muscular dystrophy, with considerable clinical variability even within families. No treatment or prevention of symptoms are available, prenatal diagnosis is complicated and pregnancy termination of affected fetuses - ethically controversial. FSHD genetic testing is important for prognosis and genetic counseling, since clinical overlap exists between FSHD and other LGMDs.

The gene causing FSHD has not been identified, but molecular diagnosis can be made by analyzing D4Z4 repeat length on chromosome 4q35. Results can support or rule out the clinical diagnosis of FSHD, but there are also "gray zone", non-conclusive results.

66 individuals were tested during the years 2000-6, including 7 asymptomatic individuals.

We present our results and conclusions and recommendations regarding the percentage of conclusive results obtained after FSHD genetic testing, cognitive involvement frequency and anticipation in our patient sample. Additionally, based on our results, recommendations for genetic counseling of individuals and families referred for FSHD testing are given, including addressing the issue of presymptomatic testing.

P01.204

A novel mutation in FKRP gene in Italian patient with LGMD

R. Cittadella¹, A. La Russa¹, P. Valentino², V. Andreoli¹, F. Trecroci¹, I. Manna¹, M. Liguori¹, P. Spadafora¹, A. Quattrone^{1,2};

¹Institute of Neurological Science National Research Council, Cosenza, Italy,

²Institute of Neurology, University "Magna Graecia", Catanzaro, Italy.

Limb-girdle muscular dystrophy type 2I (LGMD2I) is an autosomal recessive muscular dystrophy caused by mutations in the gene coding for fukutin-related protein (FKRP). LGMD2I is clinically heterogeneous, and it is allelic to MDC1C (congenital muscular dystrophy type1C) with onset in the neonatal period. The function of FKRP in skeletal muscle is largely unknown; however, indirect evidence suggests that FKRP may be a putative glycosyltransferase involved in α -dystroglycan (α -DG) processing. Muscle biopsies of patients affected by either LG-

MD2I or MDC1C show a variable reduction of α -DG glycosylation. We report a 70 year-old man he was referred for muscle weakness of the lower limbs starting at age 20 and mild but progressive hypotrophy of girdle. After informed consent, mutations screening was performed on genomic DNA in regard to of CAV3 and CAPN3 genes. The patient found negative screening of these genes, has been investigated for mutations of FKRP gene. The mutation analysis showed a missense change (Ser115Leu), in heterozygous state, never described. To confirm that the alteration found was mutation and not polymorphism, a screening was carried out with 100 control Caucasian chromosomes. In conclusion this mutation of the FKRP gene could even be responsible for mild phenotype of the patient.

P01.205

Mutation analysis of the CAPN3 gene in Italian patients with suspected LGMD type 2

A. La Russa¹, P. Valentino², V. Andreoli¹, F. Trecroci¹, I. Manna¹, M. Liguori¹, P. Spadafora¹, R. Cittadella¹;

¹Institute of Neurological Science, National Research Council, Cosenza, Cosenza, Italy, ²Institute of Neurology, University "Magna Graecia, Catanzaro, Italy.

Autosomal recessive limb girdle muscular dystrophies (LGMD type 2) are a clinically and genetically heterogeneous group of disorders, characterized by progressive involvement of proximal limb girdle muscles. LGMD2A (MIM# 253600), whose locus has been mapped to chromosome 15q15.1, is considered to be the most frequent form of recessive LGMD. LGMD2A is caused by single or small nucleotide changes widespread along a 40-kb gene, named CAPN3 (MIM# 114240), which encodes for the calpain-3 protein. Aims of this study were to assess the frequency of mutations in 30 Calabrian patients suspected diagnosis LGMD and identify possible genotype-phenotype correlation as prognostic factors. At the screening of gene CAPN3 have been identified already described mutation (R748X) in exon 21 and a new polymorphism (CTCT) in intron 14, while all other samples had already described polymorphisms. The subject bearer of R748X mutation in heterozygosity had a mild phenotype, in fact related onset of disease at 48 years and the muscle biopsy showed a slight myopathy associated with a pain and weakness in the lower limbs. In particular, this mutation was associated with another exchange in exon 5 Ala236Thr described in the literature as polymorphism. However, the combination of a polymorphism in one copy of the CAPN3 gene with an LGMD2A mutation in the other copy could even be responsible for very mild phenotype with low penetrance. Patients with LGMD2 phenotype in the absence of mutations in CAPN3 should be investigated for the genes responsible for other forms of LGMD2.

P01.206

Myopathy - an early finding in several rare genetic syndromes

M. Bembea, C. Jurca, C. Skrypyk, D. Bembea, C. Moldovan, C. Cladovan, K. Kozma;

Clinical Municipal Hospital "dr. G. Curteanu", ORADEA, Romania.

Introduction. Myopathies are part of the larger group of neuromuscular disorders. The main clinical manifestation is muscular weakness. Myopathy is associated with over 150 hereditary entities and may be the first clinical manifestation in several rare genetic syndromes. Objective. To present a case series of rare monogenic syndromes that were initially diagnosed based on the finding of myopathic features. Results. We are presenting a case of Schwartz-Jumpel syndrome with familial distribution (consanguineous parents with three affected daughters), a case of Dubowitz syndrome with familial distribution (consanguineous parents with two affected sons) and a case of Camurati-Engelmann syndrome. In all cases, the first manifestations of disease that prompted medical care were myopathic in nature. Conclusion. Muscle weakness in children, if no clear cause is found, should prompt further investigation to rule out rare genetic disorders.

P01.207

Prenatal diagnosis of Duchenne/Becker muscular dystrophy in Serbia-twelve years experience

T. Lalic, D. Radivojevic, M. Djuricic, M. Guc-Sccekic, V. Ivanovski;

Mother and Child Health Institute of Serbia, Belgrade, Serbia.

In Serbia, prenatal testing for Duchenne/Becker muscular dystrophy (D/BMD) is an option for women at risk of having an affected son,

since 1996.

During period 1996-2007 in total 54 prenatal tests were performed in 43 families. From these, 34 pregnancies were male pregnancies at risk of D/BMD and 8 of them (23.5%) showed an increased risk.

DNA extraction was done from chorionic villuses samples in 41 (76%) cases, amniotic fluid cells in 11 (20.3%) cases and in 2 cases (3.7%) from fetal blood samples. Prenatal diagnosis was based on direct detection of the mutation in 51 cases. In 49 of them, we used standard multiplex PCR for simultaneous amplification of 18 DMD exons. In two cases MLPA was applied for determining carrier status of mothers and the detection of the duplications in DMD gene of fetuses. In 3 cases (5.55%), with unknown mutation in proband, prenatal diagnosis was done by indirect DNA analysis. Maternal contamination has been excluded in all cases using polymorphic CA markers.

Since no clinically applicable and effective therapy for DMD patients has yet been developed, a molecular diagnosis should be proposed to the families in order to detect the carrier women and to suggest an antenatal diagnosis.

P01.208

Genetic testing, carrier detection and prenatal diagnosis of 300 Egyptian families with Duchenne muscular dystrophy: a 10 years experience

K. S. Amr, A. Elharouni, L. K. Effat;

National Research Centre, Cairo, Egypt.

Duchenne Muscular Dystrophy (DMD) is the most common lethal X-linked recessive muscle disorder that is caused by mutations in the dystrophin gene. Due to lack of efficient rehabilitation and treatment, prenatal diagnosis and counseling of families with DMD are of great importance. Here we report a 10 years Egyptian experience on the molecular diagnosis and genetic counseling of 300 families with DMD at the National Research Centre, Cairo.

300 probands with DMD were screened for dystrophin gene deletion mutations by multiplex PCR. Four CA dinucleotide repeats and three restriction fragment length polymorphisms (RFLPs) were used to detect the carrier status in 35 families. Prenatal molecular diagnosis was pursued for 32 pregnant mothers at risk of having a child with DMD by multiplex PCR when there is a deletion mutation in the affected sib or by intragenic markers in families with no deletion mutations.

55% of probands had deletion mutations. 60% of detected deletions involved multiple exons spanning the major and/or minor hotspots of the gene while 40% involved single exon deletions. The combined use of CA repeats and RFLPs detected the carrier status in all families identifying 20 female carriers. Molecular diagnosis of the fetal DNA showed that 15 fetuses inherited the same deletion mutations present in the index cases. A high acceptability of seeking prenatal diagnosis and a change in attitude towards the decision of abortion was noticed.

Molecular diagnosis, carrier detection and prenatal diagnosis are effective tools for definitive diagnosis and genetic counseling in families affected with DMD.

P01.209

Prenatal diagnosis in a DMD family at risk

D. F. Albu, C. Albu, E. Severin;

"Carol Davila" Univ Med Pharm, Bucharest, Romania.

A 23-year-old pregnant woman is the sister of a patient who is affected by Duchenne muscular dystrophy (DMD). Her brother, an 18-year-old male, was detected to have a novel mutation in exon 6 of the DMD gene (c.587delAT). She asked for prenatal diagnosis to detect whether her unborn child has DMD or not. A prenatal diagnosis by chorionic villi sampling (CVS) was performed at 10 weeks of pregnancy. Analysis consisted of PCR amplification followed by direct sequencing of the entire coding region of the DMD gene. The fetus showed a normal male karyotype (46,XY) and no abnormality of the dystrophin gene. In this case, prenatal diagnosis by CVS was able to exclude DMD in the unborn child.

P01.210**The high frequency of new mutations in dystrophin gene in the group of Polish patients affected with Duchenne/Becker muscular dystrophy**

J. G. Zimowski, M. Holding, W. Szirkowicz, E. Fidzianska, J. Kubalska, E. Zdzienicka, J. Zaremba;

Institute of Psychiatry and Neurology, Warsaw, Poland.

The frequency of Duchenne/Becker muscular dystrophy (DMD/BMD) among the newborn males is 1: 3500. The constant of DMD/BMD incidence in male population is the evidence of the stable frequency of new mutations. Although men affected with DMD/BMD usually are not able to reproduce incidence of the disease remains the same. It is assumed that 1/3 of single DMD/BMD male are the cases of new mutations.

The study of carriership was carried out in a group of 249 mothers with one son affected with DMD/BMD in whom deletions in dystrophin gene were found. The studies of microsatellite sequences in the mothers revealed the presence of two different alleles in 138 females, therefore their carriership could be excluded. In 38 cases, in which mothers or daughters (sisters of affected males) were tested, the presence of the deletion was observed. The homozygosity was detected among 73 females. Some of them may be instances of hemizygoty. The exclusion of carriership in 55% of tested females is statistically different from the expected incidence of 33%.

Support from State Committee Scientific Research (PBZ-KBN-122/P05/2004)

P01.211**Two novel mutations in a Russian family with X-linked Emery-Dreifuss muscular dystrophy**

A. L. Chuhrova, T. B. Tiburkova, O. A. Schagina, E. L. Dadaly, A. V. Polyakov; *Research centre for medical genetics, Moscow, Russian Federation.*

Emery-Dreifuss muscular dystrophy (EDMD) is a neuromuscular disease characterised by early contractures of Achilles-heel, elbows and spine, slow progression and symmetric weakness prominent in humero-peroneal muscle, cardiac conduction abnormality and/or cardiomyopathy and myopathic features. Two main modes of inheritance exist: X-linked and autosomal dominant. The frequency of the X-linked form is at 1:100 000. *EMD* gene mutations, which encodes a nuclear membrane protein named emerin, are causes of the X-linked form of EDMD. *EMD* gene has been mapped to the region Xq28. Mutation analysis in *EMD* gene was performed by direct automatic sequence on Genetic Analyzer 3130 of all exons and exon-intron splices. We describe two novel mutations in the *EMD* gene in two Russian families. Mutations change nucleotide sequence of the sixth exon in the *EMD* gene. Family 1 had a c.664C>T (p.Gln222Stop) which causes a premature stop-codon at position 222. In second family we found the mutation c.449+1delG which causes a disappearance donor splicing-site and subsequent - a premature stop-codone at position 221.

P01.212**Genotype-phenotype correlates in autosomal recessive Myotonia Congenita**

I. Torrente¹, A. Modon², E. Pisaneschi¹, A. D'Amico², L. Merlini³, G. Silvestri², E. M. Valente^{1,4}, B. Dallapiccola^{1,5}, M. Lo Monaco²;

¹CSS-Mendel Institute, Rome, Italy, ²Department of Neuroscience, Catholic University of Rome, Rome, Italy, ³Department of Experimental and Diagnostic Medicine, Division of Medical Genetics, University of Ferrara, Ferrara, Italy, ⁴Dpt of Medical and Surgical Pediatric Science, University of Messina, Messina, Italy, ⁵Department of Experimental Medicine and Pathology, "La Sapienza" University of Rome, Rome, Italy.

Myotonia Congenita (MC) is a chloride channel disorder due to mutations in the *CLCN1* gene, inherited in autosomal dominant or recessive fashion. Beside myotonia of variable severity, transitory weakness (TW) can be detected, especially in recessive cases. Neurophysiologically, TW corresponds to a transitory depression (TD) of the compound muscle action potential during repetitive nerve stimulation (RNS). We sought to correlate specific *CLCN1* mutations with both TW and RNS-induced TD in 28 patients with recessive MC, by adopting a low frequency RNS protocol (3Hz for 500 stimuli). The 3Hz RNS induced a significant TD in 19 patients, all of whom experienced variable episodes of TW. Several mutations appeared to correlate with specific TD patterns. In particular, the homozygous exon 9 deletion, C481X

and IVS1+3A>T mutations (5 cases), as well as the compound heterozygous mutations G482R and T550R (1 case), always resulted in marked TD. Conversely, F167L seems to associate with mild or no TD, since 8 of 10 patients carrying this mutation (in compound heterozygosity with other mutations) had clinical absence of TW and a negative RNS test. Finally, the 3 patients heterozygous for the A531V change (compound with either R377X or R894X) presented a peculiar pattern of fluctuating TD. This study shows that the 3Hz RNS protocol, well tolerated by patients, is able to identify distinct neurophysiological TD patterns correlating with specific *CLCN1* mutations. In turn, this may help understand the molecular basis underlying the phenotypic variability of MC, and may represent a step towards rational therapeutic strategies.

P01.213**DNA-diagnostics of myotonic dystrophy type 1 in Belarus**

T. Asadchuk, K. Mosse, N. Rumyantseva;

Scientific-Practical Center "Mother and Child", Minsk, Belarus.

Myotonic dystrophy type 1 (DM1) is an autosomal dominant, multisystemic disease, with an estimated incidence of 1 in 8000. DM is caused by expansion of CTG trinucleotide repeats located in the 3' untranslated region of the myotonin protein kinase (DMPK) gene. The range of expansion varies widely from 50 to several thousand repeats. First, we analysed the distribution of CTG-repeats in a cohort of normal individuals from the Belarusian population, and assessed the heterozygosity and number of alleles. PCR-products were analysed by the automated capillary electrophoresis on the ABI Prism 310. We found 15 different allelic variants from 5 up to 28 CTG-repeats. The most common alleles had 5 repeats (38%). The heterozygosity of the CTG polymorphism of the Belarusian population was established as 78%. DNA-diagnostics of DM1 was done in 75 patients from 32 families showing different symptoms related to the disease. We found small expansions with 70 and 86 CTG repeats in two affected men from two different families. PCR analysis also shows the high risk of mutation of the DMPK gene in 10 patients from 3 families, further confirmed by the Southern blot. So our PCR-based protocol allows amplification of normal-sized alleles and small expansions. For the large expansion Southern blot analysis is still the method of choice.

P01.214**Molecular studies on two myotonic dystrophies (DM1 and DM2) in Polish patients group**

W. Krysa¹, A. Sulek-Piatkowska¹, M. Rajkiewicz¹, E. Szmiedt-Salkowska², A. Kamińska², J. Zaremba¹;

¹Institute of Psychiatry and Neurology, Warsaw, Poland, ²Medical University, Warsaw, Poland.

Myotonic dystrophies type 1 and type 2 (DM1 and DM2) are autosomal dominant disorders and share similar symptoms comprising myotonia, muscular dystrophy, and multisystem involvement (cataracts, diabetes and hypogonadism), but overall clinical picture of these two conditions is not identical.

Molecular defect causing DM1 and DM2 is known as dynamic mutation in DMPK and ZNF7 genes respectively. Expansions up to 4000 CTG repeats result in DM1 whereas a CCTG tetramers up to 11000 in patients with DM2 are observed.

Molecular testing is the only reliable diagnostic definition in DM1 and DM2. Prior to its introduction we have performed the analysis of normal alleles distribution in Polish control group. For DM1 locus the range is 5-31 repeats and for DM2 the range of repeat motif varied from 123 to 159 bp.

For 5 years 372 individuals were tested for DM1 and/or DM2 by routine PCR, then all homozygous cases were analyzed by TP-PCR. Among them we have identified 76 pedigrees with 144 DM1 and 34 pedigrees with 35 DM2 mutation carriers. Within the group of DM1 patients we identified one family with a case of premutation which resulted in full mutation in the following generation. Moreover, we identified a patient with a coexistence of full mutation and premutation in DMPK gene. Among DM2 group we came across a family with two patients having extended alleles - 189 bp and 197 bp i.e. clearly above the normal range but below the considered as pathogenic range in DM2 (normal range 104-176 bp).

P01.215**The CTG repeat expansion size correlates with the splicing defects observed in muscles from myotonic dystrophy type 1 patients**

A. Botta¹, F. Rinaldi¹, C. Catali², L. Vergani², E. Bonifazi², V. Romeo³, E. Loro³, A. Viola¹, C. Angelini³, G. Novelli^{1,2};

¹Tor Vergata University of Rome, Rome, Italy, ²Tor Vergata Hospital, Rome, Italy, ³University of Padoa, Padoa, Italy.

Myotonic dystrophy type 1 (DM1; MIM#160900) is caused by an unstable (CTG)_n repetition located in the 3'UTR of the DMPK gene. Untranslated expanded DMPK transcripts are retained in ribonuclear foci and sequester CUG-binding proteins essential for the maturation of pre-mRNAs. In this study, we investigated the effects of CTG expansion length on three molecular parameters associated with the DM1 muscle pathology: 1) the expression level of the DMPK gene; 2) the degree of splicing misregulation and 3) the number of ribonuclear foci. To this purpose, we selected 6 muscle biopsies from DM1 patients with an expansion below 500 repetitions, 6 muscle samples from DM1 patients carrying a mutation above 1000 CTGs and 6 controls muscle samples. Splicing analysis of the IR, MBNL1, c-TNT and CLCN1 genes demonstrated that the level of aberrant splicing isoforms is strikingly different between the two groups of DM1 muscle samples. In addition, a significant correlation was observed in the extent of abnormal splicing and the CTG repeat length for all the genes studied. RNA-FISH analysis reveals that the number of ribonuclear foci accumulating in DM1 muscle sections increases in patients with a higher (CTG)_n number. On the contrary, we did not find any relationships between the expression level of the DMPK gene transcript and average expansion sizes. These data indicate that the CTG repeat length plays a key role in the extent of splicing misregulation and foci formation, thus providing a useful link between the genotype and the molecular cellular phenotype in DM1.

P01.216**The results of a systematic screening for new mutations in NAIP gene**

P. Apostol¹, D. Cimponeriu¹, M. Stavarachi¹, N. Butoianu¹, I. Minciu¹, C. Burloiu¹, M. Toma¹, D. Cheta¹, C. Serafinceanu¹, L. Gavrilă¹;

¹Institute of Genetics, Bucharest, Romania.

Background: The NAIP gene is located in an inverted duplicated region (5q13), enclosed to some repetitive elements which predispose to chromosomal rearrangements. However, a small number of NAIP mutations/polymorphisms were reported in this region which is considered a hot-spot mutational. The most common NAIP mutation is a deletion involving exon 5, which has been reported to be associated with spinal muscular atrophy (SMA) complications.

Aim: The aim of this study was to screen the NAIP gene for new mutations/polymorphisms.

Material and methods: We selected for this study SMA patients (n=63), dialyzed patients (n=200) and healthy clinical subjects (control group, n=370) after informed consent obtaining. The DNA samples for all subjects were screened for presence of NAIP exon 5 by PCR. We also used specific molecular methods to test the presence of additional mutations in this region.

Results and discussion: The homozygous absence of NAIP exon 5 was observed in 20,6% SMA patients and in 1% of dialyzed and control subjects. The restriction pattern (DraI) and the indirect methods have been shown that a sample from dialyzed lot has an abnormal electrophoretic and melting compartment. The sequencing analyses have confirmed a heterozygous state for a G/T substitution (Arginine/Serine), which creates a new restriction site for DraI endonuclease. The etiology of renal failure could not be established.

Conclusion: In this study we have identified a new coding G/T SNP in NAIP gene and the highest frequency of homozygous NAIP exon 5 deletion in SMA patients (20,6%).

P01.217**Soluble expanded PABPN1 exacerbates cell death in Oculopharyngeal Muscular Dystrophy**

C. Messaëd^{1,2}, P. Dion¹, A. Abu-Baker¹, D. Rochefort¹, J. Laganiere¹, B. Brais¹, G. A. Rouleau¹;

¹Center of excellence in neuromics, Notre-Dame-CHUM, Montreal, Canada,

QC, Canada, ²University of McGill, Montreal, QC, Canada.

Oculopharyngeal muscular dystrophy (OPMD) is an autosomal dominant late-onset myopathy characterized by progressive eyelid drooping, swallowing difficulty and proximal limb weakness. OPMD results from the expansion of a polyalanine repeat (GCG)₈₋₁₃ in exon 1 of the *poly(A)binding protein nuclear1* (PABPN1) gene. Nuclear aggregates consisting of tubular filaments within muscle fibers of OPMD patients are the pathological hallmark of the disease. These aggregates contain expanded PABPN1 (expPABPN1), poly(A)RNA as well as components of the ubiquitin-proteasome degradation pathway and molecular chaperones. Whether nuclear aggregates are pathogenic or simply the consequence of a molecular defense mechanism remains controversial in OPMD and in the field of neurodegenerative disorders. To evaluate the contribution of nuclear aggregates to cellular toxicity, we first targeted molecular mechanisms known to interfere with expPABPN1 aggregation. Our cellular model shows that increasing the availability of nuclear soluble expPABPN1 significantly exacerbates cell death. We also used time lapse imaging to follow the evolution of cells overexpressing expPABPN1 without interfering with any cellular pathway. Cells with nuclear aggregates show a significantly prolonged lifespan compared to cells harbouring a diffusely distributed soluble expPABPN1. This is the first report indicating the beneficial effect of nuclear aggregation in OPMD. The formation of nuclear aggregates may reflect an active process by which cells sequester and inactivate the soluble toxic form of expPABPN1. The structural change in expPABPN1, induced by the pathogenic alanine expansion, may lead to a gain of aberrant protein interactions, or alternatively prevent normally occurring interactions to take place.

P01.218**Spinal muscular atrophy in University Hospital Brno, Czech Republic- Genetic counselling, DNA analysis, Prenatal analysis**

²University Hospital Brno, Brno, Czech Republic.

Spinal muscular atrophy (SMA) is the second most frequent lethal autosomal recessive disease in Europeans with the incidence of 1/6000 -10 000 and a carrier frequency of 1/40-50. SMA is in approximately 96% of cases caused by homozygous deletion of the SMN1 gene. 4% of SMA patients have a combination of the deletion or conversion in one allele and an intragenic mutation on the second one. The SMA-determining gene (survival motor neuron - SMN), is present on 5q13 in two copies, a telomeric SMN1 gene and a centromeric SMN2 gene, which are highly homologous and contain only five base-pair differences. However, increased SMN2 gene copy number, which can occur as the result of gene conversion events, is associated with a milder SMA phenotype.

Since 1999, we have performed the DNA analysis of SMA, the carrier detection from 2003 and from 2005 we analysed the copy number of SMN2 gene.

Until now, we examined more than 300 SMA patients, only one SMN1 copy was detected in 17 of them, we identified 6 point mutations.

Currently, we perform the genetic counselling in families with SMA occurrence, we offer DNA analysis of the SMN1 gene in the proband and the detection of SMA carriers. We offer the DNA analysis of SMN1 gene for partners of SMA carriers. In families with high risk of SMA in the child we offer prenatal DNA diagnostics from cultivated amniotic cells.

P01.219**Accuracy of marker analysis, quantitative real time PCR and Multiple Ligation-dependent Probe Amplification to determine SMN2 copy number in patients with spinal muscular atrophy**

L. Alias¹, M. J. Barcelo¹, S. Bernal¹, E. Also-Rallo¹, R. Martínez¹, M. Baena¹, P. Galiano¹, M. Baiget¹, E. F. Tizzano¹;

¹Hospital Sant Pau, Barcelona, Spain.

Spinal muscular atrophy (SMA) is an autosomal recessive disease characterised by degeneration of motor neurons of the spinal cord and is caused by mutations in the SMN1 gene. The SMN2 gene is the highly homologous SMN1 copy that is present in all patients. There is

evidence that the number of SMN2 copies acts as a phenotypic modifier. Acute type I patients usually have one-two copies and chronic type II and III patients usually have three-four copies. Traditionally, the linkage analysis with C212 and C272(ag1-CA) markers was helpful in estimating the SMN2 copies. Quantitative real time analysis (Q-RT) and recently multiple ligation-dependent probe amplification (MLPA) have been incorporated into laboratory diagnosis to establish the SMN2 copies with greater accuracy.

We compared the SMN2 copy number of 22 unrelated Spanish SMA patients with SMN1 absence, correlating the three aforementioned approaches. Using marker analysis, we determined the maximum number of alleles by C212 or C272(ag1-CA), estimating the number of SMN2 copies. The marker results of the respective parents were used to confirm the copy number. In 4 cases, marker analysis predicted two SMN2 copies and Q-RT (LightCycler) and MLPA revealed three SMN2 copies. This discordance may be the result of an uninformative marker. In 2 other cases, marker results predicted at least three SMN2 copies although Q-RT showed two copies and MLPA results were compatible with three copies. This discordance may reflect the lack of probe hybridisation in some samples and highlights the importance of matching results of the three approaches. FIS05-2416/CIBERER/Proyect GE-NAME.

P01.220

DNA diagnostic of Duchenne-Becker muscular dystrophy in Belarus

S. Miasnikov¹, I. Naumchik², R. Khmeľ², N. Rumyantseva²;

¹International Sakharov Environmental University, Minsk, Belarus, ²National centre of research and applied medicine «Mother and child», Minsk, Belarus.

Duchenne-Becker muscular dystrophy (D/BMD) is X-linked recessive muscle-wasting disease with incidence 1:3500 and 1:20000 of male newborns respectively. The cause of this disorder is mutations of the gene DMD, located on locus Xp21. The most frequent mutation - gross deletions in «hot spot» regions of 2-19 and 41-53 exons, which detected in 35-75% of cases in different populations.

We have performed molecular-genetic diagnostic in cohort of 52 belarussian D/BMD patients. All of them had typical clinical features and high level of CPK. To detect deletions of Pm/1, 3, 4, 6, 8, 12, 13, 16, 17, 19, 32, 34, 41-45, 47-53 and 60 exons used both multiplex and routine PCR methods. 20 of 52 (38%) patients had deletions of different size and localization. Only 7 patients had one exon deletion. The largest deletion we had found was deletion of 35 exons (region 8-44 exons). In 4 of 20 cases exon 48 was deleted. 35% of mutations localized in proximal part of gene DMD.

Thought, multiplex PCR is rapid and suitable method to detect gross deletion, due to low level of its occurrence in Belarus, there is need in other methods to find both duplication and point mutation within gene DMD.

P01.221

Molecular genetic analyses of the dystrophin gene in Hungarian Duchenne/Becker muscular dystrophy patients: Comparison of multiplex PCR, Southern blot and MLPA analyses

V. Vancso¹, H. Piko¹, B. Nagy², Z. Bar², A. Herczegfalvi², V. Karcagi¹;

¹National Institute of Environmental Health, Dept. of Molecular Genetics and Diagnostics, Budapest, Hungary, ²Semmelweis Medical School, Clinic of Obstetrics and Gynaecology, Laboratory of Genetics, Budapest, Hungary, ³Bethesda Children's Hospital, Dept. of Neurology, Budapest, Hungary.

Duchenne/Becker muscular dystrophy (DMD/BMD) is a severe X-linked neuromuscular disease caused by mutations in the dystrophin gene. Deletions, rarely duplications and point mutations can occur almost anywhere in the gene, which makes the molecular diagnosis difficult. Here we present a comprehensive study of a large portion of the Hungarian DMD/BMD families using different molecular approaches. Deletions in the hot spots regions were identified by multiplex PCR, whereas rare deletions and duplications were detected by Southern blot analysis and Multiplex Ligation-dependent Probe Amplification (MLPA) technique in the patients. Moreover, the same techniques were used for detecting carrier status in female relatives and in manifesting carriers and efficiencies of the two techniques were compared.

Here we report the genetic results of 121 affected males and 95 female relatives. The DMD/BMD disease was confirmed in 77 males using multiplex PCR. With Southern blot analyses and later on, by MLPA

rare exon deletions were detected in 7 male patients, whereas duplications were observed in 5 cases. Thus, the overall deletion frequency was 69% in the Hungarian DMD/BMD patients. Out of the 95 female samples analysed by Southern blot and MLPA techniques, 41 female relatives proved to be carriers, including two duplication events and three manifesting carriers.

With the help of this reliable new method a large portion of the Hungarian DMD/BMD patients and their female relatives were exactly genotyped and given a precise genetic counselling. Moreover, this opens the perspective for participation in future therapeutic interventions, also for the Hungarian patients.

P01.222

Three mutations in the DYSF gene in a LGMD2B patient

L. González-Quereda¹, N. de Luna², J. Juan³, M. Rodríguez³, E. Gallardo⁴, E. Tizzano³, I. Illa⁴, M. Baiget³, P. Gallano³;

¹Ciberer, Genetics, Hospital Sant Pau, Barcelona, Spain, ²Cibered, Neurology, Hospital Sant Pau, Barcelona, Spain, ³Genetics, Hospital Sant Pau, Barcelona, Spain, ⁴Neurology, Hospital Sant Pau, Barcelona, Spain.

Mutations in the dysferlin gene (*DYSF*) give rise to different muscular dystrophy phenotypes with autosomal recessive inheritance including Limb Girdle Muscular Dystrophy 2B (LGMD2B), Miyoshi Myopathy (MM) and Distal Anterior Compartment Myopathy (DAT). The *DYSF* gene, which maps to chromosome 2p13, has 55 exons and codifies a protein of about 237 kDa. Given that dysferlin is expressed in peripheral blood monocytes in addition to skeletal muscle, we performed the screening of mutations in the *DYSF* gene by sequencing monocytes cDNA. This strategy improves the isolation of the mRNA as a source that is less invasive than the muscle biopsy.

In parallel, we analysed dysferlin expression by immunohistochemistry in muscle biopsies and by Western blot in peripheral blood monocytes.

We report here an sporadic case of LGMD2B, presenting a reduced staining in immunohistochemistry and Western Blot analyses using anti-dysferlin antibodies.

The mutational screening revealed the presence of three mutations:

- 1) A nonsense mutation located in exon 34: **c.3805 G>T; p.Glu1269X**.
- 2) A missense mutation located in exon 44: **c.4820 T>C ; p.Ile1607Thr**.
- 3) A splice site mutation located in intron 21: **c.2055+1 G>A**, a mutation not described to date.

The independent sequencing of the two alleles will enable us to determine the distribution of the mutations. The distribution of the three mutations could account for the reduced expression of dysferlin in muscle biopsy and monocytes in contrast to the total absence in dysferlinopathy patients.

P01.223

Genotype and phenotype studies of myotonic dystrophy type 1 (DM1) in Hungarian patients

A. Herczegfalvi¹, H. Piko², H. Merkl³, R. Horvath⁴, V. Karcagi²;

¹Bethesda Children's Hospital, Dept. of Neurology, Budapest, Hungary, ²National Institute of Environmental Health, Dept. of Molecular Genetics and Diagnostics, Budapest, Hungary, ³Medical University of Pecs, Dept. Clinic for Neurology, Pecs, Hungary, ⁴Jahn Ferenc Hospital, Dept. of Neurology, Budapest, Hungary.

Dystrophia myotonica type 1 (DM1) is a diffuse systemic disorder and is inherited as an autosomal dominant trait with a variable penetrance. An unstable expansion of (CTG)_n repeats in the 3' untranslated region encoding a member of the protein kinase family in 19q13.3 is the causative mutation for myotonic dystrophy. Healthy individuals harbour 5-37 CTG repeats, whereas in affected individuals repeat expansion varies between 37 and 4000. To examine the correlation between clinical expression and CTG trinucleotide repeat length, Southern blot analyses using probe p5B1.4 were carried out in families clinically diagnosed with myotonic dystrophy. So far, 61 patients and 15 family members from 47 families were analysed and in 34 cases the mutation in DMPK gene was confirmed. The expanded CTG repeats were transmitted maternally as well as paternally. In the maternally transmitted cases the expanded fragment lengths were always larger than in the paternally transmitted ones. Moreover, a clear correlation was established between phenotype severity and the length of the CTG ex-

pansion. Longer expansions resulted in earlier onset of the symptoms. Phenotypes varied between congenital onset, classical forms and mild symptoms even within the same family corresponding to the size of the expansion.

Additionally, we were able to offer prenatal diagnosis in three families where all fetuses inherited the pathogenic DMPK gene. In two fetuses with maternal inheritance the estimated size of the CTG repeat expansion predicted a congenital form, whereas one fetus with paternal inheritance inherited a moderate expansion size. This latter baby has been born recently.

P01.224

Normal variation of (CTG)_n repeat in the Dystrophia Myotonica Protein Kinase gene in Slovak non-Romany and Romany population

J. Radvansky¹, A. Ficek^{1,2}, M. BaldoVIC¹, G. Minarik¹, L. Kadasi^{1,2};

¹Comenius University, Faculty of Natural Sciences, Bratislava, Slovakia, ²SAS, Institute of Molecular Physiology and Genetics, Bratislava, Slovakia.

Myotonic dystrophy type 1 (DM1) is a neuromuscular disorder caused by a CTG trinucleotide expansion in the Dystrophia Myotonica Protein Kinase gene (DMPK). This repeat is highly polymorphic in healthy population with alleles in a range of 5 to 37 CTG repeats. The CTG expansion can vary from 50 to several thousand repeats in affected individuals. In many populations healthy alleles show trimodal distribution with 5, 9-17 and 18-35 repeats. A correlation between the frequency of large-sized normal alleles and the prevalence of DM1 in different ethnic groups was shown in several studies. We have analyzed the CTG repeat length in samples of healthy, unrelated individuals from the Slovak Romany and non-Romany population by PCR with fluorescent labelled primers using fragment analysis in genetic analyzer. We have found larger number of different alleles in the sample from non-Romany population than from Romanies, however the (CTG)_n allele size range was broader in the latter group. In both populations we found trimodal distributions with the majority of chromosomes belonging to the groups (CTG)₅ and (CTG)₉₋₁₇. Our results show lower frequency of (CTG)₅ and (CTG)₁₈₋₃₇ and higher frequency of (CTG)₉₋₁₇ alleles in the Romany than in the non-Romany population. Since many linguistic and genetic studies place the origin of Romanies to Indian subcontinent, we decided to compare our results to the available data about (CTG)_n allele frequencies in European and Indian populations. Our preliminary comparison showed similar distribution pattern among Slovak Romany and Indian population, and among Slovak non-Romany and mixed European population.

P01.225

Application of western blot for analyzing of Dystrophin in Iranian patients with mild Dystrophinopathy

J. Gharepouran, E. Darabi, K. Kahrizi, Y. Shafaghathi, M. Banan, H. Najmabadi, E. Keyhani;

Genetics Research Center, Tehran, Islamic Republic of Iran.

Dystrophinopathies (Duchenne muscular dystrophy and Becker muscular dystrophy) are X-linked recessive disorders manifesting with muscle degeneration and weakness. The gene which is defective in Dystrophinopathies is the largest known gene, consisting of almost 0.1% of the human genome (2,500 Kbp). The product of this gene in normal muscle, Dystrophin, is a 427 kDa rod-shaped protein. Dystrophin is an essential part of a large complex that links the actin cytoskeleton with the cell membrane and the extracellular matrix and stabilizes the myofibers during contractions. The value of analyzing Dystrophin on western blots of skeletal muscle for the differential diagnosis of Xp21 muscular dystrophies is now fairly well established especially for mild forms of the diseases (BMD) which immunohistochemistry techniques are not sufficient for the definite diagnosis. Here we describe a sensitive system based on monoclonal antibodies to Dystrophin. System has been set up using GAPDH protein as control that extracted from K562 cells. The specificity of the antibodies was established by dot blot and experiments were undertaken to identify the source of Dystrophin-related protein bands which were detected on blots of normal skeletal muscle. In our study which was the first application of western blot analysis in muscle disorders in Iran, we examined muscle samples taken from clinically suspected to BMD and DMD, first by immunohistochemistry methods and then by western blot analysis. Results show the necessity of blotting techniques in diagnosis panel of mild forms of Dystrophinopathies.

P01.226

Charcot-Marie-Tooth disease 1B and phenotype-genotyping correlation

V. P. Fedotov¹, S. A. Kurbatov¹, O. A. Schagina²;

¹VOCDC genetic counseling, Voronezh, Russian Federation, ²Research Centre for Medical Genetics, Moscow, Russian Federation, Moscow, Russian Federation.

DNA analysis of 96 CMT1-patients revealed 76 cases (79%) of dup17p11.2, (PMP22 gene), point mutation CX32 in 15 cases (16%), and 5 point mutations in the MPZ gene (S63F, R98C, K130R, D134E and not previously described P133S).

In three unrelated families (15 affected subjects) mutation K130R in MPZ was revealed in two families and D134E mutation in one family. All patients has early manifestation of CMT disease before five years old. Late onset of independent walking (18-24 month of birth), unsteady gait, discoordination, distal paresis, muscular atrophies, proprioceptive and superficial hyperesthesia of feet and hands, generalized tendon areflexia, ataxia, foot deformity and nervous swelling were present in all patients with K130R and D134E mutations.

In the patients with R98C and D134E mutations Dejerine-Sottas syndrome with hearing loss was observed. In contrast, the S63F mutation leads to a slowly progressive disease. Independent ambulation was possible until 40-50 years old.

All patients have very low MNCV n. medianus 12,4 +2,4 m/s, n. tibialis - 8,8 +2,6 m/s, distal motor latency 12,5 +5,1 ms; 21,3 +8,7 ms, and very low C - 0,27 +0,18 mV during ten years from two years old. This suggest that abnormalities of nervous fiber myelination may be congenital in origin.

P01.227

A novel mutation in GDAP1 and a change in MFN2 genes in a family with a severe form of Charcot-Marie-Tooth

I. Banchs¹, C. Casasnovas², L. De Jorge¹, J. Martinez-Matos², V. Volpini¹;

¹IDIBELL, L'hospitalet de Llobregat, Spain, ²Hospital Universitari de Bellvitge-IDIBELL, L'hospitalet de Llobregat, Spain.

Recessive form of Charcot-Marie-Tooth disease with hoarseness (CMT2K, MIM#607831) is caused by mutations in ganglioside-induced differentiation-associated in protein 1 (GDAP1) (MIM606598), located in chromosome 8 (8q21.1). Dominant axonal forms of CMT (CMT2 A2) (MIM#609260) can be caused by mutations in the mitochondrial fusion protein mitofusin 2 (MFN2) (MIM608507), in chromosome 1 (1p36.2). We report a patient with a severe form of CMT, with mutations in both genes and the molecular findings in 9 family members.

PATIENT: A 62-year-old woman with severe distal muscle weakness since childhood. The patient is wheelchair dependent since she was in the thirties. Electrophysiological studies revealed a sensory and motor neuropathy with mild demyelinating features and severe axonal degeneration. Analysis of GDAP1 revealed the mutation Gln95Stop in homozygous state. On the other hand, MFN2 analysis revealed the change Arg468His in heterozygous state. Clinical and Molecular analysis of eight family members shows two members with the MFN2 change and no GDAP1 mutation, a 56-years-old male with a mild axonal form of neuropathy and his 18-year old daughter still without clinics. Three other members have the mutation in GDAP1 gene but in heterozygous state and no change in MFN2 gene. They have normal clinical and electrophysiological examinations. Duplication/deletion and point mutations in PMP22 and MPZ were ruled out.

P01.228

A case presentation: X-linked pattern of Charcot-Marie-tooth Disease

S. Akbaroghli^{1,2,3}, M. Houshmand³;

¹Deputy for Cultural Affairs and Prevention of Welfare Organization, Tehran, Islamic Republic of Iran, ²Dr. Susan Akbaroghli Genetic Counselling Center, Tehran, Islamic Republic of Iran, ³Special Medical Center, Tehran, Islamic Republic of Iran.

A family with the presence of X-linked pattern of Charcot-Marie-tooth Disease. The proband is a woman who is coming after a consanguineous marriage for genetic counseling before pregnancy and her father has CMT disease and DM type 2. In the pedigree there are two male cases of CMT disease that are cousins of the proband case.

The clinical and paraclinic manifestations of the proband's father are: -A 50 years old man with muscular weakness and chronic paraparesis

- Paresthesia in lower extremities, tingling and burning sensations of the feet
- Sensitivity of the lower extremities to the cold weather
- Gait problems
- Foot drop
- Pes cavus
- Hair loss of the lower limbs
- Tendons and hypotenar atrophy
- Loss of deep tendon reflexes
- Finger movement disorder in feet and hands
- High levels of LDH
- Chronic sensory-motor polyneuropathy in EMG and NCV.

P01.229

MFN2 point mutations occur in 2% of Charcot-Marie-Tooth families - An investigation of 400 Norwegian CMT families

G. J. Braathen^{1,2,3}, J. C. Sandø⁴, A. Lobato², H. Høyer³, M. B. Russell^{1,2,4};

¹Faculty Division Akershus University Hospital, University of Oslo, Oslo, Norway, ²Department of Neurology, Akershus University Hospital, Oslo, Norway, ³Department of Laboratory Medicine, Section of Medical Genetics, Telemark Hospital, Skien, Norway, ⁴Center of Research, Akershus University Hospital, Oslo, Norway.

Background. Mutations in mitofusin 2 (MFN2) is the most common cause of Charcot-Marie-Tooth type 2 (CMT2).

Methods. Four-hundred Norwegian CMT families were screened for point mutations in the MFN2 gene.

Results. Of the 400 families eight had mutations in the MFN2 gene. We identified four novel point mutations located in exon 14, 15 and 18 (2 families). Clinically the known point mutations caused CMT2. The novel point mutations caused CMT2, distal Hereditary Motor Neuropathy (dHMN), intermediate CMT and CMT1 in each of the other families.

Conclusions. Our mutations broaden the clinical picture that can be seen with mutations in the MFN2 gene.

P01.230

De novo point mutations in Cx32, EGR2, MFN2, MPZ, PMP22 and SIMPLE. A population based survey of Charcot-Marie-Tooth disorder

G. J. Braathen^{1,2,3}, J. C. Sandø⁴, A. Lobato², H. Høyer³, M. B. Russell^{1,2,4};

¹Faculty Division Akershus University Hospital, University of Oslo, Oslo, Norway, ²Department of Neurology, Akershus University Hospital, Oslo, Norway, ³Department of Laboratory Medicine, Section of Medical Genetics, Telemark Hospital, Skien, Norway, ⁴Center of Research, Akershus University Hospital, Oslo, Norway.

Background. An analysis of de novo mutations in persons residing in eastern Akershus County with Charcot-Marie-Tooth (CMT) disease.

Methods. The CMT patients were recruited from the Institute of Medical Genetics, University of Oslo and Departments of Neurology, Neurophysiology and Paediatric in eastern part of Akershus County, Norway. The CMT patients were examined by geneticist and neurologist GJB. The Cx32, EGR2, MFN2, MPZ, PMP22 and SIMPLE genes were analyzed. Paternity tests were performed.

Results. We identified one de novo mutation in the MPZ gene and two de novo mutations in MFN2.

Conclusion. De novo point mutations are rare but less rare than previously anticipated.

P01.231

Hereditary motor and sensory neuropathy type I in Russia

T. B. Tiburkova¹, O. A. Schagina¹, E. L. Dadali¹, V. P. Fedotov², A. V. Polyakov¹;

¹Research centre for medical genetics, Moscow, Russian Federation, ²VOCDC genetic counseling, Voronezh, Russian Federation.

Hereditary motor and sensory neuropathy, also known as Charcot-Marie-Tooth (CMT) disease, is a large group of genetically heterogeneous hereditary disorders of distal nervous system. A group of 298 families with clinical and electrophysiological CMT1 phenotype was investigated by us.

Mutations analysis was performed for three genes: *PMP22*, *GJB1* and *PO*. First, the duplication in chromosome 17 (17p11.2-p12) was investigated by PCR-AFLP analysis of STR. Mutations analysis for *PMP22*, *GJB1* and *PO* genes was performed by direct automatic sequence on

Genetic Analyzer 3130 (Applied Biosystems).

Duplication of chromosome 17 was found in 189 families. This is 63,4% of all cases CMT1 in Russian patients. *GJB1* gene mutations caused of CMT1 in 60 families, or 20,1%. Mutations in the *PO* gene were found in 19 families, equaling 6,4%. Point mutation in the *PMP22* gene were found in 2 families, that is 0,7%. In 28 families mutations were not found in any of these genes. Other genes, mutations of which lead to this disorder, will be analyzed in our next investigations.

P01.232

The ARG94GLN mutation in MFN2 gene can be the cause of axonal Charcot-Marie-Tooth disease with optic atrophy

L. De Jorge¹, I. Banchs¹, C. Casasnovas², J. Martinez-Matos², V. Volpini¹;

¹IDIBELL, L'hospitalet de Llobregat, Spain, ²Hospital Universitari de Bellvitge-IDIBELL, L'hospitalet de Llobregat, Spain.

Some mutations in the mitochondrial GTPase mitofusin 2 (MFN 2) (MIM608507) have been related to the axonal form of Charcot-Marie-Tooth (CMT) disease with optic atrophy. We report a family with severe CMT disease and dominant inheritance. Electrophysiological studies revealed a severe sensory and motor neuropathy with conserved nerve conduction velocities (NCV). One of the family members presented a sub acute visual impairment. The ophthalmological studies revealed optic atrophy (OpA). Cranial Magnetic Resonance studies were normal. Molecular studies revealed the Arg94Gln mutation in exon 4 of MFN2 gene. This mutation had been previously reported, but only associated with "pure" axonal CMT and CMT with tremor. This is the first family with this mutation related to CMT with OpA reported, showing the importance of ophthalmological examinations in patients with axonal CMT caused by mutations in MFN2 gene.

P01.233

Molecular study of MFN2 gene in spanish population

C. Casasnovas¹, I. Banchs², L. De Jorge², J. Martinez-Matos¹, V. Volpini²;

¹Hospital Universitari de Bellvitge-IDIBELL, L'hospitalet de Llobregat, Spain, ²IDIBELL, L'hospitalet de Llobregat, Spain.

The axonal dominant form Charcot-Marie-Tooth type 2A (CMT2 A2) (MIM#609260) is caused by mutations in mitochondrial fusion protein mitofusin 2 (MFN2) (MIM608507). We report the molecular analysis of 101 families with suspected CMT 2. The 19 exons of the MFN2 have been amplified by polymerase chain reaction with the previously described primers by Zuchner et al. (2004) Amplified DNA samples were directly sequenced by applying the BigDye V3.1 (Applied Biosystems) and subjected to an capillary sequencer genetic analyzer. Duplication/deletion and point mutations of PMP22, connexin 32 and MPZ were previously ruled out.

The 83% of the families have been already studied. We have found 7 point mutations in 9 different families. The mutations were located in exons 4, 8, 9, 11 and 14. The study of the promotor region reveals one change of one nucleotide and two families with a deletion of 15 nucleotides. On the other hand, we have found 18 different polymorphisms. One of the found point mutations was not previously described. The frequencies of changes in MFN2 found in our population are similar to previously described studies; these findings confirm the importance of this gene in the physiopathology of the axonal type of CMT 2 A2 in our population too.

P01.234

Dating the mutation Leu239Phe of the GDAP1 gene in CMT Russian families

A. V. Polyakov¹, O. A. Schagina¹, E. L. Dadali¹, V. P. Fedotov²;

¹Research Centre for Medical Genetics, Moscow, Russian Federation, ²VOCDC genetic counseling, Voronezh, Russian Federation.

Mutations in the ganglioside - induced differentiation-associated protein 1 (*GDAP1*) gene are common cause of the Charcot-Marie-Tooth (CMT4A) disease with autosomal recessive mode of inheritance. To date more than twenty mutations in the *GDAP1* gene have been reported in patients suffering from the demyelinating, axonal or mixed form of Charcot-Marie-Tooth disease.

In our study 110 patients from 72 unrelated families with CMT were screened for mutations by SSCP analysis with following direct sequencing of abnormal conformers.

A c.715C>T at substitution codon 239 (Leu239Phe) was detected in nine affected subjects from six apparently unrelated families. Allelic

frequency of this mutation averaged about 7% of all investigated chromosomes and 71% of chromosomes with mutations in *GDAP1* gene. Analysis of the *GDAP1* locus for markers D8S279-D8S1776-D8S286-D8S551-D8S548-D8S1805-D8S1705-D8S1757 demonstrated a common haplotype for markers D8S286; D8S551, D8S548, and D8S1805 on the chromosomes with c.715C>T mutation. The association of the mutation with a common haplotype suggested a common ancestor. The date of diffusion of the mutation has been calculated by linkage disequilibrium between disease locus and these polymorphic markers. The "age" of mutation c.715C>T in Russian was approximately 1000 years.

P01.235

Investigation of *GDAP1* Gene in Iranian CMT Patients

A. Abbasi¹, M. Sadeghizadeh¹, O. Arian², H. Tonekaboni³, M. H. Sanati⁴, M. Houshmand⁴;

¹Department of Biology, Tarbiat Modares University, Tehran, Islamic Republic of Iran, ²Special Medical Center, Tehran, Islamic Republic of Iran, ³Mofid Hospital, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran, ⁴National Institute for Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran.

Charcot-Marie-Tooth disease (CMT) is the most frequently occurring inherited peripheral neuropathy, affecting 1 in 2,500. The disease is characterized by distal muscle weakness and atrophy, predominantly involving the legs. CMT disease caused by mutations in the ganglioside-induced differentiation-associated protein 1 (*GDAP1*) gene is a severe autosomal recessive neuropathy originally reported in families with either demyelinating CMT4A neuropathy or axonal neuropathy with vocal cord paresis which maps to the CMT4A locus on chromosome 8q21.1. *GDAP1* is a 358 amino acid protein which expressed in both the central and peripheral nervous system. 22 Iranian families with a diagnosis of CMT disease, either axonal or demyelinating, were available for genetic analysis of *GDAP1*. Total genomic DNA was extracted from all family members using standard procedure. In all cases linkage analysis with different markers for the *PMP22*, *MPZ*, and *GJB1* genes were used to exclude mentioned genes involving. In the 8 remaining families genotyping for the 3 microsatellite markers linked to the CMT4A locus was performed using different PCR protocols for each marker (D8S164, D8S286, and D8S551). PCR products were run on a 12% non denaturing polyacrylamide gel and allele fragments were visualised by silver staining. Our results showed the usefulness of linkage studies in diagnosis of CMT patients. We could identify and confirm CMT4A in 4 patients with use of these markers. The data in this study could also be used in prenatal diagnosis and carrier detection.

P01.236

Control population distribution and in silico functional analysis of novel genetic variants in Charcot-Marie-Tooth-Disease patients

C. Concheiro Alvarez¹, P. Blanco-Arias^{1,2}, M. Zennaro¹, M. Sobrido^{3,2}, A. Carcedo^{1,3,2};

¹Grupo de Medicina Xenómica-USC, Santiago de Compostela, Spain, ²Centro de Investigación en Red de Enfermedades Raras (CIBERER), ISCIII, Santiago de Compostela, Spain, ³Fundación Pública Galega de Medicina Xenómica, Santiago de Compostela, Spain.

When a variation (uncertain variant, UV) is found in a disease candidate gene, it is critical to establish whether this change is neutral or responsible for the observed disorder. As a result of sequence mutation screening of *PMP22*, *MPZ*, *GDAP1*, *GJB1*, *EGR2*, *NEFL* and *LITAF* in a group of 47 Spanish patients with a clinical diagnosis of Charcot-Marie-Tooth disease we found three non-synonymous, four synonymous and five intronic nucleotide substitutions not contained in dbSNP. In order to assess the possible pathogenic role of these 12 UVs, two approaches were used:

1) Screening of 296 Caucasian controls, 200 of which are Galician individuals without any neurological disorder.

2) *In silico* analysis to explore:

- conservation across animal species (UCSC Genome Browser)
- the impact of an amino acid substitution on the structure and function of a human protein (Polyphen)
- a potential role as a exonic splicing enhancer (ESEfinder)

We present this strategy as a valuable mean to select the UVs most likely to have a biological function warranting further study by experimental models.

P01.237

Rapid diagnosis of CMT1A Deletion/duplication by real-time quantitative polymerase chain reaction

S. Zare¹, S. Akbari¹, M. Karimpour^{1,2}, M. Akbari^{1,3};

¹Tehran Medical Genetics Laboratory, Tehran, Islamic Republic of Iran, ²Molecular Medicine Dept. Biotechnology Research Center, Pasteur Institute of Iran, Tehran, Tehran, Islamic Republic of Iran, ³Department of Medical Genetics, Tarbiat Modares University, Tehran, Islamic Republic of Iran.

Charcot-Marie-Tooth disease (CMT) is the most common form of hereditary motor and sensory neuropathy (HMSN). CMT has been classified into demyelinating (CMT1) and axonal (CMT2) forms.

Around 70% of CMT1A cases are caused by a dominantly inherited 1.5 Mb duplication at 17p11.2-12 encompassing the peripheral Myelin protein 22 (*PMP22*) gene. In contrast, hereditary neuropathy with liability to pressure palsies (HNPP) is caused by reciprocal deletion of the same 1.5 Mb region. In the present study, we developed a highly sensitive and specific quantitative gene dosage method for detecting the *PMP22* duplication and deletion using Real time PCR. Real time quantitative PCR is a sensitive, specific and reproducible method for diagnosing *PMP22* duplication and deletion. The method is fast, and requires no post-PCR handling.

P01.238

Molecular diagnosis of CMT1A and HNPP using Multiplex Ligation-dependent Probe Amplification (MLPA): Comparison with the PFGE-Southern blot analysis

H. Choung;

Samsung medical center, Seoul, Republic of Korea.

Background: Charcot-Marie-Tooth disease type 1A (CMT1A) and hereditary neuropathy with liability to pressure palsies (HNPP) are the two most common peripheral neuropathies caused by a duplication or deletion of the 1.5-Mb region containing *PMP22* gene on 17p11.2, respectively. Although pulsed-field gel electrophoresis (PFGE)-Southern blot (SB) analysis is considered as the reference method for molecular diagnosis of CMT1A/HNPP, several methods such as fluorescence in situ hybridization (FISH), short tandem repeat (STR) analysis, multiplex fluorescence PCR, and real-time PCR have been tried to avoid laborious and time-consuming PFGE-SB method.

Methods: We tried to evaluate newly developed multiplex ligation-mediated probe amplification (MLPA) method for the detection of the specific 1.5-Mb duplication/deletion by prospectively testing 31 patients referred for differential diagnoses of CMT1A or HNPP. MLPA probe-mixes contain *TEKT3*, *PMP22*, *FLJ25830*, *BX089850* and *COX10* genes within the CMT1A/HNPP region. The results with MLPA method were compared with our current PFGE-SB method.

Results: Thirteen out of 31 patients were diagnosed as having either duplication (n=3) or deletion (n=9) by PFGE-SB method and all the results were concordant with those by MLPA analysis. The turnaround time (TAT) by MLPA is estimated to be 4 days while TAT by PFGE-SB is approximately 17 days.

Conclusions: MLPA is a sensitive and specific technique for the detection of duplication or deletion of *PMP22* gene and its turnaround time is much shorter than the PFGE-Southern blotting. Therefore, MLPA could be a good alternative method replacing laborious PFGE-SB analysis.

P01.239

Subependymal heterotopia in the severe variant subtype of Adams-Oliver syndrome

B. Dallapiccola^{1,2}, F. Brancati¹, R. Mingarelli¹;

¹IRCCS CSS Mendel Institute, Rome, Italy, ²Department of Experimental Medicine and Pathology, La Sapienza University, Rome, Italy.

We recently ascertained a 7-year-old female born from non-consanguineous healthy parents with left talipes equinovarus, bilaterally absent/severely hypoplastic/malformed toes with absence of nails. Her psychomotor development was severely delayed and she suffered of seizures since the age of 3 years. At the time of examination (aged 13 years) she shows bilateral transverse reduction of digits, prominent veins over the trunk with rare café-au-lait spots and severe mental retardation with aggressive behaviour. Brain magnetic resonance scan shows bilateral nodular foci of tissue in the subependymal region lining the lateral ventricles. A focal area of irregular cortical surface is also present, suggesting cortical dysplasia.

This girl fits the diagnosis of Adams-Oliver syndrome (AOS) and cor-

robore the existence of a clinically recognizable group of AOS patients with psychomotor delay, mental retardation, central nervous system (CNS) manifestations and seizures. Furthermore, subependymal heterotopia, never reported before in AOS, broadens the phenotypic spectrum of CNS abnormalities to include neuronal migration defects. This severe variant of AOS, whose phenotype has been recently delineated, is likely inherited in autosomal recessive fashion. Hence, the importance of a timely diagnosis not only to manage CNS manifestations but also to properly counsel the families.

P01.240

Aplasia Cutis Congenita type III, congenital scalp defects with distal limb reduction anomalies - Adams-Olivier syndrome.

J. Paprocka¹, E. Jamroz¹, A. Pyrkosz², A. Jezela-Stanek³, S. Hacia⁴, J. Baron⁴, E. Marszał¹;

¹Child Neurology Department, Silesian Medical University, Katowice 40-752, Poland, ²Department of Molecular Biology and Genetics, Silesian Medical University, Katowice 40-752, Poland, ³Department of Clinical Genetics, Memorial Children's Health Institute, Warsaw, Poland, ⁴Student's Association at the Child Neurology Department, Silesian Medical University, Katowice 40-752, Poland.

Aplasia cutis congenita (ACC) are the heterogeneous group of disorders with various clinical manifestations. Adams-Olivier syndrome (AOS, MIM 100300), a rare congenital disorder, belongs to the type III by Sybert classification of ACC, and is characterized by aplasia cutis congenita of the scalp and variable degrees of terminal transverse limb defects. Other associated anomalies include vascular defects: cutis marmorata, dilated scalp veins, small eyes, hypoplastic optic nerve, submucous cleft palate, cardiovascular and brain malformations (cortical malformations- polymicrogyria, encephalocele, hypoplasia of the left arteria cerebri media).

Adams-Olivier syndrome is a genetic defect that causes a vasculopathy and leads to a variety of phenotypes. Inheritance of Adams-Olivier syndrome is autosomal dominant but there are also reports of possible autosomal recessive mode of inheritance.

The authors present a 27-month-old-boy with phenotype of Adams-Olivier syndrome and Peter's anomaly (central leukomata with variable iridocorneal and keratolenticular adhesions and cataract), refractory epilepsy and psychomotor retardation. The molecular investigation is ongoing in order to identify the genetic cause of AOS.

P01.241

Manifestation of X-linked Adrenoleukodystrophy in heterozygous carriers

S. V. Mikhaylova¹, G. E. Rudenskaya², N. Y. Kalinchenko³, O. V. Shekhter²;

¹Russian Children's Hospital, Moscow, Russian Federation, ²Research Centre for Medical Genetics, Moscow, Russian Federation, ³Endocrinological Research Center, Moscow, Russian Federation.

X-linked adrenoleukodystrophy (ALD, MIM 300100) has several phenotypes, clinical manifestation in women-heterozygous carriers among them. About 15-20% of carriers develop neurological signs, typically lower spastic paraparesis resembling adrenomyeloneuropathy (AMN) without adrenal insufficiency. After 40 yrs this proportion amounts 50%. Though, ALD manifestation in women is often misdiagnosed. In our sample of 50 unrelated families with verified ALD there were two families with evident manifestation in women. Low proportion of these cases may be partly due to the young age of most mothers in the sample. In one family, 7-year-old proband had childhood cerebral ALD, in his younger brother presymptomatic stage of disease was found out. Their 26-year-old maternal uncle showed typical presentations of AMN, 52-year-old grandmother had progressive spastic paraparesis since 35-40 yrs. Prior to ALD discovering in the proband they had diagnosis of Strumpell's disease despite evident adrenal insufficiency in the uncle. In 3-year-old proband from another family ALD manifested by adrenal insufficiency as early as in 2.5 yrs, brain MRI proved childhood cerebral form. His 32-year-old mother and her monozygotic twin since 27 yrs suffered spastic paraparesis with bladder disturbances and normal MRI, their previous diagnosis was multiple sclerosis. Such cases along with reported earlier [Krenn et al, 2001; O'Neill et al, 2001; Shaw-Smith et al, 2004] point that women suspicious for Strumpell's disease or familial multiple sclerosis should be tested for ALD if pedigree permits X-linked inheritance. Both families, particularly the first one, also support the known fact of different ALD phenotypes intrafamilial co-existence.

P01.242

New mutations and sequence variations in galician patients with familiar Alzheimer's Disease

M. Garcia-Murias¹, A. Robles², G. Martínez-Nieto¹, M. Arias², A. Koukoulis³, B. Quintáns^{4,5}, P. Blanco-Arias^{5,6}, A. Sesa², A. Carracedo^{1,6,5}, M. Sobrido^{1,5};

¹Fundación Pública Galega de Medicina Xenómica, Santiago de Compostela, Spain, ²Department of Neurology, Hospital Clínico, Santiago de Compostela, Spain, ³Department of Neurology, Hospital Xeral-Cies, Vigo, Spain, ⁴Hospital Clínico-SERGAS, Santiago de Compostela, Spain, ⁵Centro Para Investigación en Red de Enfermedades Raras CIBERER, ISCIII, Santiago de Compostela, Spain, ⁶Grupo de Medicina Xenómica-USC, Santiago de Compostela, Spain.

Mutations in presenilin 1 (*PSEN1*) are detected in 30-70% of familiar Alzheimer disease (FAD) while presenilin 2 (*PSEN2*) and amyloid precursor protein (*APP*) mutations are much less frequent. We studied 61 clinical-based cases with a diagnosis of probable FAD. We sequenced all coding exons of *PSEN1* and *PSEN2*, as well as exons 16 and 17 of *APP* on an ABI3730 sequencer. Sequence analysis was performed with the Staden package. A novel L424V mutation was identified in exon 12 of *PSEN1* in a patient with very young onset dementia. Another new mutation, I408T, was identified in exon 11 of *PSEN1* in a family. In two other cases of FAD missense mutations were detected in *PSEN2*: A415T and R435Q, both in exon 12. Five patients showed intronic changes of unknown significance not reported in the searchable databases if human polymorphisms. We identified the single nucleotide substitution c.338+39G>A in intron 4 of *PSEN1*, a 6 bp deletion in intron 17 of *APP* and three intronic variants in *PSEN2*: c.119-31G>A (intron 4), c.887-19A>C (intron 8), c.1191+57T>A (intron 11). A synonymous change (S236S) in *PSEN2* was present in two individuals. All new mutations and sequence variations were screened in a panel of 186 Galician control individuals without neurological disorders. Globally mutations were detected in 6.6% of the cases (18% if we consider both missense mutations and sequence variations of unknown significance). This low frequency of mutations may be due to not very restrictive referring criteria. Alternatively, other genes may explain most FAD in our region.

P01.243

Left Ventricular Outflow Tract Obstructions (LVOTO): family data and NOTCH1 mutations

W. S. Kerstjens-Frederikse, R. M. F. Berger, Y. J. Vos, R. M. W. Hofstra; University Medical Center, Groningen, The Netherlands.

Left ventricular outflow tract obstructions (LVOTO) are often familial. Early detection of (latent) LVOTO or increased familial risk can prevent unexpected cardiac death. To analyse the percentage of familial cases all new and known patients with left sided anomalies seen after april 1st 2006 by the department of pediatric cardiology (170) were offered genetic counselling. Thirty-one patients refused genetic counseling, the others were seen by the same clinical geneticist. In 44 an aortic valve stenosis was diagnosed, in 21 a bicuspid aortic valve without stenosis, in 28 a hypoplastic left heart, in 67 an aortic coarctation and in 10 other left sided anomalies. In 17 patients the family history combined with ultrasound of first degree relatives revealed a LVOTO and in another 19 probands a relative with yet another congenital heart defect was found.

The first mutations in *NOTCH1* were published in 2005 by Garg et al. in two families with bicuspid aortic valve and other heart defects, and so far two small series showed mutations in approximately 4% of the patients. In our patient group, sequencing has been finished in 40 patients, and 3 mutations have been found.

We conclude that LVOTO is often familial and most pedigrees are compatible with autosomal dominant inheritance with incomplete penetrance. *NOTCH1* mutations are found in a small percentage of familial and non-familial cases.

P01.244

Asymptomatic neurocutaneous melanosis: A case report and review of literature

N. O. Dávalos^{1,2}, V. M. Anguiano-Alvarez³, G. H. Galicia-Hernandez³, R. E. Vega^{3,4}, D. A. Guzmán-Sánchez⁶, M. Gonzalez-Cruz⁶, M. E. Sánchez-Castellanos⁷, J. C. Salas-Alanis³;

¹Instituto de Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Mexico, ²Hospital Valentin Gomez Farias, Servicio de Genética, ISSSTE, Guadalajara, Jalisco, México., Guadalajara, Mexico, ³Instituto de Genética Hu-

mana, CUCS, Universidad de Guadalajara, Guadalajara, Mexico, ⁴Doctorado de Genética Humana, CUCS, Universidad de Guadalajara, Jalisco, México., Guadalajara, Mexico, ⁵Hospital México Americano, Guadalajara, Jalisco, México., Guadalajara, Mexico, ⁶Hospital Valentin Gomez Farias, Servicio de Neuropediatría, ISSSTE, Guadalajara, Jalisco, México., Guadalajara, Mexico, ⁷Instituto Dermatológico de Jalisco Dr. José Barba Rubio, Zapopan, Jalisco, México., Guadalajara, Mexico.

Neurocutaneous melanosis (NCM) is a rare congenital syndrome characterized by the presence of Giant Congenital Melanocytic Nevi (GCMN), either multiple Smaller Congenital Melanocytic Nevi (SCMN), or both. NCM has characteristically been reported to manifest early in life, usually by age 2 to 2.3 years of age and the incidence for asymptomatic NCM with abnormal MRI is 4.8%. The Proposita is a 2 years-old, Hispanic female, was the product of the 5th, full-term and uncomplicated pregnancy; from non-consanguineous parents. She has a history of Giant Congenital Nevi and several episodes of hydrocephaly. Clinically, she has Psychomotor delayed; macrocephaly, hydrocephalus; hemangiomas, multiple congenital pigmented nevi and a nevus approximately 38 x 30 cm. that covers the lumbosacral area, lower abdomen and both thighs. This nevus is dark brown and black colored, with irregular borders; and is covered by thin hair in some areas. Face, neck, arms, chest, upper back and abdomen are covered with multiple satellite melanocytic nevi, which measure 1 to 5 cm. in their largest diameter. Palms and soles are not affected. The CT scan showed dilatation of all ventricles; MRI with gadolinium reported severe hydrocephalus and there were non-hyperintensity regions. We concluded that the patient has NCM associated to GCMN and numerous congenital melanocytic nevi.

P01.245

A deficit of ATP-ase subunit 8 : with contribution for two new cases

M. Stancheva¹, B. Radeva¹, E. Naumova²;

¹University Children Hospital, Sofia, Bulgaria, ²Central laboratory of Clinical Immunology, UMBAL "Alexandrovska", Sofia, Bulgaria.

In two consanguineous children ,brother and sister, was reported a rare mitochondrial disorder, still not described in literature, caused by mutation of the gene MT-ATP8: base change T8412C with aminoacid change : methionin-threonin which lead to dolichocephaly, protruding metopic sutura, muscle hypotonia , ataxia and mental retardation.The EEG showed diffuse changes of teta type.The CAT showed atrophy of the brain of the first child.The investigation of the mother showed the same mutation which will help the prenatal diagnosis .A treatment was started with high doses of vit.B1, B6, B12, L-carnitine, coenzyme Q10 with the aim to stimulate the enzyme processes and compensatory to increase the ATP by alternative metabolic pathways.The clinical investigation continues.

X-linked α thalassaemia/mental retardation syndrome - a case with gonadal dysgenesis, caused by a novel mutation in ATRX gene

A. Jezela-Stanek¹, C. Fisher², M. Szarras-Czpnik³, R. J. Gibbons², M. Krajewska-Walasek¹;

¹Department of Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland, ²MRC Molecular Haematology Unit, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, United Kingdom, ³Department of Endocrinology, The Children's Memorial Health Institute, Warsaw, Poland.

X-linked α thalassaemia/mental retardation (ATR-X) syndrome is one of the genetic conditions that results in X-linked mental retardation. Its principal features are: learning difficulties, microcephaly with characteristic facial features (hypertelorism, nose with flat bridge and triangular, upturned tip, full, everted lower lip) and α thalassaemia. Other known traits of ATR-X are genital abnormalities, the severity of which varies from cryptorchidism to ambiguous genitalia. We present a family referred to the genetic service with suspicion of Smith-Lemli-Opitz (SLO) syndrome after the birth of a child with facial dysmorphism, atrioventricular defect and ambiguous genitalia. Unfortunately, he died before diagnostics. In a subsequent pregnancy, chromosomal analysis showed the foetus had a normal male karyotype (46, XY) and SLO syndrome was also excluded. However, at birth the baby exhibited the same spectrum of clinical features as in the previous child. Amongst

other abnormalities, external female genitalia and dysgenetic testes were detected. He was screened for subtelomeric aberrations but no rearrangements were identified. Observed genital anomalies, together with the distinct facial appearance and the presence of Haemoglobin H inclusions in the red blood cells, led to a diagnosis of ATR-X syndrome. Further molecular study revealed a novel mutation in ATRX (c.G590>T, p.Cys197Phe), coding for a change from a highly conserved cysteine to a phenylalanine residue. The same mutation was identified in the mother, so we can speculate that her elder child was also affected with ATR-X syndrome.

Work was supported by KBN 2P05A 161 28 and PBZ- KBN-122/P05/01-10.

CADHERIN-11 as a possible candidate gene for autism

A. Crepel¹, H. Peeters¹, J. R. Vermeesch¹, J. Steyaert², D. Wallegem³, K. Devriendt¹;

¹Center for Human Genetics, Leuven, Belgium, ²Dept. Child Psychiatry, Leuven, Belgium, ³University Center for Child and Youth Psychiatry, Antwerp, Belgium.

Background:

Positional cloning of chromosomal translocation breakpoints in autism patients is a valuable strategy towards the identification of candidate genes, especially in isolated autism, and when the aberration is de novo and family history is negative for autism.⁽¹⁾

Objectives:

We describe a nondysmorphic patient with autism and full scale IQ of 76, who carries a complex translocation involving chromosomes 3,5,16 and a pericentromeric inversion on chromosome 4.

Methods:

1Mb BAC array-CHG was performed to uncover possible submicroscopic imbalances. The breakpoints were finemapped with FISH.

Results:

On array-CGH, a ~1Mb microdeletion encompassing the clone NON-SC8G10 was detected. Only 1 gene, cadherin-11 (*CDH11*) was located in this region. Of the remaining 6 breakpoints, one disrupted the *AK13094* gene, another was near *GFOD* and *RANBP10*.

Conclusions:

In this patient with a complex chromosomal aberration, the *CDH11* gene was found to be heterozygously deleted. *Cdh11* is expressed in the limbic system and hippocampus in mice and may play a role in the organisation of central synapses.⁽²⁾ Interestingly, there is evidence that altered synaptogenesis is implicated in the pathogenesis of autism. For instance, the cell adhesion molecules *NLGN-3* and *-4* are implicated in autism through their role in the establishment of functional presynaptic terminals in contacting axons.⁽³⁾ Thus, *CHD11* represents both a positional and functional candidate gene for autism. Mutation screening in a larger cohort of autism patients is ongoing.

FMR1 gene: prevalence of premutation and intermediate/grey zone alleles in an autistic Basque sample

I. Arrieta Saez¹, O. Peñagarikano², M. Tález¹, M. Barasoain¹, I. Huerta¹, J. Ramirez¹, B. Criado³, P. Flores⁴, A. González⁵;

¹Dpto Genetica, Antropología Física y Fisiología animal Facultad de Ciencia y Tecnología, Bilbao, Spain, ²Emory University School of Medicine, Atlanta, GA, United States, ³High School Da Maia, CESPU, Porto, Portugal, ⁴Dpto de enfermería, Escuela de Enfermería, Bilbao, Spain, ⁵Dpto Medicina Interna, Facultad de Medicina, Bilbao, Spain.

Fragile X Syndrome (FXS) is associated with an unstable CGG repeat sequence in the 5' untranslated region of the first exon of the FMR1 gene. The location of this gene coincides with a Fragile Site (FS) FRAXA. The CGG sequence is polymorphic with respect to size and purity of the repeat. Although only the full mutation (>200 CGG) is associated with clinical expression of FXS, premutation (55-200 CGG) and intermediate/grey zone allele carriers (35-54 CGG) have been also associated to distinctive phenotypes, one of these are mental retardation and/or autism. Autism is a behavioral disorder of early onset marked by social and cognitive deficiencies. Our Previous studies of chromosomal fragility in autistic and normal individuals show higher frequency of FS and FRAXA full mutation in autistic individuals. The

aim of this study was to analyze a sample of autistic patient without FRAXA full mutation to know the correlation of premutation and intermediate/grey zone size FMR1 alleles and autism. The results show that the prevalence of premutation alleles is 2/10 in patients, however we did not found intermediate/grey zone alleles. Beside the overall repeat size and the AGG interspersed pattern suggest instability.

Autosomal dominant Alport syndrome: molecular analysis of the COL4A4 gene and clinical outcome

E. Marcocci¹, V. Uliana¹, M. Silengo², M. Zeria³, F. Bergesio⁴, A. Amoroso⁵, M. Pennes⁶, D. Giachino⁷, C. Rosatelli⁸, C. Dresch Martinhago⁹, M. Carmellini¹⁰, F. Mari¹, M. Bruttini¹, I. Longo¹, A. Renieri¹;

¹Medical Genetics, Department Molecular Biology, University of Siena, Italy, ²Clinical Genetic Unit, Department of Pediatrics, University of Turin, Italy, ³Department of Paediatrics, M. Bufalini Hospital, Cesena, Italy, ⁴Nephrology and Dialysis Units, Azienda Ospedaliera Careggi, Florence, Italy, ⁵Transplantation Immunology, San Giovanni Battista Hospital, Torino, Italy, ⁶Department of Paediatrics, IRCCS Burlo Garofolo, Trieste, Italy, ⁷Department of Clinical and Biological Sciences, Division of Medical Genetics, University of Turin, Orbassano, Italy, ⁸Department of Biomedical Sciences and Biotechnology, University of Cagliari, Italy, ⁹Department of Genetics, Ribeirão Preto Medical School, University of São Paulo, Brazil, ¹⁰UOC Chirurgia dei Trapianti, Azienda Ospedaliera Universitaria Senese, Siena, Italy.

Alport syndrome is a clinically and genetically heterogeneous nephropathy characterized by irregular thinning, thickening, and splitting of the glomerular basement membrane often associated with hearing loss and ocular symptoms. While the X-linked and the autosomal recessive forms are well known, the autosomal dominant form is not well acknowledged. We have investigated 37 patients with a clinical and molecular diagnosis of autosomal ATS belonging to 8 different families. The mean age of patients was 38.7 years ranging from 6 to 76 years. Only 9 out of 37 (24.3%) patients reached the ESRD, at the mean age of 51.2 years. Four patients (13.8%) had hearing loss and none ocular changes. DHPLC analysis revealed 8 novel private COL4A4 gene mutations: 3 frameshift, 3 missense and 2 splice-site mutations. These data indicate autosomal dominant Alport syndrome as a disease with a low risk of ocular and hearing anomalies but with a significant risk to develop renal insufficiency although at an older age than autosomal recessive and X-linked forms.

These clinical features make difficult differential diagnosis with the benign familial hematuria due to heterozygous mutations of COL4A4. On the other hand, we are unable to demonstrate a genotype-phenotype correlation with the type and the site of the COL4A4 mutations. A correct diagnosis and prognosis is based on a comprehensive clinical investigation in as many family members as possible.

P01.250

COL4A1 mutation in Axenfeld-Rieger anomaly with leukoencephalopathy and stroke

I. Coupry¹, I. Sibon², I. Orignac¹, I. Burgelin¹, J. Orgogozo², D. Lacombe^{3,1}, B. Arveiler^{1,3}, C. Goizet^{1,3};

¹Laboratoire de Génétique Humaine, Bordeaux, France, ²Fédération des Neurosciences Cliniques, Bordeaux, France, ³Service de Génétique Médicale, Bordeaux, France.

INTRODUCTION : Axenfeld-Rieger anomalies (ARA), refer to a wide variety of abnormalities of the anterior segment of the eye that belong to the heterogeneous family of the anterior segment dysgenesis. ARA appears to be genetically heterogeneous: it has been associated with mutations in three genes: PITX2 (on chromosome 4q25), FOXC1 (also named FKHL7) (6p25), and PAX6 (11p13).

SUBJECTS AND METHODS : Five members of a three-generation family affected by vascular leukoencephalopathy and ARA, were clinically and genetically investigated.

RESULTS : Diffuse leukoencephalopathy associated with ocular malformations of the Axenfeld-Rieger type was observed in the 5 affected individuals. Genetic linkage analyses directed toward three loci associated with hereditary vasculopathies and on the four loci known to be associated with ARA showed a possible association with the two loci 11p13(PAX6) and 13q34 (COL4A1). Direct sequencing of the COL4A1 gene led to the identification of a novel missense mutation p.G720D, which cosegregates with the disease.

CONCLUSION : We delineate a novel association between the Axen-

feld-Rieger anomaly and leukoencephalopathy and stroke. Our data confirm that mutations in the COL4A1 gene can be responsible for ARA in humans, as suggested by previous studies in Col4a1-mutated mice.

De novo balanced chromosomal translocation (2;10)(q11.2;q24) associated with dysmorphic features and mental retardation. Case report.

D. Locmele¹, B. Lace^{1,2}, D. Bauze¹, G. Kalnberza¹, A. Dzalbs¹;

¹Children Clinical University Hospital, Medical Genetic Clinic, Riga, Latvia,

²Rigas Stradins University, Department of Medical Biology and Genetics, Riga, Latvia.

We report a clinical case of a reciprocal translocation between the long arms of the 2nd and 10th chromosomes observed in a 12 years old male with dysmorphic features, mental retardation and compulsive - obsessive behaviour.

From anamnesis: boy was born from uncomplicated 1st pregnancy from nonconsanguineous marriage. Delivery on 40th week of gestation, birth weight 3450g, height 58cm. At the age of 6 months he had first episode of seizures after injury of the head. Seizures repeated two times till 12 months of age, later they have never been observed. Motor and speech development were normal. Behavioural problems first noticed at 4 years of age.

Psychiatric findings: marked hyperactive behaviour, always in motion, restless, enthusiastic, frequently clownish, mincing, dyslalia and echolalia, might be aggressiveness to others and to himself, moderate mental retardation.

Dysmorphic features: downslanting palpebral fissures, facial asymmetry, left eyelid ptosis, hypotelorism, esotropia, and irregular tooth placement.

There was performed a conventional GTG karyotyping. Result: 46,XY,t(2;10)(q11.2;q24). Chromosomal breakpoint was confirmed with FISH (Kreatech MYCN (2p24) & LAF (2q11)) analysis.

It still remains a question of discussion if balanced translocation could be associated with dysmorphic features and mental retardation. To evaluate possibility of certain genes loss in breakpoint regions, further SNPs analysis of regions is in progress.

P01.252

Bardet Biedl Syndrome Analysis Among Iranian Families

M. Dehghan Manshadi, M. Rostami, T. Majidzadeh, K. Banihashemi, M. Houshmand;

Special Medical Center, Tehran, Islamic Republic of Iran.

Bardet-Biedl syndrome (BBS) is characterized by cone-rod dystrophy, truncal obesity, postaxial polydactyly, cognitive impairment, male hypogonadotropic hypogonadism, complex female genitourinary malformations, and renal dysfunction. Birth weight is usually normal, but significant weight gain begins within the first year and becomes a life-long issue for most individuals. A majority of individuals have significant learning difficulties, but only a minority has severe impairment on IQ testing. Renal disease is a major cause of morbidity and mortality. In our own study the initial diagnosis of Bardet-Biedl syndrome is established by clinical findings in our specialists' thorough exam.

Twelve genes are known to be associated with Bardet-Biedl syndrome: BBS1, BBS2, ARL6/BBS3, BBS4, BBS5, MKKS/BBS6, BBS7, TTC8/BBS8, B1/BBS9, BBS10, TRIM32/BBS11, and BBS12. Indirect molecular diagnosis using Bardet-Biedle markers facilitate prenatal diagnosis of Bardet-Biedl children.

During the period of 2007 all referred patients to our lab have undergone molecular genetics analysis. Five molecular markers: D11S913, D16S408, D3S1254, D15S131, D4S402 are used for covering the analysis according to the previous surveys.

The primary results showed that in all families' segregation of alleles are according to mendelian inheritance and affected chromosomes are distinguishable from unaffected ones. The patients' molecular genetics profile has been completed through PCR amplifications and Electrophoresis in PAGE gel and the final linkage analysis showed that BBS4, BBS7 were the most associated gene with the Bardet-Biedl in Iranian families.

P01.253

The first case of Berardinelli-Seip congenital lipodystrophy reported in LithuaniaL. Cimbalistienė¹, V. Černiauskienė², V. Kučinskas¹;¹Department of Human and Medical Genetics of Vilnius University, Vilnius, Lithuania, ²Vilnius University Children's Hospital, Vilnius, Lithuania.

Berardinelli-Seip congenital lipodystrophy (BSCL) syndrome is an extremely rare autosomal recessive disorder, with estimated prevalence of 1 in 10 million population. Two genes are known to be associated with BSCL: *AGPAT* and *BSCL2*. Individuals with mutations in *BSCL2* include whites of varying ethnicities originated mostly from Europe and Middle East, and with mutations in *AGPAT2* typically originate from sub-Saharan Africa and Maghreb.

Case report. Our presented patient, male, was the first child of non consanguineous parents Lithuanian origin. BSCL syndrome was diagnosed one month after birth by the phenotypic characteristics of the syndrome. At the age of the 9 years patient had total loss of subcutaneous fat, muscular hypertrophy, long extremities, acromegalic appearance, dry and curly hair, umbilical hernia, hyperhidrosis, distinct acanthosis nigricans, marked hepatosplenomegaly, divergent alternant strabismus, hypermethropia, slight mental retardation. Patient's pubertal status was stage 2 according to Tanner's charts, the bone age was of 14 years. His blood pressure was slightly increased, he had increased fasting glucose, dyslipidemia, mild proteinuria, marked hyperinsulinemia, increased hepatic enzymes, signs of left ventricular hypertrophy. Liver biopsy showed steatohepatitis of low activity and hepatic fibrosis. Mutation analysis revealed that our patient was compound heterozygous for two mutations of *BSCL2* gene [c.458C>A]+[c.412C>T] (testing was performed in Belgium, Loverval, Human Genetic Centre). The results confirmed the clinical diagnosis of BSCL and allowed assignment to type 2. To our knowledge this is the first report of Berardinelli-Seip syndrome in Lithuania.

P01.254

Biallelic BRCA2 -the first Greek Cypriot Family reportedV. C. Anastasiadou¹, E. S Aristidou¹, A. Kotti², T. Delikurt¹, D. Georgiou³, A. Hadjisavvas⁴, K. Kyriacou⁴;¹Clinical Genetics Service, Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, ²Clinical Genetics Service, Makarios Medical Centre, Nicosia, Cyprus, ³Department of Cytogenetics, Makarios Medical Centre, Nicosia, Cyprus, ⁴Department of Electron Microscopy and Molecular Pathology, Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

MM was born with multiple congenital anomalies, affecting mainly her growth, limbs, digits and kidneys. She also had short stature, microcephaly and dysmorphic facial features. Her right thumb was ectopic whereas her left thumb was absent. Fanconi anemia (FA) was suggested.

Chromosomal examination revealed anomalies (end to end fusion, deletions and chromatid breaks) also compatible with the clinical diagnosis of FA. MM was diagnosed with metastatic neuroblastoma at six months of age and passed away a month later.

Parents had three miscarriages. At the 24th week of their fifth pregnancy (in vitro fertilization) fetus was found to be microcephalic and were referred back for genetic counselling. Based on family history of breast cancer both parents were tested for BRCA mutations and found to be positive for the BRCA2 mutation 8984DelG which has been reported as a founder mutation among Greek Cypriots. DNA stored from MM was tested and found homozygous for BRCA2 alleles. The FA phenotype related to biallelic BRCA2 is associated with high spontaneous chromosome aberration rate, less frequent bone marrow suppression and a different spectrum of childhood cancers. Cancer risk for children with biallelic BRCA2 mutations may be very high. This is the first family diagnosed among Greek Cypriots with biallelic BRCA2 mutations manifesting breast cancer and FA.

P01.255

Expansion and diversity of the phenotype and results of molecular studies in patients with blepharocheilodontic syndromeA. Maat-Kievit¹, J. Hoogeboom¹, M. Whiteford², A. de Klein¹;¹Dept of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands, ²Ferguson-Smith Centre for Medical Genetics, Glasgow, United Kingdom.

Blepharocheilodontic (BCD) syndrome is one of the at least 400 orofacial clefting syndromes known, first described by Elschnig in 1912 and recognised as a syndrome and named by Gorlin in 1996. It is a rare, but possibly underdiagnosed, autosomal dominant condition with variable expressivity in which the main clinical features are orofacial clefts, ectodermal defects and ocular abnormalities. The ectodermal defects are mainly oligodontia, delayed dentition, conical crown form, hair abnormalities (pili torti, sparse hair, eyebrows and eyelashes) and hypo/dysplastic nails. The ocular abnormalities comprise ectropion of the lower eyelid, distichiasis of the upper eyelid, euryblepharon and lagophthalmos. Other dysmorphic features have been described in BCD patients, like hypertelorism, ptosis, broad forehead with high frontal hairline, dysplastic ears, clinodactyly and syndactyly. Also ankyloblepharon, hypothyroidism, dermoid cysts and membranous imperforate anus were suggested to be part of the spectrum.

While BCD and lagophthalmos syndrome are a continuum, as suggested by Gorlin, BCD syndrome shows clinical overlap with ectrodactyly-ectodermal dysplasia-cleft lip/palate (EEC) syndrome, ankyloblepharon-ectodermal defects-cleft lip/palate (AEC) or Hay Wells syndrome and van der Woude/popliteal pterygium syndrome. A gene for BCD syndrome has not yet been identified and might be involved in neural crest and/or branchial arch development.

The variable clinical features of two families comprising nine patients and three other sporadic patients with BCD syndrome will be presented and compared to the patients described before. It will be discussed if the phenotype can be expanded with neural tube defects. Also the results of molecular studies in these patients will be shown.

P01.256

A three generation Serbian family with C263T mutation in MPZ geneM. P. Keckarevic-Markovic¹, J. Dackovic², J. Mladenovic³, M. Kecmanovic¹, D. Keckarevic¹, V. Milic-Rasic³, S. Romac¹;¹Faculty of Biology, Belgrade, Serbia, ²Institute of Neurology, Belgrade, Serbia, ³Institute of Child Neurology and Psychiatry, Belgrade, Serbia.

The myelin protein zero (MPZ) gene encodes an integral membrane protein with immunoglobulin-like extracellular domain. MPZ is expressed only in peripheral nerves, and is localized in compact myelin. Mutations in MPZ gene are the common cause of peripheral neuropathies. Depending on the location and type of the mutation, MPZ is associated or with demyelinating either with axonal phenotypes. Mostly, mutations that lie in extracellular domain of MPZ and affect tertiary structure of the protein important for myelin sheet formation lead to demyelinating neuropathies, and mutations affecting myelin-axon communication induce axonal degeneration.

Here we present a three generation family with C263T mutation that affects extracellular domain of MPZ.

Clinical features are listed in a table:

Patient	Age (years)	Gender	Age at onset of symptoms of weakness (years)	Motor nerve conduction velocity (MNCV) for median nerve (m/s)
III1	65	F	Unknown	Not done
III2	47	F	>40	22
III1	40	M	11-20	35.7
III2	38	F	6-10	17.6
III3	20	F	11-20	22
IV1	7	F	/	18.5

Mutations causing peripheral neuropathies show intra- and interfamilial variability. In presented family MNCVs are severely reduced, except for the only male patient, whose MNCV is 35.7 m/s and could fit even in a group of axonal neuropathies. There is no extensive intrafamilial variability in this family, but, the only male patient displays milder symptoms than other, female patients.

Although, there were no previously reported association between MPZ gene mutations, sex and the severity of the disease, cases like this should be recognized in order to remind us that our knowledge of biology of myelin sheet and peripheral nervous system is limited and, probably, more complex than we assume.

P01.257

S248F mutation in CHNRA4 gene has a pathogenic role in autosomal dominant nocturnal frontal lobe epilepsy

A. Zuniga, E. Pineda, I. Pitarch, A. Guerrero;

Hospital de la Ribera, Alzira (Valencia), Spain.

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE, OMIM 600513) has long been misdiagnosed as nocturnal paroxysmal dystonia, parasomnias, or psychiatric disturbances. It is characterized by clusters of brief nocturnal motor seizures, which originate in the frontal cortex. The results of interictal electroencephalogram are usually normal, as are computed tomographic scans and magnetic resonance images. Seizures are usually well controlled by carbamazepine; however, the recurrence risk after drug withdrawal often persists for life. This syndrome is inherited as an autosomal dominant disorder with a penetrance of 70% to 80%. Mutations in the alpha-4 subunit of the neuronal nicotinic acetylcholine receptor gene (CHRNA4) has been described in several families as responsible of ADNFLE.

We have studied a family with ADNFLE from the east of Spain. The clinical appearance of the disease in this family was very similar to previously described cases in which mutations in exon 5 of the CHRNA4 gene were found. So, the exon 5 of the CHRNA4 gene was amplified between nucleotides 535 and 825 and polymerase chain reaction products were purified and sequenced directly. We have identified in three affected members of family a identify a C-to-T transition in the CHRNA4 gene, resulting in a Ser-248-to-Phe (S248F) substitution in the sixth amino acid position of the transmembrane domain 2 (M2). Some authors have suggested that the mutation caused reduced receptor function. These data support the hypothesis that the phenotypic expression of autosomal dominant nocturnal frontal lobe epilepsy is caused by mutations in the CHRNA4 gene.

P01.258

Further delineation of the partial trisomy 3q phenotypeD. Mueller¹, W. Mueller², F. Fresser¹, G. Utermann¹, D. Kotzot¹;¹Division for Clinical Genetics, Innsbruck, Austria, ²Department of Pediatrics, Reutte, Austria.

Partial trisomy 3q is characterized by postnatal growth retardation, microcephaly, developmental delay, and distinct facial dysmorphisms.

Here, we report on a 3 years and 7 months old girl with minor dysmorphic features (high frontal hairline, down-slanting palpebral fissures, telecanthus, epicanthus, bulbous nasal tip, long philtrum, tapering fingers, and short 5th fingers) and language accentuated development delay due to partial trisomy 3q and partial monosomy 4p born to healthy parents (mother 20 years, father 33 years). After an unremarkable pregnancy, she was spontaneously delivered at term. Weight was 3920g (>90th percentile), length was 51cm (50-75th percentile), and OFC was 36.5cm (>90th percentile). At the age of 39 months height was 100cm (50-75th percentile), weight was 17.3kg (90-97th percentile), and OFC was 52cm (97th percentile).

GTG-banding and FISH with subtelomeric probes (Total Telomer Probe Panel, Vysis[®]) and a probe specific for the Wolf-Hirschhorn syndrome critical region (WHSCR) were performed according to standard procedures and revealed a de novo trisomy 3q27->qtel and monosomy 4p16->p16 with a breakpoint distal to the WHSCR and proximal to the subtelomeric 4p probe (karyotype: 46,XX,der(4)t(3;4)(q27;p16).ish der(4)t(3;4)(D3S4560+;D4S3359-,WHSC1+CEP4+)). For a more exact breakpoint determination SNP-array analysis is underway.

In accordance with the cytogenetic results the girl shows no clinical features of WHS, but facial dysmorphisms clearly resembling partial trisomy 3q. The lack of postnatal growth retardation, microcephaly, and malformations in our patient will help to improve genotype-phenotype correlation in partial trisomy 3q.

P01.259

Optimizing clinical diagnosis for some genetic syndromes with cleft lip and/or palate (Iasi Medical Genetics Center's experience)

E. Braha, M. Volosciuc, C. Rusu, M. Covic;

University of Medicine and Pharmacy, Iasi, Romania.

Clefts of the lip (CL) and/or palate (CP) are among the most common birth defects and require multidisciplinary approach for diagnosis and treatment. The purpose of this report is to optimizing the clinical diagnosis of some genetic syndromes for the patients with CL/P. We selected 106 patients (58 boys and 48 girls) with CL/P from the 8615 total

patients evaluated in Iasi Medical Genetics Centre in 2000-2004. The most patients (47.2%) had CLP (19.8% bilateral) or a CP (47.2%); only 5.66% had CL. We look at other anomalies associated with CL/P, associations which have a high power to suggest the diagnosis. We used diagnosis algorithms and POSSUM, OMD databases. The 52.83% (56 patients) had CL/P associated with syndromes that include anomalies involving multiple organs. Only 47.17% were non-syndromic. Base on evocative signs the syndromes diagnosed in our selected cohort were: oculo-auriculo-vertebral spectrum (6), velocardiofacial syndrome (6), chromosomal anomalies (5), amniotic bands (3), Smith Lemli Opitz (3), EEC (3), holoprosencephaly (2), fetal alcohol (2), Aarskog (2), other rare syndromes (18). For accurate assessment, correct diagnosis, and management, the patients should be dealt with in a team approach. CL/P are frequent associated with others anomalies which emphasize the importance of plurimalformative syndromes identification. Clinical proper diagnosis is essential to initiate genetic test, the correct management and genetic counselling.

P01.260

Bannayan-Riley-Ruvalcaba syndrome confirmed by mutation in PTEN gene

R. Zordania, A. Lehtmets, H. Pöder, K. Joost;

Tallinn Children's Hospital, Tallinn, Estonia.

Bannayan-Riley-Ruvalcaba (BRRS) and Cowden (CS) syndromes are autosomal dominant allelic multiple hamartoma syndromes, both in 60-80% cases due to germline mutations in tumor suppressor *PTEN* gene. Clinical signs in childhood have many similarities, early diagnosis using molecular genetic analysis is important as syndromes give increased risk for different tumors.

We describe a family, where both young parents of our index patient were treated due to tumors- mother had bladder carcinoma, treated during pregnancy and father was treated due to embryonal testicular carcinoma.

Proband is the first and only child in the family. His birth anthropometry (4020g/52cm, OFC 41cm) was above 97th centile. During the first two years of his life he had psychomotor developmental problems, hypotonia, seizures with EEG changes, autistic features, unilateral hydrocele and macrocephaly. Metabolic workshop excluded metabolic disorders.

At the age of three years three lipomas were (histologically proved) diagnosed- two subcutaneous and one pancreatic. The patient had different skin symptoms, no pigmentation of the glans penis. He had macrocephaly and mild mental retardation and some autistic features and speech problems.

Mutation analysis of *PTEN* gene was performed by Dr.D.O.Robinson (Salisbury Health Care NHS Trust). The patient is carrying a C>A substitution at base 144, in exon 2 of the *PTEN* gene. This mutation impairs the function of *PTEN* and is the cause of the patient's symptoms.

Conclusion: clinical, pedigree data and results of molecular genetic investigations of the patient having Bannayan-Riley-Ruvalcaba syndrome are presented. This is the first case of this syndrome in Estonia confirmed *PTEN* gene mutation.

P01.261

Report of cockayne syndrome from Iranian families

F. Afroozan, N. Almadani, Y. Shafeghati, M. H. Kariminejad;

Kariminejad-Najmabadi Pathology and Genetics Center, Tehran, Islamic Republic of Iran.

Cockayne Syndrome is an autosomal recessive multisystemic condition, characterized by usually senile-like changes beginning in infancy.

Retinal degeneration, Impaired hearing and photosensitivity of thin-skin.

The disease is known to be genetically heterogeneous for which 3 different Loci have been identified on chromosomes 10,12,13. We have studied five Iranian families, each with one affected child (three male, two female). Three of these cases are results of consanguineous marriage and the parents of the two cases are offspring of unrelated couples. Their features and radiology were compatible with Cockayne Syndrome.

The ophthalmologist showed salt&pepper retinal pigmentation for two of the affected children and optic atrophy for other three cases.

Assays of DNA repair are performed on skin fibroblasts. The most-

consistent finding in Cockayne Syndrome, fibroblasts, marked sensitivity to UV radiation, deficient recovery or RNA synthesis following UV damage (and impaired repair of) activity transcribed genes, or transcription couple repair.

PND of CS has been reported by analysis of UV light sensitivity and DNA repair in fetal cells obtained by CV or Amniocentesis.

P01.262

Complete androgen insensitivity syndrome within a large Turkish family from Southeast of Anatolia

G. Cankus¹, G. Ogu², E. Ozturk³, C. Kilicarslan¹, O. Balat³, S. Pehlivan¹;

¹Gaziantep University, Faculty of Medicine, Department of Medical Biology, Gaziantep, Turkey, ²Ondokuz Mayıs University, Faculty of Medicine, Department of Medical Genetics, Gaziantep, Turkey, ³Gaziantep University, Faculty of Medicine, Department of Gynecology and Obstetrics, Gaziantep, Turkey.

Complete androgen insensitivity syndrome (CAIS) due to inactivating mutations of the androgen receptor (AR) is an androgen receptor function disorder. Here, we present a large family with 6 children out of which 4 was CAIS affected. Cytogenetic analysis of the two healthy sibs revealed one brother (46,XY), one sister (46,XX) and four affected sisters with a normal male karyotype: 46,XY. The mother, the father and 5 sisters were tested with STR markers from X and Y chromosomes to evaluate the origin of X chromosomes in affected versus non-affected siblings. AMEL, XE1 (DXS6803), XE3 (DXS6809), XHPRT (DXS6854), X22 (DXS8377) markers were used for the X chromosome and SRY, AMEL, YE4 markers were used for the Y chromosome. In all affected CAIS sisters, an X pattern similar to one of the two X chromosomes from the mother was observed and the Y markers correlated well with the father's Y markers as expected. The unaffected sister did not possess the relevant X haplotype; thus, she was presumed not to be a carrier. Lately this unaffected girl is reported to have two healthy daughters.

Key words: Complete androgen insensitivity syndrome, large family, STR markers, PCR.

Evaluation and management of patients with complex chromosomal abnormalities

C. Rusu, M. Gramescu, V. Gorduz, A. Sireteanu, I. Ivanov, M. Covic;
University of Medicine, Iasi, Romania.

We present 5 cases, apparently simple, but with complex chromosomal abnormalities on the karyotype, in order to discuss the importance of the cytogenetic evaluation for the management of the case and the genetic counselling offered to the family.

Case 1: male, 7 years old, first child of an apparently healthy, young, unrelated couple, who had also a miscarriage. The mother was pregnant again. Physical examination: typical aspect of Down syndrome. Karyotype: 46,XY,-13,+rob(13;21)/47,XXY,-13,+rob(13,21). Mother: carrier of the robertsonian translocation, as well as the fetus.

Case 2: male, 6 month old, third child of an young, unrelated couple. The mother has been diagnosed with syphilis during the pregnancy. Physical examination: mild aspect of Down syndrome. Karyotype: 47,XY,t(1;2)(p32-pter;q37-qter),-3,-21,+der(3)rcp(3;21)(p11.1;q22.2),+der(21)rcp(3;21)(p11.1;q22.2),+21. Parents: normal karyotype.

Case 3: female, 7 years old, first child of an apparently healthy, young, unrelated couple, that has also a healthy son. Physical examination: mild aspect of Turner syndrome. Karyotype: 44,X,der(13;14). Father: carrier of the robertsonian translocation.

Case 4: male, 5 years old, first child of an apparently healthy, young, unrelated couple, that has also a healthy son. Physical examination: typical aspect of trisomy 8. Karyotype: 47,XY,+8/47,XY,+8q/46,XY/45,X. Parents: normal karyotype.

Case 5: female, evaluated duet o fertility problems. Karyotype: 45,X,inv9/47,XXX,inv9.

The mechanism that led to the complex chromosomal abnormality, as well as the clinical picture, the management and genetic counselling are discussed for all cases.

In conclusion, we present 5 cases of complex chromosomal rearrangements to illustrate particular situations (apparently simple cases, but with complex karyotype) and to discuss genetic counselling in these situations.

P01.264

Importance of early track down of congenital cardiac malformations

D. Iacob¹, M. Boia¹, R. E. Iacob², A. Manea¹, M. Dima¹;

¹University of Medicine and Pharmacy Timisoara, Romania, Timisoara, Romania, ²Clinical emergency Hospital Arad - Pediatric Surgery and Orthopedics Department, Arad, Romania.

Introduction: Congenital malformations are the main cause of death in the first year of life; therefore, early identification of etiology and right therapeutic decision are vital problems in pediatric services.

Objectives: genetic consult and family investigation; examination, investigation and selection of cases which require special methods of diagnosis, interdisciplinary consult, adaptation of European pattern for the anomalies management.

Material and method: The study includes 187 children with age of 0-1 year, consulted, hospitalized and investigated in Premature and Neonatology Department of Clinical Emergency Hospital for Children 'L. Turcanu' Timisoara between 2001 and 2006. Case distribution by etiology shows a clear prevalence of genetic determination: chromosomal 45 cases (24%), monogenic 17 cases (9%), and polygenic 86 cases (46%), in comparison with epigenetic etiology 39 cases (21%). The study of chromosomal anomalies case distribution with cardiac involvement shows an increased frequency of Down syndrome cases and cardiac disorders (50%). Cardiac pathology associated to some monogenic syndromes is obvious in Holt-Oram syndrome, Marfan syndrome, Bourneville tuberose sclerosis, Hurler syndrome and Carpenter syndrome; the distribution is similar to the one reported in similar studies and correlated with the incidence of these diseases in general population.

Conclusion: Congenital cardiac diseases represent pathology difficult to quantify.

These patients and their families are confronted with dramatic situations because of diagnosis delay, absence of therapeutic response and, mostly, of lack of sanitary and social support.

P01.265

Preventive effect of periconceptional folic acid supplementation on the risk of congenital heart defects: A registry based case-control study in the Netherlands

H. E. K. De Walle;

Eurocat registration Northern Netherlands, Groningen, The Netherlands.

Evidence is emerging that multivitamins containing periconceptional folic acid supplementation protects against the occurrence of congenital heart defects (CHD). Postulating that folic acid is responsible for the reduction in CHD risk we used data from a large surveillance for birth defects (EUROCAT- Northern Netherlands registry from 1981 to 2006) to perform a case-control study to investigate the effect of periconceptional folic acid supplementation on CHD risk.

The cases consisted of mothers who delivered infants with isolated or complex heart defects, without any syndrome or genetic abnormality (N=613, years 1996-2005). The control group consisted of mothers who gave birth to children with a known chromosomal or genetic defect or infants with other congenital malformations (N=2385). In both the case and control group, mothers of children with oral cleft, urinary tract, limb reduction and neural tube defects were excluded, because the risk of these defects are probably reduced by maternal folic acid supplementation. Potential confounding factors of periconceptional folic acid use included; maternal body mass index, education, maternal age at delivery of index baby, smoking behaviour and alcohol use during pregnancy were explored.

Adequate use of periconceptional folic acid supplements revealed an odds ratio of 0.81 (95%CI 0.67-0.96) for all types of CHD. Subgroup analysis showed an odds ratio of 0.60 (95%CI 0.42-0.86) for isolated ventricular septal defects. Periconceptional folic acid supplements appear to reduce the prevalence of CHD with approximately 20%. Considering the relatively high prevalence of CHD worldwide the findings of this study are important for public health.

P01.266

Clinical characterization and NIPBL mutation analysis of 42 Portuguese patients with Cornelia de Lange Syndrome

C. Dias¹, E. Costa², J. Oliveira², J. Silva¹, M. Martins¹, A. M. Fortuna¹, A. B. Sousa³, J. P. Basto¹, I. Soares-Silva⁴, T. Kay⁴, H. Santos⁵, A. Medeira³, I. Cordeiro³, T. Lourenço⁴, L. Nunes⁴, R. Santos², M. Reis-Lima¹;

¹Unidade de Genética Médica, Centro de Genética Médica Doutor Jacinto Magalhães, INSA, Porto, Portugal, ²Unidade de Genética Molecular, Centro de Genética Médica Doutor Jacinto Magalhães, INSA, Porto, Portugal, ³Serviço de Genética Médica, Hospital de Santa Maria, Lisboa, Portugal, ⁴Serviço de Genética Médica, Hospital Dona Estefânia, Lisboa, Portugal, ⁵Genomed, Instituto de Medicina Molecular, Lisboa, Portugal.

Cornelia de Lange Syndrome [CdLS (MIM#122470)] is a rare multi-system disorder (prevalence 1:10.000) characterized by psychomotor developmental and growth delay, distinctive facial dysmorphism, microcephaly and limb anomalies. Mutations in the NIPBL [5p13.1 (MIM*608667)] gene that encodes for delangin, a protein involved in sister chromatid cohesion, have been described in 27-56% of patients. A smaller number of patients have been found to have mutations in two other genes SMC1A [Xp11.2 (MIM*300040)] and SMC3 [10q25 (MIM*606062)] thought to be involved in chromatin cohesion.

We present data on 42 Portuguese patients with Cornelia de Lange Syndrome, observed by Clinical Geneticists according to the same clinical protocol, including prenatal and birth history, development, physical features and multisystem involvement. According to their phenotype patients were classified as mild, moderate or severe. The entire coding region (exons 2 to 47) and exon-intron junctions of the NIPBL gene was sequenced. Population screening was carried out for undocumented variants. In mutation positive cases sequence analysis was extended to the parents. Ongoing sequencing of NIPBL to date revealed the presence of heterozygous mutations in 11 patients from 10 unrelated families, 7 of which are novel. Two individuals with a nonsense mutation in NIPBL are siblings with a mild phenotype, providing further evidence that CdLS familial cases may remain under diagnosed. We highlight the importance of a thorough clinical assessment in order to recognize milder phenotypes of CdLS. We discuss phenotype-genotype correlation and its implication in terms of clinical prognosis and the importance of molecular diagnosis for genetic counselling.

P01.267

Clinical-epidemiological study of the congenital anomalies of the corpus callosum

I. Ejarque^{1,2}, E. Bermejo^{1,3}, J. Mendioroz^{1,3}, E. ECEMC working group⁴;

¹ECEMC (Spanish Collaborative Study of Congenital Malformations), Institute of Health Carlos III., Madrid, Spain, ²Dpt of Clinical Analysis. University Hospital La Fe., Valencia, Spain, ³Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII., Madrid, Spain, ⁴ECEMC working group, Several cities of Spain., Spain.

The corpus callosum is the largest interhemispheric commissure of euterian mammals. We've studied the Epidemiology of the Congenital Anomalies of the Corpus Callosum (CACC) throughout the ECEMC [Spanish Collaborative Study of Congenital Malformations] database. ECEMC is a hospital-based case-control study covering, in 2005, 22,96% of total of newborns in Spain. Here we present the results of the epidemiological study of some clinical and etiological characteristics of infants with CACC registered by ECEMC programme.

The ECEMC calculated a frequency of 1.08/10,000 births for the CACC. Non-specified type of agenesis was the most frequent group and total agenesis the most infrequent. Taking into account the clinical features, the isolated cases represented only 6% of total newborns; the syndromic ones accounted for 29%, and multiply malformed (several congenital defects without an identified etiologic link) represented 65%. If we correlate the clinical and the anatomopathologic types, the most frequent among the isolated cases was non-specified agenesis. Correlating the anatomopathology and the genetic aetiology, 48,21% of them had a chromosomal origin. It has been described an association of CACC with several chromosomal alterations: del(5p), del(1qter), del(18q), del(6p25), dup(3q) and del(10q).

In order to carry out a right follow-up of the cases with CACC, whether prenatal or postnatal, the most important points to take into account are: 1) detailed ultrasound of Central Nervous System, 2) precise familial anamnesis including three generations, 3) foetal or neonatal

high-resolution karyotype, and 4) Magnetic Resonance Imaging. All these facts will lead us to a genetic counselling in the best conditions.

P01.268

New case of Cranio-Lenticulo-Sutural Dysplasia - a recently described genetic syndrome with late-closing fontanels

S. A. Boyadjiev Boyd¹, C. Nauta¹, E. Zacka², J. Kim¹;

¹Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA, United States, ²Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA, United States.

We delineated Cranio-lenticulo-sutural dysplasia (CLSD; Boyadjiev-Jabs syndrome) as a new autosomal-recessive syndrome in a consanguineous family where five males and one female have similar craniofacial features (large and late-closing fontanels, hypertelorism), early onset cataracts, and mild generalized skeletal dysplasia. Linkage analysis mapped the locus to chromosome 14q13-q21 and a F382L causative mutation was identified in SEC23A. Detailed molecular and biochemical analysis of wild type and mutant SEC23A, an integral member of the COPII-mediated ER-to-Golgi trafficking pathway, led to better characterization of intracellular trafficking in health and disease. A zebrafish morpholino model recapitulated the human phenotype. Recently, an unrelated individual with clinical features consistent with CLSD was identified. Molecular analysis of SEC23A identified a novel heterozygous SEC23A mutation involving a highly conserved residue. This missense mutation was inherited from the unaffected father and was not present in 400 control chromosomes. No mutations were found in the maternal alleles and SEC23A real-time PCR analysis showed normal expression of the alleles. Biochemical characterization by *in vitro* COPII budding assay is in progress. Our data suggest that CLSD may be more common than previously thought and should be considered in the evaluation of patients with late-closing fontanels. Alternative inheritance patterns may exist for this syndrome.

P01.269

A 340 kb de novo 16p13.3 microduplication encompassing only 5 genes

S. Gimelli¹, A. Bottani¹, I. Bouchardy¹, D. Martine², J. Beckmann², S. Antonarakis¹, M. A. Morris¹, F. Béna¹;

¹Service of Medical Genetics, Geneva University Hospitals, Geneva, Switzerland, ²Service of Medical Genetics, Centre Hospitalier Universitaire Vaudois (CHUV), Lausanne, Switzerland.

We describe an 8-year-old female who was shown by MLPA to have a *de novo* interstitial duplication of the Rubinstein-Taybi Syndrome region. Characterization by array CGH (Agilent) revealed a 340 kb duplication of 16p13.3 containing only 5 genes, one of them being CREBBP.

The patient was born at term after an uneventful pregnancy. Dysmorphic facial features and a left hip dysplasia, initially treated by cast and later by a Pavlik harness, were noted. Aged 19 months, global psychomotor delay was noted (sitting at 11 months, but no speech or walking), as well as dysmorphic facial features, with round face, erythematous cheeks, short hypoplastic nose, long convex philtrum, microstomia, and low-set small ears. Pelvis X-rays showed changes in the left femoral head, atypical for classical congenital hip dysplasia. Based on these findings, the hypothesis of some form of chondrodysplasia punctata was raised, but could not be substantiated radiologically. Follow-up confirmed the mild global learning disability with normal growth parameters, apart from a leg-length discrepancy, the left being 2 cm shorter.

The rarity of published patients with comparable duplications make genotype-phenotype correlations difficult. Given a previous report of a duplication 16p13 in a patient with chondrodysplasia punctata (Hunter, 1985), we hypothesise that overexpression of gene(s) in the microduplication is responsible for abnormal bone development leading to teratological hip dysplasia. Given the known role of CREBBP in skeletal and mental development, this gene represents an excellent candidate.

P01.270

Genetic study of chromosome 5 aberrations

L. A. Hosny, S. Hammad, M. Shihab;
National Research Centre, Cairo, Egypt.

This work presents clinical picture of 12 cases having chromosome 5 aberrations .

Material & Methods:- 6 children, a couple seeking premarietal genetic counselling and 5 couples seeking advice for, intrauterine and neonatal deaths. Chromosomal study of the children, their parents and the couples was per formed

Results & discussion: 5p- in 4 children diagnosed as cri du chat syndrome, three with normal karyotype of both parents . in the fourth child , the mother was a balanced translocation carrier t(5;22)(P14;P11.2) , sister was unbalanced carrier t(5;22)(P14;P11.2) , 5p+ and the aunt had 5p-. Fifth child had 46 , xy , del (5)P15.2 , inv (9)(P11;q12) showing features of both cri du chat and Goldenhar syndromes. The sixth child had 5p+ and his father was a balanced translocation carrier t(3;5)(P22;P15) . 5 paracentric inversion was found in the mother in a couple ,the other 5 couples showed chromosome 5 balanced translocation.

In one couple, the father was a balanced carrier t(5;7)(P15;P15) having a normal son with a balanced translocation and daughter with multiple congenital anomalies and a normal karyotype . The present study illustrates that chromosome 5 inversion or balanced translocation in one of the parents results in chromosome 5 aberrations in the offspring leading to intrauterine and neonatal deaths as well as genetic syndromes.

CONCLUSION:-Cytogenetic study of parents of children with chromosome 5 aberrations , couples seeking premarietal genetic counseling or having repeated abortions, intrauterine and neonatal deaths is of considerable value to give a proper genetic counseling for next generations.

P01.271

Expanding the mutational spectrum of CRLF1 in Crisponi Syndrome.

L. Crisponi¹, A. Meloni¹, F. Chiappe^{1,2}, G. Zampino³, I. Okur⁴, S. Danda⁵, G. Crisponi⁶, F. Rutsch⁷;

¹Istituto di Neurogenetica e Neurofarmacologia, Consiglio Nazionale delle Ricerche, Monserrato, Italy, ²Università degli Studi di Cagliari, Cagliari, Italy, ³Departments of Paediatrics, Catholic University, Rome, Italy, ⁴Gazi University Medical School, Department of Pediatric Nutrition and Metabolism, Ankara, Turkey, ⁵Clinical Genetics Unit, Department of Gastrointestinal Sciences, Christian Medical College, Vellore, India, ⁶Casa di cura Sant' Anna, Cagliari, Italy, ⁷Department of General Pediatrics, University Children's Hospital, Muenster, Germany.

Crisponi syndrome (CS) is a severe autosomal recessive disorder manifesting in infancy, characterized by contractions of facial muscles, dysmorphic features, camptodactyly, feeding and respiratory difficulties. Characteristic hyperthermic crisis frequently lead to death within the first months of life. Surviving patients usually develop a severe progressive kyphoscoliosis requiring corset therapy or corrective surgery. We have also observed paradoxical sweating after exposure to low ambient temperature in some affected adolescents. We found that mutations in the CRLF1 gene are associated with CS, showing allelism with Cold Induced Sweating syndrome type 1 (CISS1). We are currently expanding the mutational analysis of CRLF1 gene on more cases, which have been referred to our group. Up to now we found four different novel mutations; two missense mutations in an Italian patient, c.[338A>T;341T>C], p.[N113I;L114P]; one nonsense mutation in a Turkish patient, c.829C>T, p.R277X; the deletion of the entire exon 1 in an Indian patient. All these mutations are present on both alleles in the patients. CS and CISS1 belong to a group of conditions with overlapping phenotypes, also including Cold-Induced Sweating syndrome type 2 (CISS2) and Stüve-Wiedemann syndrome (SWS)/Schwartz-Jampel syndrome type 2 (SJS2), all caused by mutations of genes in the ciliary neurotrophic factor receptor (CNTFR) pathway. We are currently characterizing in details the clinical phenotype of all the patients collected with CS and CISS1 to establish a genotype/phenotype correlation. These studies may yield valuable information for prospective investigations of sweating disorders, thermoregulatory alterations and bone development.

P01.272

Neonatal outcome of 937 children born after transfer of cryopreserved embryos obtained by ICSI and IVF and comparison with data of fresh cycles

F. Belva¹, E. Van den Abbeel¹, M. Camus², P. Devroey², J. Van der Elst¹, I. Liebaers¹, M. Bonduelle¹;

¹Medical Genetics, UZ Brussel, Brussel, Belgium, ²Centre for Reproductive Medicine, UZ Brussel, Brussel, Belgium.

Background To evaluate the safety of cryopreservation in combination with IVF or ICSI, prenatal diagnosis and neonatal outcome were investigated in children conceived from frozen-thawed ICSI embryos (cryo ICSI) and frozen-thawed IVF embryos (cryo IVF). Data were also compared with earlier published results from fresh ICSI and IVF embryos. Methods Questionnaire data and results of physical examination at 2 months of age of 547 cryo ICSI children and 390 cryo IVF children were also compared with those of infants born after transfer of fresh embryos.

Results Birth characteristics were comparable for cryo ICSI and cryo IVF. Cryo singletons showed a trend towards higher mean birthweight compared to fresh singletons, in ICSI and IVF, reaching significance when all cryo (ICSI plus IVF) singletons were considered. Low birthweight rate according to multiplicity was comparable between fresh and cryo, in ICSI and IVF. Comparable rates of de-novo chromosomal anomalies (3.2%) were found in cryo ICSI fetuses/children versus the fresh ICSI group (1.7%) (Relative Risk 1.93; 95% CI 0.93-3.99). Major malformations were more frequently observed at birth in cryo ICSI liveborns (6.4%) than in cryo IVF liveborns (3.1%) (RR 2.08; 95% CI 1.09-3.95) and fresh ICSI liveborns (3.4%) (RR 1.89; 95% CI 1.30-2.76).

Conclusion In cryo ICSI versus cryo IVF, prenatal and neonatal outcome results were comparable besides a higher major malformation rate in cryo ICSI. In the total cryo group versus the total fresh group, we found a higher mean birthweight in singletons and a higher major malformation rate in liveborns.

P01.273

Autosomal Recessive Cutis Laxa Syndrome revisited

E. Morava¹, U. Kornak², D. Lefeber¹, Z. Urban³, S. Mundlos², R. Wevers¹;

¹UMC Nijmegen, Nijmegen, The Netherlands, ²Institute for Medical Genetics, Charité Universitaetsmedizin Berlin, Berlin, Germany, ³Washington University, StLouis, MO, United States.

The clinical spectrum of the autosomal recessive cutis laxa syndromes is highly heterogeneous, both with respect to organ involvement and severity. One of the major diagnostic criteria for cutis laxa is to detect abnormal elastin fibers in skin biopsy. In several other, clinically similar autosomal recessive syndromes, however, the classic histological anomalies are not present, and the clinical diagnosis remains uncertain. In some children with cutis laxa mutations have been demonstrated in the elastin and fibulin genes, but the underlying genetic etiology is still unknown in the majority of patients. Recently, mutations were discovered in the *ATP6V020* gene in several consanguineous families with autosomal recessive cutis laxa. This genetic defect is associated with abnormal glycosylation in the Golgi apparatus, leading to a distinct combined N- and O-linked glycosylation disorder. Interestingly, similar mutations were also confirmed in patients with wrinkly skin syndrome, without the presence of severe skin symptoms with elastin deficiency. These findings suggest that the cutis laxa and wrinkly skin syndromes are phenotypic variants of the same disorder. The variable presence of protein glycosylation disorders in patients with diverse phenotype in the wrinkled skin-cutis laxa spectrum necessitates revisiting the definition of clinical diagnostic criteria in order to offer adequate prognosis assessment and counselling. Hereby we describe the spectrum of clinical features of the various forms of ARCL syndrome. Based on the recently unravelled novel disease entity we review the genetic aspects including genotype-phenotype relations and suggest a practical diagnostic approach.

P01.274

Unusual malformative association in Dandy-Walker syndrome

C. Jurca, M. Bembea, C. Skrypnik, K. Kozma, A. Jurca, S. Bembea, S.

Costea;

Clinical Municipal Hospital "dr. G. Curteanu", Oradea, Romania.

INTRODUCTION. Dandy-Walker syndrome (DWS) or Dandy-Walker complex (DWC) is a rare congenital anomaly (1:25000 live births)

characterized by vermis agenesis or hypoplasia, cystic dilation of the 4th ventricle and a large posterior fossa. The syndrome is defined by the presence of these three signs. There are three closely associated types of DWS: DWS malformation, DWS mega cisterna magna and DWS variant. **OBJECTIVE.** Presentation and discussion of three cases with different morphological and clinical forms of DWS. In all three cases, diagnosis was reached by incorporation of clinical (macrocephaly, seizures) and imaging (X-ray, CT, MRI) data. **RESULTS.** Patient #1 was diagnosed with Dandy-Walker malformation; he has a sister with Fraser syndrome. Patient #2 was diagnosed with a posterior fossa arachnoid cyst, left-sided Claude-Bernard-Horner syndrome, congenital heart disease (coarctation of the aorta, mitral stenosis) and gastroesophageal reflux. Patient #3 was diagnosed with Dandy-Walker variant in a rare association with neurofibromatosis. **CONCLUSIONS.** DWS is a malformative association of the central nervous system with variable phenotype; it is frequently associated with other anomalies and an uncommon familial genetic load.

P01.275

De Morsier syndrome - case presentation

M. Boia, A. Manea, E. S. Boia, I. Cioata, D. Iacob, M. Dima;

University of Medicine and Pharmacy Timisoara, Timisoara, Romania.

Introduction: De Morsier syndrome is an extremely rare affection in medical practice, its diagnosis in the neonate period is exceptional. It is characterized by association of structural and functional anomalies of nervous system and endocrine glands (especially hypothalamus and hypophysis). The lesions of nervous system can involve optical nerves with optical nerve atrophy and agenesis of corpus callosum and cavum septum pellucidum.

Material and method: The presented patient is a girl with age of 6 month, female gender, held in our Clinics' evidence for prematurity, extreme hypotonia, agenesis of corpus callosum, nystagmus, eye disorders. The clinical - biological evolution was poor, with low level regarding stature and weight and major delay in psychomotor acquisitions. **Results:** Several investigations and biological explorations were done: cranial ultrasonography - which shows agenesis of corpus callosum, stationary hydrocephaly; MRI: agenesis of corpus callosum, increased ventricles dimensions.

Ophthalmological examination and eye ultrasound shows optical nerve atrophy. The presence of the early puberty signs (pubic hair) and statural deficit are signs of endocrine disorders without being major modifications of hormonal doses.

Conclusions: Extremely rare affection in pediatric medical practice. Positive diagnosis is established based on association of major clinical signs: eye manifestations (optical atrophy, nystagmus) early puberty, agenesis of corpus callosum, confirmed by specific investigations: cranial ultrasonography, MRI, specific blood tests.

P01.276

F142L mutation in GJB2 gene in a patient with uncommon skin disorder and deafness

I. Barisic¹, I. Sansovic¹, S. Murat-Susic², R. L. Alford³, G. Minarik⁴, F. Barisic⁵;

¹Children's University Hospital Zagreb, Zagreb, Croatia, ²Department of Dermatology, Clinical Hospital Centre Salata, Zagreb, Croatia, ³Bobby R. Alford Department of Otolaryngology-Head and Neck Surgery, Baylor College of, Houston, TX, United States, ⁴Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia, ⁵Health Care Center Zagreb, Zagreb, Croatia.

Dominant mutations in the human GJB2 gene, which encodes connexin 26 (Cx26) can cause non-syndromic hearing loss, but can also manifest with various skin disorders including palmoplantar keratosis (PPK), Vohwinkel syndrome, Bart-Pumphrey syndrome (BPS) and keratitis-ichthyosis-deafness (KID) syndrome. We present a girl with congenital hearing impairment, plantar keratosis, extensive skin changes in form of follicular inflammatory papules, and erythematous, often scaly patches affecting whole body, including scalp and face. In addition, she had extensive mucosal involvement including oral and esophageal mucosa and perigenital region. Her hair was sparse and thin, she had submucosal cleft palate, and hypodontia. No other abnormalities were observed. Laboratory studies excluded immune/autoimmune deficiencies. Karyotype and FISH for 22q11.2 microdeletion were normal. Sequencing of the coding region of the GJB2 gene revealed a de novo heterozygous F142L mutation located in the third transmembrane domain of the Cx26 gene. This mutation has been

reported only once, also in a patient with unusual mucocutaneous findings and deafness. Our patient confirms the pathogenic nature of this mutation, delineating associated clinical manifestations. It also points out at the broad and overlapping nature of ectoderm derived tissue changes due to the autosomal dominant GJB2 mutations.

P01.277

X-linked deafness type 3 (DFN3) phenotype associated with a paracentric inversion

J. J. MacKenzie^{1,2}, K. McKenzie^{1,2}, K. K. Brown³, C. C. Morton^{3,4}, K. J. Harrison^{1,2};

¹Queen's University, Kingston, ON, Canada, ²Kingston General Hospital, Kingston, ON, Canada, ³Harvard Medical School, Boston, MA, United States, ⁴Brigham and Women's Hospital, Boston, MA, United States.

We report a 7 year old male with severe sensorineural hearing loss diagnosed at 8 months. His features included a round face, hypertelorism, epicanthic folds and a broad nasal root. Initial developmental concerns resolved once he was in an appropriate educational program. Sequencing for *GJB2* and *GJB6*, Fragile X testing, echocardiogram, and abdominal ultrasound were normal. An ECG revealed an incomplete RBBB. The CT scan revealed a large fundus of the internal auditory canals and absence of the bony partition between the fundus and the adjacent cochlear turns with a widened modiolus bilaterally. Therefore, he was at risk for a fistulous communication between the subarachnoid space and inner ear resulting in a perilymphatic gusher upon stapes manipulation. These findings are consistent with those described in persons with DFN3 hereditary deafness. His karyotype was 46,inv(X)(q13q24),Y,ish inv(X)(XIST+). Successive FISH experiments refined the breakpoints to inv(X)(q21.1q22.3). The Xq21.1 breakpoint was narrowed to a 25 kb region about 450 kb centromeric to the DFN3 gene, *POU3F4*. Other DFN3 patients lacking mutations within *POU3F4* have been reported. Ten had deletions centromeric to *POU3F4*, one had an inversion and deletion centromeric to *POU3F4* and one had a duplication centromeric to *POU3F4* and an inversion including *POU3F4*. In the present case there were no detectable deletions or duplications near the Xq21.1 breakpoint. Thus, we hypothesize that the hearing loss phenotype in this patient is caused by dysregulation of *POU3F4* due to separation from *cis*-acting regulatory elements. The patient's asymptomatic mother had a karyotype of 46,X,inv(X)(q13q24)[19]/45,X[11].

Polymorphisms in the glucocorticoid receptor in children with difficult bronchial asthma

M. V. Zhdanova, V. S. Tikhoniva, A. N. Voitovich, M. A. Bogdanova, G. A.

Novik, D. S. Korostovcev, V. I. Larionova;

Saint-Petersburg Pediatric Medical Academy, Saint-Petersburg, Russian Federation.

Objective. We investigated allele and genotype frequencies of the Bcl and Tth111I polymorphisms in the glucocorticoid receptor (GR) gene among children with difficult bronchial asthma.

Patients and methods. Our study group consisted of 59 children (43 boys and 16 girls) in age of 2-17 suffering from difficult asthma and control group consisted of 151 healthy children (78 boys and 73 girls) in age of 4-17. The Bcl and Tth111I polymorphisms were detected by PCR-RFLP using the primers and methods previously described (Fleury I. et al., 2003; Van Rossum EFC. et al., 2004). Data were compared through Chi-square test.

Results. Table 1. Genotype frequencies in asthma patients and controls

Genotypes	Study group (59)		Control group (151)	
	boys 43 (72,9%)	girls 16 (27.1%)	boys 78 (51,7%)	girls 73 (48,3%)
Bcl-CC	39,5 %	37,5 %	32%	34,2%
Bcl-CG	48,8 %	50 %	51,3%	52,1%
Bcl-GG	11,6 %	12,5 %	16,7%	13,7%
Tth111I-CC	36,6 %	37,5 %	47,4%	49,3%
Tth111I-CT	56 %	50 %	43,6%	39,7%
Tth111I-TT	7,3 %	12,5 %	9,0%	11,0%

Conclusion. Allele and genotype distributions of Bcl and Tth111I polymorphisms of the GR gene were similar in asthma patients and controls and previously reported populations. There were no significant differences in allele and genotype frequencies in groups of children with different sex.

P01.279

Dilated cardiomyopathy with hearing loss - a new form?

E. V. Zaklyazminskaya¹, A. Revishvil², T. Nikolaishvil², A. Polyakov¹;

¹Center of Molecular Genetics, Odintsovo, Russian Federation, ²Bakulev's Scientific Center for Cardiac Surgery, Moscow, Russian Federation.

Background: Dilated cardiomyopathy (DCM) is a myocardial disorder characterized by ventricular dilatation, and impaired systolic function leading to heart failure and death. To date 12 genes and 10 chromosomal loci have been associated with this condition, but only autosomal-dominant DCM, 1J (MIM: #605362) caused by mutations in *EYA4* gene is also associated with sensorineural hearing loss (SNHL).

Methods: Clinical examination of parents and four children was performed, including ECG, Holter, Echo-CG; blood and urine biochemistry, and tandem mass-spectrometry (to exclude mitochondrial diseases). The phenotype of a deceased sibling was obtained from hospital and out-patient information. Genetic testing was performed by direct sequencing of coding and adjacent intronic areas of the *EYA4* gene.

Results: An Uyghur family with DCM was investigated. The proband and the oldest brother had progressive SNHL, complete A-V block, DCM, and died due to heart failure at the age of 14 y.o. and 9 y.o., respectively. Two younger brothers had incomplete A-V block, LBBB, and SNHL at the age 6 y.o. and 11 y.o. All symptoms became more pronounced with age. A sister (9 y. o.) has normal hearing but A-B block(I) and incomplete LBBB. Both parents are healthy. We didn't find any mutations of *EYA4* gene. Unfortunately, the small size of the family and unclear phenotype of the 9 y.o. girl precludes informative linkage analysis. Pedigree analysis reveals recessive inheritance of DCM, conduction defects and SNHL (autosomal or X-linked) in this Uyghur family. We propose that this family has a novel genetic form of DCM.

P01.280

Novel Tyrosine Hydroxylase Gene Mutation In Three Turkish Siblings With Dopamine-Responsive Dystonia

E. Karaca, S. Basaran Yilmaz, G. Yesil, A. Yuksel;

Istanbul University, Cerrahpasa Medical Faculty, Department of Medical Genetics, Istanbul, Turkey.

Dopa-responsive dystonia (DRD) is a rare, autosomal dominant (GTP-cyclohydroxylase gene mutation) or rarely recessive (tyrosine hydroxylase gene mutation) inherited disorder. Both enzymes take part in dopamine synthesis. Their deficiencies cause the dopamine level reduction. The first clinical symptoms occur in the childhood

We report here three siblings who were borned to first cousins; with a novel recessive mutation in Tyrosine hydroxylase gene that results in dopa- responsive dystonia. Older brothers were monozygotic twins. They are now at the age of 4^{6/12} and 1^{9/12} years. All of them have development delay and also motor dysfunction. They displayed extrapyramidal signs in early infancy. The clinical diagnoses were confirmed by mutation analyses of Tyrosine hydroxylase gene which detected a novel mutation of P492R (1475 C>G) in the homozygotic state. After diagnosis, L-DOPA treatment was started, however clinical picture did not change. Therefore selegiline (selective MAO-B inhibitor) was added to therapy. Low dose L-DOPA and selegiline markedly improved clinical picture.

Here we are presenting the clinical features and outcomes of the L-DOPA/Selegiline treatment in three siblings with Dopa-responsive dystonia results from a novel recessive mutation in Tyrosine hydroxylase gene, reviewing of the literature.

P01.281

Familial duplication 8p without phenotypic effect

E. G. Okuneva, N. V. Shilova, N. Y. Kuzina, T. V. Zolotukhina;

Medical Genetics Research Center, Moscow, Russian Federation.

We report a family where 3 members have rearrangement of chromosome 8 with normal phenotype. A proband 14-year-old girl was tested because of hypogonadism. G-banded chromosome studies were carried out and showed karyotype 46, XX, der (8). Her father's karyotype was normal - 46, XY, but mother and 28-year-old sister had the same chromosome 8 rearrangement without any clinical signs. The elder sister's 3-year-old daughter had normal phenotype.

Later at the age of 18 the proband was tested again during pregnancy. An abnormal chromosome 8 with additional material of unknown origin on the terminal region of short arm was tested. To identify this finding FISH analysis was performed using painting (wcp) and telomere spe-

cific (tel) DNA-probes for chromosome 8. FISH characterization of the abnormal chromosome with wcp 8 and tel 8p probes was estimated as duplication of a short-arm segment 8p23: 46,XX, add(8)(p23). ish dup(8)(p23)(wcp8+,pter+) (ISCN 2005). Euchromatic abnormality of no phenotypic consequence such as euchromatic duplication in terminal region p23.1-p23.3 of chromosome 8 is known as chromosome variant. Variant chromosomes being normal chromosomes behave normally at meiosis and show 1:1 segregation. A person carrying a variant chromosome has no increased risk for having abnormal offspring. Normal results of maternal serum biochemical screening and high quality ultrasound scanning during the pregnancy had allowed to avoid an invasive procedure. After 40 weeks of pregnancy there was born male newborn without any clinical signs of chromosomal pathology.

P01.282

DYSCERNE: An electronic Dysmorphology Diagnostic System (DDS)

S. Gardner¹, P. Griffiths¹, K. Strong¹, R. Day¹, D. Donnai², B. Kerr¹, H. Brunner², B. Dallapiccola³, K. Devriendt⁴, M. Krajewska-Walasek⁵, N. Philip⁶, J. Clayton-Smith¹;

¹University of Manchester, Manchester, United Kingdom, ²UMC St Radboud, Nijmegen, The Netherlands, ³IRCCS-CSS, San Giovanni Rotondo, Italy, ⁴KU Leuven, Leuven, Belgium, ⁵IP-CZD, Warsaw, Poland, ⁶Hopitaux de Marseille, Marseille, France.

Over 2,500 rare and difficult to diagnose conditions presenting with patterns of birth defects have been identified. The rarity of these dysmorphic conditions means that even in Centres of Expertise, experience may be limited resulting in delayed or uncertain diagnosis. Making a correct diagnosis is the cornerstone of patient management, enabling clinicians to locate other patients with the same condition, share clinical experience and increase individual and collective knowledge about rare conditions.

One of the main aims of the DYSCERNE project (www.dyscerne.org) is to develop an electronic Dysmorphology Diagnostic System (DDS) which will link existing European Centres of Expertise to form a powerful diagnostic resource for rare dysmorphic conditions.

The DDS will allow clinicians to submit difficult to diagnose cases, for evaluation by an international panel of experts. A diagnostic report including suggested management plans for the patient will be prepared from the consensus of expert opinions and sent to the submitting clinician. Case histories will be stored in an archive which will be reviewed periodically.

An on-line educational tool for the description of dysmorphic features will also be developed which will increase diagnostic skills in the evaluation of rare dysmorphic diseases.

The DDS will facilitate rapid and equitable access for clinicians from all EU countries to expert opinions. It will increase capacity and accuracy of diagnoses and decrease time from presentation to diagnosis. This will facilitate definition and classification of rare dysmorphic conditions and promote further clinical research into these complex disorders.

P01.283

Clinical Variability in Acro-(Cardio)-Facial-Syndrome

A. Kariminejad¹, B. Bozorgmehr¹, M. A. Sedighi Gila², N. Almadani¹, M. H. Kariminejad¹;

¹Kariminejad & Najmabadi Genetic and Pathology Center, Tehran, Islamic Republic of Iran, ²Department of Andrology, Royan Institute, Tehran, Islamic Republic of Iran.

In 1987 Richieri-Costa and Orquizas described a Brazilian patient born to consanguineous parents with ectrodactyly, cleft lip/palate and congenital heart defect. Four additional cases with ectrodactyly, genital anomalies, congenital heart defect and cleft lip/palate or high arched palate have been published [Giannotti et al., 1995; Guion-Almeida et al., 2000; and Mingarelli et al., 2005].

Giannotti et al. [1995] reported on a brother and sister with cleft palate, cardiac defect, genital anomalies and ectrodactyly, suggesting the acronym CCGE standing for cleft palate, cardiac defect, genital anomalies and ectrodactyly. An autosomal recessive pattern of inheritance was suggested considering these pedigrees. Guion-Almeida reported on a 4-month-old infant with ectrodactyly, clefting ear anomaly, CHD, cortical atrophy of the brain and growth retardation, with possible acrocardio-facial Syndrome (ACFS).

We report on a 25-year-old man with ectrodactyly and genital anomaly

lies whose parents are first cousins. Their second child died 4 days after birth with severe limb defects and imperforate anus. Our patient may represent clinical variability of the acro-cardio-facial syndrome. If our case has the ACF syndrome, it would be the mildest form of this condition.

P01.284

Unusual pattern of inheritance and orodental changes in the Ellis-van Creveld Syndrome

M. I. Mostafa, S. A. Temtamy, M. A. El-Gammal, I. M. Mazen;
National Research Centre, Cairo, Egypt.

Ellis-van Creveld (EVC) syndrome (chondroectodermal dysplasia, mesoectodermal dysplasia, OMIM 225500) is an autosomal recessive skeletal dysplasia characterized by short limbs, short ribs, postaxial polydactyly and dysplastic nails and teeth. Oral manifestations tend to be pathognomonic such as multiple broad labial frenula and congenital missing teeth.

In this study we report 3 Egyptian families with six cases of EVC syndrome.

An unusual pattern of inheritance with father to son or to daughter transmission was observed in 2 consanguineous families thus demonstrating quasidominant inheritance, probably for the first time in the literature. A new consistent orodental anomaly found in all our cases was bifid tip of the tongue. We emphasize study of orodental anomalies in future cases for accurate diagnosis of Ellis-van Creveld syndrome and its probable differential diagnosis from Weyers Acrorenal dysostosis.

P01.285

Encephalocraniocutaneous lipomatosis: A propos of a boy with an unusual pattern of genital anomalies

A. P. Marques-de-Faria, G. Guerra-Júnior, S. G. Moraes, A. Maciel-Guerra;
State University of Campinas (UNICAMP) School of Medicine, Campinas, Brazil.

Encephalocraniocutaneous lipomatosis (ECCL) is a sporadic, congenital neurocutaneous disorder, characterized by cerebral, ocular and cutaneous abnormalities, including asymmetrical cerebral atrophy, intracranial and spinal lipomas, mental retardation and/or epilepsy, epibulbar dermoids or choristomas, alopecia, facial skin-tags, craniofacial lipomas and a peculiar hairless fatty tissue nevus of the scalp, designated as psiloliparus. The pathogenesis remains undetermined; one hypothesis is a lethal autosomal dominant mutation only surviving in a mosaic state. There is a considerable overlap with other neuroectodermal disorders, as oculocutaneous syndrome (OCCS), Goldenhar syndrome, and epidermal nevus syndrome. Recently, some clinical features of ECCL and OCCS were reviewed and diagnostic criteria were established. Herein, we describe a male infant whose clinical signs suggest ECCL. Besides the main features, he also had a compound odontoma, already reported but not frequent in ECCL and in similar conditions. However, the pattern of genital anomalies has not been reported so far. It includes asymmetrical penoscrotal transposition, ectopic left hypoplastic hemiscrotum, and a pedunculated perineal mass, whose aspect suggested a rudimentary accessory scrotum; the phallus had a normal length with an increase of subcutaneous tissue in prepuce region. This phenotype is quite rare and has been described in association with perineal lipoma or lipoblastoma, which probably arose in the perineum and divided the moving labioscrotal swelling into three parts, during early fetal life. The same mechanism is proposed in present case, considering that in ECCL there are a few reports of lipomas, lipomatous mass and/or skin-tags located outside the craniofacial region, including in genital area.

P01.286

„Stat rosa pristina nomine, nomina nuda tenemus“: a survey on attitude of Italian clinical geneticists towards eponyms

E. Di Maria^{1,2}, R. Tenconi³;

¹Dept. of Neuroscience, Ophthalmology and Genetics, University of Genova, Genova, Italy, ²Laboratory of Genetics, Galliera Hospital, Genova, Italy, ³Clinical Genetics, Department of Pediatrics, University of Padova, Padova, Italy.

An eponym is a person after whom a discovery, invention, etc., is named. Eponyms are widely used in all clinical disciplines. Recently, a provocative editorial published in British Medical Journal argued that their use should be abandoned. The London Dysmorphology Data-

base currently reports >5000 diseases: 44% of them are designated by eponyms.

We wondered how eponyms are perceived among clinical geneticists in Italy. By administering a questionnaire on the use of eponyms, we wanted to explore also the attitude of clinical geneticists towards nomenclature and its regulation. The home-made, Likert-type questionnaire consisted of 10 items exploring the attitude towards eponyms through the following domains: role of historical aspects, value in learning, use in clinical practice, facilitation of scientific discussion, convenience. Two additional items pertained to the need for rules in nomenclature. Scores were modelled as discrete variables and analysed by descriptive statistics.

We collected 102 (84%) fully filled-in questionnaires. The median value of the total score modelling the attitude towards eponyms was close to neutrality, with a trend in favour of eponyms. When the participants were asked to state a radical position (keep or abolish), 73% answered to prefer keeping use of eponyms. We found a marginally significant correlation between attitude in favour of eponyms and both age and years of practice. Regardless their position with respect to eponyms, the vast majority stated that the use of nomenclatures should be ruled by guidelines. Our findings provided a surprising impression of interest in the subject and underscored the need for recommendations.

P01.287

Molecular diagnosis of familial mediterranean fever in Armenians

T. F. Sarkisian, H. S. Hajrapetyan, G. R. Shahsuvaryan, A. A. Beglaryan, A. R. Egiazaryan;
Center of Medical Genetics, Yerevan, Armenia.

Familial Mediterranean Fever (FMF) is an inherited, recessively transmitted inflammatory condition usually occurred in populations from Mediterranean decent. The prevalence of heterozygous carriers of one of the mutations of MEFV gene is as high as 1 in 5 healthy individuals in Armenians.

Genetic testing of this rare Mendelian disorder (MIM no 249100) is efficient for early diagnosis, especially for atypic cases. Certain mutations have significant correlation with renal amyloidosis, the most severe possible manifestation of FMF. Also genetic testing is very important for colchicine therapy correction.

Twelve MEFV mutations are identified in more than 8000 FMF patients (heterozygotes, homozygotes and compound heterozygotes) in comparison with healthy individuals has revealed the most frequent mutations and genotypes. Every week we have 35-50 new cases. We have revealed that FMF is caused by presence of single mutation in 18.6% of heterozygote carriers.

Our results confirm that the MEFV gene analysis provides the objective diagnostic criterion for FMF (characterisation of the two MEFV mutated alleles in more than 90% of the patients). Molecular testing is also used to screen the MEFV gene for mutations in patients with a clinical suspicion of FMF. We also demonstrated the unfavourable prognostic value of the M694V homozygous genotype, and provided the first molecular evidence for incomplete penetrance and pseudo-dominant transmission of the disease. Overall, these data, which confirm the involvement of the MEFV gene in the development of FMF, should be essential in clinical practice, leading to new ways of management and treatment of FMF patients.

P01.288

Midline Facial Defects with Hypertelorism: investigation of neuropsychological aspects and 22q11.2 deletion by FISH

M. Simioni, S. D. A. Giffoni, É. L. Freitas, T. P. Vieira, I. E. Guimarães, S. M. Ciasca, I. Lopes-Cendes, V. L. Gil-da-Silva-Lopes;

Faculdade de Ciências Médicas - UNICAMP, Campinas, Brazil.

Midline facial defects with hypertelorism (MFDH) are a group of rare and heterogeneous condition involving anomalies of frontonasal process. In some patients it is associated with structural and functional anomalies of the central nervous system. These CNS abnormalities have similarity with those found in patients with 22q11.2 deletion syndromes. In addition, there are some isolated reports of MFDH in which 22q11.2 deletion were detected. Furthermore, even in the absence of anatomical abnormalities detected by neuroimaging, functional disabilities could be present in patients with MFDH, which would be better investigated by neuropsychological assessment. Therefore, the main

objectives of our study were to characterize the neuropsychological aspects of patients with MFDH, to correlate them with neuroimaging findings and to investigate the 22q11.2 deletion in these patients. Neuropsychological evaluation was performed using the Luria Nebraska Battery and WISC for children and WAIS for adults; the 22q11.2 deletion was investigated by FISH. Heterogeneous results on neuropsychological evaluation involved difficulties cognitive domains such as picture arrangement, expressive language, comprehension, arithmetic, digit span and motor ability. These abnormalities are similar, in part, to those reported in deletion of 22q11.2 region, which was not detected in all cases. In conclusion, we found a relationship between neuropsychological and radiological CNS alterations in MFDH. As the 22q11.2 region is recognized as critical for embryonic development of midline, in view of the clinical-genetic heterogeneity and the specificity of the probe used, the involvement of 22q11.2 region in the etiology of MFDH needs to be further investigated.

P01.289

Associated malformations in patients with gastroschisis and omphalocele

C. Stoll, Y. Alembik, B. Dott, M. Roth;
Genétique médicale, Strasbourg, France.

The etiology of gastroschisis and omphalocele (exomphalos) is unclear and their pathogenesis is controversial. However, the reported types and frequency of malformations associated with omphalocele and gastroschisis vary between studies. The purpose of this investigation was to assess, in a geographically defined population, the prevalences at birth of associated malformations in patients with omphalocele and gastroschisis which were ascertained between 1979 and 2003 in 334,262 consecutive births. Of the 86 patients with omphalocele, 64 (74.4%) had associated malformations including chromosomal abnormalities (25 cases, 29.0%); non chromosomal recognized syndromes including Beckwith-Wiedemann, Goltz, Marshall-Smith, Meckel-Gruber, Oto-palato-digital type II, CHARGE, and fetal valproate; sequences, including ectopia cordis, body stalk anomaly, exstrophy of bladder, exstrophy of cloaca, and OEIS; malformation complex including Pentalogy of Cantrell, and patients with non syndromic multiple congenital anomalies (MCA) (26 cases, 30.2%). Malformations of the musculoskeletal system (23.5%), the urogenital system (20.4%), the cardiovascular system (15.1%), and the central nervous system (9.1%), were the most common other congenital anomalies occurring in patients with omphalocele and MCA. For gastroschisis, the total prevalence was 1.79 per 10,000. However, there was a significant increase over the study period in the total prevalence. The maternal age-specific prevalence was highest in the 15-19 year age group. Of the 60 patients with gastroschisis, 10 (16.6%) had associated malformations including one skeletal dysplasia, one amyoplasia congenita, and 7 non syndromic MCA. In conclusion the overall prevalences of malformations associated with omphalocele and gastroschisis are quite different and emphasizes the need for a thorough screening of cases for other malformations.

P01.290

Discordance of primary congenital glaucoma in monozygotic twins

F. Sürü^{1,2}, S. Paylakhi³, S. Yazdani⁴, S. Zeinali⁵, M. Sajedifar⁶, S. Zargar¹, E. Elahi^{1,2};

¹School of Biology, University College of Science, University of Tehran, Tehran, Islamic Republic of Iran, ²National Institute of Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran, ³School of Biology, University College of Science, University of Tarbiat Modarres, Tehran, Islamic Republic of Iran, ⁴Ophthalmic Research Center, Shaheed Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran, ⁵Biotechnology Department, Pasteur Institute of Iran, Tehran, Islamic Republic of Iran, ⁶Kausar Biotechnology Company, Tehran, Islamic Republic of Iran.

Glaucoma is a heterogeneous group of optic neuropathies characterized by degeneration of the optic nerve, usually associated with elevated intraocular pressure. It is the cause of 15% of blindness worldwide. Primary Congenital Glaucoma (PCG), one of the three major forms of the disease, becomes apparent at birth or before the age of three and is a major cause of childhood blindness. Mutations in both alleles of the cytochrome P4501B1 (*CYP1B1*) gene, which is the only gene thus far linked to PCG, result in the disease phenotype. It has been recently shown that mutations in this gene are cause of disease in approxi-

mately 70% of Iranian PCG patients and that the common mutations in the population are G61E, R368H, R390H, and R469V.

We report here the observation of highly variable expression of primary congenital glaucoma in two individuals who are identical twins. Both carried the G61E mutation in the homozygous state. The identical twin status of the individuals was confirmed using several microsatellite markers.

P01.291

Cloning & Expression of Human rFVII in Insect Cells

N. Masroori, M. Habibi Roudkenar PhD;

Iranian Blood Transfusion Organization, Tehran, Islamic Republic of Iran.

Hemophilia is one of the most prevalent genetic disorders. It is inherited as sex-linked pattern. Obtaining factor from plasma or by recombinant technology, in high dose is one of the major challenges for treatment of Hemophilia. However 25% of these patients naturally raised antibody against factor VIII. Viral contamination and availability in very low dose is another challenge to obtain factor VIII from plasma. Administration of Recombinant factor VII for patients who raised antibody against FVIII can be one of the solution for mention problem. Isolation, cloning and expression of recombinant FVII by Gateway technology was the aim of this study. Factor VII gene was isolated from HepG₂ cell line and cloned to TOPO vector by TOPO cloning method. The construct was ligated to Baculovirus destination vector by LR recombination using gateway technology and the recombinant virus was transfected to, insect cell line, SF9. Expression of recombinant FVII was detected by SDS-PAGE, ELISA and western blot analysis.

A prenatally detected case of congenital hepatoblastoma

H. Ergin¹, B. Yıldırım², E. Dageviren¹, B. Yagci³, F. Ozen⁴, N. Sen Turk⁵, S. E. Duzcan⁵;

¹Department of Pediatrics, Pamukkale University Faculty of Medicine, Denizli, Turkey, ²Department of Obstetrics and Gynecology, Pamukkale University Faculty of Medicine, Denizli, Turkey, ³Department of Radiology, Pamukkale University Faculty of Medicine, Denizli, Turkey, ⁴Department of Pediatrics, Ege Hospital, Denizli, Turkey, ⁵Department of Pathology, Pamukkale University Faculty of Medicine, Denizli, Turkey.

Hepatoblastoma is a rare tumor of childhood. The incidence of hepatoblastoma in the first year of life is about one in a million. The mean time of its onset is 14 to 24 months. Forty-two congenital hepatoblastoma cases were reported so far. Among 42 congenital hepatoblastoma patients, seven cases have been detected in the prenatal period. Only one out of seven cases detected in the prenatal period has been diagnosed as hepatoblastoma. The etiology of hepatoblastoma is unknown. However, it has been shown to be associated with prematurity, low birth weight, hepatitis B, familial adenomatous polyposis, Beckwith-Wiedemann syndrome and hemihypertrophy. In this report, we report a rare case of hepatoblastoma detected before birth and confirmed by postmortem.

P01.293

Genotype-phenotype correlation in hereditary hemorrhagic telangiectasia in patients with ACVRL1 mutations: Is c.1112dupG mutation a milder mutation?

S. Dupuis-Girod¹, S. Giraud¹, E. Decullier¹, B. Gilbert-Dussardier², M. Carette³, G. Plessis⁴, S. Riviere⁵, P. Magro⁶, G. Lesca¹, P. Ederly¹, A. Calender¹, H. Plauchu¹;

¹Hospices Civils de Lyon, LYON, France, ²Hôpital Jean Bernard, POITIERS, France, ³Assistance Publique - hôpitaux de Paris, PARIS, France, ⁴Hôpital Côte de Nacre, CAEN, France, ⁵Hôpital Saint Eloi, Montpellier, France, ⁶Hôpital Bretonneau, TOURS, France.

Introduction: Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disorder characterized by recurrent epistaxis, cutaneous telangiectasia, and visceral arteriovenous malformations (AVMs) that affecting lungs (PAVM), gastrointestinal tract (DAVM), liver (HAVM), and brain (CAVM) and resulting from mutations in two major genes: *ENG* (HHT1) or *ACVRL1* (HHT2).

Our objective was to determine the influence of c.1112dupG mutation on clinical phenotype in HHT2 patients.

Methods: We retrospectively compared the frequency of clinical features of HHT between a subgroup of patients with mutation c.1112dupG (group A) and those with the other *ACVRL1* mutations (group B), using

a clinical HHT database (CIROCO), build by the HHT reference centre in France and used by the French-Italian Network.

Results: 351 HHT2 patients were included in 6 HHT centres in France. Eighty three patients were in group A and 268 patients were in group B. Epistaxis were present in both groups and occurred at a younger age in group B patients (Median = 16 vs 21 years old, $p < 0.001$). Pulmonary involvement appeared to be significantly more frequent in group B patients (8 vs 18 %, $p = 0.03$). Frequency of hepatic, digestive and neurological AVM were not significantly different in both group but hepatic AVM were more severe in group B. Indeed, no hepatic transplantation were performed in group A (0 versus 5%, $p = 0.04$).

Conclusion: This study pointed out major differences between clinical expression of ACVRL1 mutation c.1112dupG, which appeared to be milder, than other ACVRL1 mutation phenotypes.

P01.294

Holoprosencephaly mutations in the Dutch population

A. D. Paulussen, D. Tserpelis, S. Spierts, H. J. Smeets, J. Herbergs;
Academic Hospital Maastricht, Maastricht, The Netherlands.

Holoprosencephaly (HPE) is a common severe malformation of the brain that involves abnormal formation and septation of the developing central nervous system. The prevalence is 1:250 during early embryogenesis, but the live born prevalence is only 1:16000. The etiology of HPE is extremely heterogeneous and can include both a teratogenic and/or genetic basis. We studied four genes known to be involved in HPE, namely *SHH*, *ZIC2*, *SIX3* and *TGIF* by sequence and MLPA analysis. A series of in total 72 sporadic and familial HPE cases with a variable clinical spectrum has been analysed. We detected 17 pathogenic mutations (24%) in total, of which 2 in *SHH*, 6 in *ZIC2* and 9 in *SIX3*. Only one mutation (Alanine-tract expansion in *ZIC2*) was reported previously and detected twice in this population, all others were novel. Two mutations were complete gene deletions (one *SIX3*, one *ZIC2* deletion) of which the deletion sizes were further characterized using the 250K *nsp I* Affymetrix SNP array. The familial mutations displayed great phenotypic heterogeneity of the disease, which makes it difficult to establish genotype-phenotype correlations. This phenotypic variability may be due both to environmental factors and to potential modifier genes. HPE development is probably a multistep process, which implicates more genes; illustrating the importance of further identification of new genes.

P01.295

Huntington disease and Huntington-like phenotype: 10 years of local molecular diagnostic experience

C. Santos¹, J. Cerqueira¹, P. Magalhães¹, M. Costa², L. Jardim³, C. Costa⁴, C. Vitor⁵, P. Coutinho⁶, P. Macie⁶, J. Sequeiros^{1,7};

¹IBMC-Instituto de Biologia Molecular e Celular, Porto, Portugal, ²ICVS - Instituto de Investigação em Ciências da Vida e Saúde, Braga, Portugal, ³Hospital Clínicas de Porto Alegre, Porto Alegre, Brazil, ⁴Hospital Fernando Fonseca, Amadora, Portugal, ⁵Hospital São Sebastião, Sta Maria da Feira, Portugal, ⁶Hospital São Sebastião, Sta Maria da Feira, Portugal, ⁷ICBAS, Porto, Portugal. CGPP/IBMC, is the reference laboratory for HD in Portugal: we performed 965 HD tests over the past ten years: 693 requests for confirmation/exclusion of a clinical diagnosis, 258 presymptomatic and 14 prenatal tests.

Only 58% of all diagnostic requests were confirmed; from those excluded, we selected 200 patients and studied them for HD-Like genes: an eight extra octapeptide repeats in the *PRNP* gene (HDL1); a CTG/CAG repeat in the junctophilin (*JPH3*) gene (HDL2); a CAG expansion in two SCA genes - *ATN1* (DRPLA) and *TBP* (HDL4/SCA17); as well as other included in the differential diagnosis of HD: neuroferritinopathy (*FTL* gene) and benign hereditary chorea (*TITF1* mutations).

Expansion of CAG repeats in *ATN1* and the insertion on *PRNP* were excluded in all cases. One family (mother and son with chorea since childhood, myoclonus, falls and dysarthria) carried a nonsense mutation in *TITF1*. A *FTL* mutation was detected in one Gypsy family (mother asymptomatic and son with mild non-progressive mental retardation, and gait disturbances by age 13; both had with pallidal involvement on MRI). We found also a CAG expansion in *TBP* (a patient with behavioural disturbances, epilepsy, aphasia, imbalance, and gait ataxia). Finally, we found a 47 CTG/CAG expansion in the *JPH3* gene, in a Brazilian patient (onset at age 44 years of bradypsychism, mutism, dysarthria, cognitive deterioration and chorea, as well as ataxic gait;

he had cortical atrophy).

Study of HD-like disorders is warranted, whenever HD has been excluded and it is clinically indicated.

P01.296

Lifestyle factors and the age at onset of Huntington disease

M. Delatycki^{1,2}, Z. Horton¹, L. Tippett³, V. Hogg³, V. Collins^{1,2}, A. Churchyard⁴, D. Velakoulis⁵, K. Trembath¹;

¹Murdoch Childrens Research Institute, Parkville, Australia, ²Genetic Health Services Victoria, Parkville, Australia, ³The University of Auckland, Auckland, New Zealand, ⁴Monash Medical Centre, Clayton, Australia, ⁵Royal Melbourne Hospital, Parkville, Australia.

Huntington disease (HD) is an autosomal dominant neurodegenerative disorder due to an expanded CAG repeat in the *IT15* gene. Transgenic HD mouse model studies have shown that raising mice in an enriched environment delays the onset of symptoms, leading us to consider whether pre-morbid lifestyle affects age-at-onset in humans. Subjects with symptomatic HD were interviewed using a questionnaire to ascertain pre-morbid lifestyle during three life stages (teens, 20s/30s, 40s/50s). Recorded activities were classified as physical, intellectual or passive, and activity scores generated. Surveys were matched with the subject's age-at-onset and CAG repeat length.

Preliminary analysis (n=92) showed a mean age-at-onset of 44.9 years (range 21-76), with a strong inverse correlation to CAG repeat length ($r = -0.728$, $p < 0.001$). Linear regression indicated a negative association between average pre-morbid leisure-time passivity and age-at-onset ($b = -0.744$, $R^2 = 0.109$, $p = 0.001$) that remained significant when adjusted for CAG repeat length ($b = -0.333$, $R^2 = 0.55$, $p = 0.048$). This association was most apparent for passivity during the teens and in men. Comparison of the mean age-at-onset in groups below and above the median passivity score showed a difference of 6.0 years (95%CI=1.2 to 10.7). No significant relationship was demonstrated between average intellectual or average physical leisure-time activity and age-at-onset or CAG repeat length. Data from over 150 interviews in Australia and New Zealand will be presented.

Passivity in leisure-time is associated with age-at-onset of HD, and CAG repeat length, suggesting that passivity contributes to earlier onset of symptoms, or is a preclinical manifestation of HD, more apparent in those with larger CAG repeat lengths.

P01.297

Familial autosomal dominant hyperinsulinism due to *SUR1* (*ABCC8*) mutation

G. Morin¹, E. Gailly¹, C. Bellanné-Chantelois², F. Moreau³, M. Mathieu¹, A. Léké³;

¹Unité de Génétique Clinique, Amiens, France, ²UF de Génétique des Maladies Métaboliques - Groupe Hospitalier Pitié-Salpêtrière, Paris, France, ³Unité de Néonatalogie, Amiens, France.

Familial congenital hyperinsulinism is responsible of prolonged hypoglycemia, secondary to mutations of genes involved in the regulation pathway of insulin secretion by β Langerhans cells. Most of the cases are in relation with recessive mutations of two genes, located in 11p15.1, named *SUR1* (*ABCC8*) and *KIR6.2* (*KCNJ11*), and coding for two subunits of the same potassium channel.

Dominant mutations of *SUR1* (*ABCC8*) were only published in two families reported by Thornton (1998 and 2003) and Huopio (2000 and 2003). In these families, the hypoglycaemia was sensible to diazoxide. In the family reported by Huopio, the eventuality of transformation in diabetes with age was noticed.

We report the observation of a female newborn presenting with severe hypoglycaemia at 36 hours of life, requiring continuous gastric nutrition at the beginning, but compatible with a normal breath feeding when diazoxide was started. Her father had similar symptoms in childhood, improved by diazoxide. In the two patients, a missense heterozygous mutation of *SUR1* (*ABCC8*) was discovered (2143G>A - V715M). Screening of other genes involved in familial dominant hyperinsulinism was negative (*HNF4*, *KIR6.2*). The mutation was not present in the two paternal grand-parents of the index case.

P01.298

Hyperphosphatasia with seizures, neurologic deficit and characteristic facial features: Five new cases of Mabry syndrome

M. D. Thompson¹, M. M. Nezarati², G. Gillissen-Kaesbach³, P. Meinecke⁴, R. Mendoza-Londono⁵, A. Munnich⁶, D. E. C. Cole⁷;

¹Dept of Lab Medicine & Pathobiology, Univ. of Toronto, Toronto, ON, Canada,

²Dept of Genetics, North York General Hospital, Toronto, ON, Canada, ³Institut für Humangenetik, Universität zu Lübeck, Germany, Lübeck, Germany,

⁴Abteilung Medizinische Genetik, Altonaer Kinderkrankenhaus, Hamburg,

Germany, ⁵Dept of Pediatrics, Univ. of Toronto, Toronto, ON, Canada, ⁶Hôpital Necker-Enfants Malades, Paris, France, ⁷Dept of Lab Medicine and Pathobiology & Dept of Pediatrics, Univ. of Toronto, Toronto, ON, Canada.

In 1970, Mabry et al. described multiple cases of persistent hyperphosphatasia associated with developmental delay and seizures in a single consanguineous family (OMIM#239300). The nosology of this condition, however, is uncertain. We report five new cases that help delineate this disorder and provide further evidence favouring autosomal recessive inheritance, with sib recurrence in one instance (French non-consanguineous parents), and consanguinity (Lebanese parents) in another. Common to all five children is the Mabry triad of tonic-clonic seizures (usually beginning around one year of age), moderate to severe developmental delay, and persistently elevated alkaline phosphatase activity, without any indication of liver or metabolic bone disease. The degree of hyperphosphatasia varies considerably amongst cases (~1.3 to 20 times the upper age-adjusted reference limit). In addition, all five display a common facial dysmorphism, characterized by hypertelorism, broad nasal bridge, and tented mouth. The three singleton cases also have brachytelephalangy, but there is no evidence of skeletal anomalies in the two siblings. In the family first described by Mabry et al., at least one affected was noted to have intracellular inclusions on biopsy of rectal mucosa but not liver. In three of our cases, inclusions have been observed in cultured cells, but the cells are not uniformly perturbed and characterization is still in progress. We are aware of additional cases in the literature which suggest a wider phenotypic spectrum, but they are consistent with an autosomal recessive condition characterized by hyperphosphatasia, seizures, and neurologic deficit - a disorder we call Mabry syndrome.

P01.299

The yield of cascade screening and risk stratification for sudden cardiac death in hypertrophic cardiomyopathy MYBPC3 gene mutation carriers

I. Christiaans¹, E. Birnie², I. M. van Langen¹, G. J. Bonse¹, A. A. M. Wilde²;

¹Department of Clinical Genetics, Academic Medical Centre, Amsterdam, The Netherlands, ²Institute of Health Policy and Management, Erasmus Medical Centre, Rotterdam, The Netherlands, ³Department of Cardiology, Academic Medical Centre, Amsterdam, The Netherlands.

Background: Hypertrophic cardiomyopathy (HCM) is a common autosomal dominant heart disease associated with heart failure and sudden cardiac death (SCD). Disease penetrance and the risk of SCD in mutation carriers are unknown. We investigated the prevalence of a clinical diagnosis of HCM and the presence of risk factors for SCD at the first cardiological evaluation after presymptomatic genetic testing in asymptomatic carriers of a MYBPC3 gene mutation.

Methods: 235 asymptomatic mutation carriers were cardiotically evaluated on the presence of HCM and risk factors for SCD. A comparison was made for different types of MYBPC3 gene mutations.

Results: A clinical diagnosis of HCM could be made in 22.6% of carriers. Disease penetrance at 65 years was incomplete for all types of MYBPC3 gene mutations. Women were affected less often ($p=0.003$) and disease penetrance was lower ($p=0.024$). 22 asymptomatic carriers had \geq two risk factors for SCD. In nine a clinical diagnosis of HCM could be made and they were therefore at high risk for SCD.

Conclusion: A diagnosis of HCM can be made in almost one quarter of mutation carriers at first evaluation. Disease penetrance of HCM in MYBPC3 gene mutation carriers is incomplete at 65 years and differs between men and women. Risk factors were frequently present and 4% of carriers appeared to be at high risk for SCD. Our data justify presymptomatic genetic testing in HCM families with a pathogenic mutation and frequent cardiological evaluation on the presence of HCM and risk factors for SCD, even until advanced age.

P01.300

Prevalence and phenotypic characteristics associated with MyBPC3 mutations in patients with hypertrophic cardiomyopathy

M. Hermida-Prieto, M. I. Rodríguez-García, M. Ortiz, R. Barriales, X. Fernandez, L. Cazón, I. Alvaríño, A. Castro-Beiras, L. Monserrat; Instituto de Ciencias de la Salud, La Coruña, Spain.

Background: Mutations in the beta-myosin heavy chain (MYH7) and myosin-binding protein C (MyBPC3) genes are the most frequent causes of hypertrophic cardiomyopathy (HCM). MyBPC3 mutations have been associated with later diagnosis and less hypertrophy than MYH7 mutations. Our objectives were to compare the prevalence of mutations and the phenotypic characteristics associated with both genes in our patients with HCM.

Methods: SSCP analysis and sequencing of fragments with abnormal MyBPC3 gene mobility were carried out in 130 consecutive index patients with HCM previously studied for the MYH7 gene (10% mutated). The phenotypes of patients with and without mutations in both genes were compared.

Results: We identified 16 MyBPC3 different mutations (8 of them novel) in 20 patients (15.4%). Age at diagnosis was similar in MyBPC3 vs. MYH7 patients (46.2 vs. 46.0, p ns). More than 50% (11) of MyBPC3 mutated patients were diagnosed before 50 years of age, 35% (7) < 40 and 15% (3) < 30. MyBPC3 patients had lower maximal thickness (25.15 vs. 30.45 mm, $p=0.045$) than those with mutations in MYH7, but higher than non-mutated patients (22.17 mm, $p=0.034$). Thirty percent of MyBPC3 patients had a maximal wall thickness \geq 28 mm (2 of them with a thickness >40 mm were younger than 45 years old).

Conclusions: MyBPC3 mutations were present in 15.4% of our families. Patients with MyBPC3 gene mutations were not older at diagnosis than patients with MYH7 mutations. MyBPC3 mutations may appear in young patients with severe hypertrophy.

P01.301

Spectrum of mutations in MyBPC3 gene in 130 families with hypertrophic cardiomyopathy

M. I. Rodríguez-García, L. Monserrat, L. Cazón, M. Ortiz, I. Alvaríño, R. Barriales, X. Fernández, A. Castro-Beiras, M. Hermida-Prieto; Instituto Universitario de Ciencias de la Salud, A Coruña, Spain.

Hypertrophic cardiomyopathy (HCM), an autosomal-dominant disorder and the leading cause of sudden cardiac death in the young, is caused by mutations in genes encoding sarcomeric proteins. One of the most common genetic causes for HCM involves mutations in MYBPC3, the gene encoding cardiac myosin binding protein C.

To determine the spectrum of mutations in MyBPC3 gene, 130 index cases were tested.

A total of 16 different mutations, including 8 novel ones, were identified in 20 families (15.4%): 9 missense (D75N, A216T, V471E, R495W, R502Q [in 2 families], E542Q [in 3 families], T957S, R1022P [in 2 families], E1179K, 4 deletions (Q327fs, K504del, K600fs, P955fs) and 3 intronic regions (IVS6+5G>A, IVS11-9G>A, IVS29+5G>A).

Ten of the mutations were identified on 7 of the 34 exons studied. Exons 16 and 17 could be "hot spots" due to the fact that 35% of the families presented a mutation in these exons. The average of age in the index cases with mutation was 50 years. Four carriers relatives weren't diagnosed HCM but they were below mean age of diagnose, so it is possible that they haven't yet developed the phenotype. Besides, there were 3 relatives without conclusive diagnostic of HCM that didn't present mutation; this could suggest mutations in other genes.

In conclusion, MyBPC3 is one of the genes most commonly affected by HCM-causing mutations which leads to a relatively mild phenotype with an adult age of onset. Furthermore, the existence of individuals with HCM but without mutation in MyBPC3, suggests the presence of additional disease-causing mutations in other genes.

P01.302

Neuroblastoma (NB) with hypothalamic dysfunction (HD): report of a series of 14 cases

J. Amiel, L. de Pontual, A. Nougayrede, A. Munnich, S. Lyonnet;

INSERM U-781, Department of Genetics, Necker Hospital, Paris, France, Paris, France.

Neuroblastoma (NB) is a frequent paediatric tumour for which recurrent somatic rearrangements are known. Congenital central hypoven-

tilation syndrome (CCHS) is a broad dysautonomia with predisposition to Hirschsprung disease and NB in 20% and 5-10% of the cases respectively. The identification of the PHOX2B gene as disease causing in CCHS allowed to find that PHOX2B could be mutated in some familial and sporadic cases of NB also. In order to find genes involved in NB predisposition, we collected syndromic NB cases. Here we report a series of 14 patients with hypoventilation and HD. Hypothalamic dysfunction is characterized by obesity, hyperprolactinemia, central hypothyroidism, disordered water balance, unresponsive growth hormone to stimulation test, corticotrophin deficiency and abnormal puberty be it precocious or delayed. Up to now, all reported cases (25) have been sporadic. The natural history of the syndrome is striking: rapid onset obesity due to hyperphagia is the first symptom, followed by hypoventilation with a mean delay of 1.5 year. Neurocognitive deceleration and mood disorders are frequently noted. The outcome remains poor in this group of patients and would benefit from early diagnosis in order to anticipate ventilation and possible metabolic disorders. Tumour predisposition is as high as 4/14 (29%) in this series. Finally, we report a familial case with recurrence in siblings and discuss a paraneoplastic syndrome an autoimmune disorder and a monogenic condition.

P01.303

Neonatal data on 530 children born after ICSI using testicular spermatozoa

F. De Schrijver¹, H. Tournaye², I. Liebaers¹, P. Devroey², P. Haentjens¹, M. Bonduelle¹;

¹center for medical genetics, Brussels, Belgium, ²center for reproductive medicine, Brussels, Belgium.

INTRODUCTION: We analysed pregnancy outcome and neonatal data of children born from a consecutive cohort of ICSI cycles performed with testicular spermatozoa.

MATERIAL & METHODS : Questionnaire data and results of physical examinations on 530 ICSI children from azoospermic fathers from whom testicular spermatozoa were obtained (period 1994-2007) were compared with control data from 2889 ICSI children. All children were examined by a geneticist during their first year of life.

A subanalysis of outcome parameters was performed in relation to the cause of azoospermia.

RESULTS: Of the 657 pregnancies obtained after ICSI using testicular spermatozoa, 426 (63.1%) were ongoing after 20 weeks leading to the birth of 530 liveborn children: 331 singletons, 178 twins and 21 triplets. Mean birthweight, length and head circumference as well as prematurity, low birthweight and perinatal mortality in singletons and twins did not differ from the ICSI control group. No increase in major malformations was observed in liveborn TESE children (4.90%) when compared to the control ICSI group. Prenatal (126) and postnatal (72) karyotype analysis revealed 2.02% *de novo* abnormalities and 0.51% inherited abnormalities compared to 0.45% *de novo* anomalies (OR 4.57; 95%CI 1.68-12.38) in the general newborn population.

Further subanalysis in relation to the cause of azoospermia did not reveal any differences in neonatal outcome parameters and major malformations rate.

CONCLUSIONS: Neonatal outcome and major malformations rate were similar in TESE children compared with a control cohort of ICSI children but more *de novo* chromosomal anomalies were found compared to the general newborn population.

P01.304

A case with interstitial deletion of 11q

D. Niedrist¹, M. Riegel¹, A. Baumer¹, P. Miny², A. Schinzel¹;

¹Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland, ²Division of Medical Genetics, University Children's Hospital, Basel, Switzerland.

We report on a 12 year-old boy with mental retardation (EQ 45), cleft palate, umbilical and unilateral inguinal hernia and discrete dysmorphic features: low frontal hairline, red hair with multiple whorls and unusual growth pattern, flat occiput, low set ears with poorly formed helices, narrow auditory canals, full eyelids, up-slanting palpebral fissures, prominent lips, small mandible, narrow sloping shoulders, discrete pectus excavatum, inverted nipples and abnormal distribution of fat tissue over the proximal forearms. On the upper limb there were proximal placement of thumbs, restricted flexion in all metacarpo-phalangeal joints, prominent finger pads and short and broad nails and

distal phalanges. On the lower limb there were diminished stability in the knees and pes planus. The boy had a good social behaviour and pleasant nature.

Karyotype revealed an interstitial deletion involving 11q14. By arrayCGH the deletion could be further defined to 11q13.5->11q14.3.

We compared our case with case reports with similar sized deletions involving the bands 11q13 and 11q14. Similar phenotypic findings included mental retardation, normal measurements at birth, low frontal hairline, dysmorphic ears, full eyelids or ptosis, small mandible, high arched or cleft palate and minor features of the fingers, thumbs or toes. In interstitial deletion 11q the facial gestalt and the incidence of joint limitations is similar to Williams-Beuren syndrome, whereas in contrast to Williams-Beuren syndrome the retardation in speech is more pronounced and there is in general no heart defect, growth retardation or microcephaly.

P01.305

A novel case of partial trisomy 2p in a 2-year old girl

S. Unlubay¹, O. Cogulu², B. Durmaz², A. Alpman¹, F. Ozkinay²;

¹Ege University Faculty of Medicine Department of Medical Genetics, Izmir, Turkey, ²Ege University Faculty of Medicine Department of Pediatrics, Izmir, Turkey.

The characteristics of partial duplication of the short arm of chromosome 2 have been documented in different reports. The clinical phenotype of trisomy 2p includes growth and psychomotor retardation, microcephaly, prominent forehead, hypertelorism, epicanthal folds, ptosis, strabismus, myopia, apparently low set and abnormal ears, flat nasal bridge, narrow high palate, micrognathia, sternal abnormalities, epileptic seizures, kyphoscoliosis, congenital heart disease, genital hypoplasia, long widely spaced fingers and toes and hypotonia. Here, we report on a new case of inv dup 2p in a 2 year-old girl. She was born to no non-consanguineous parents after an uncomplicated pregnancy. The birth weight was 2.800 kg. The physical examination revealed generalized hypotonia, pectus excavatum, frontal bossing, flat nasal bridge, hypertelorism, low-set and large ears, micrognathia, syndactyly in the 2-3-4 toes. She also had severe growth and psychomotor retardation. At 6 months, she had the first epileptic seizure and three more seizures occurred afterwards. The EEG showed abnormal discharges. She also had recurrent respiratory infections. Her thorax CT scan showed subsegmental atelectasis in the posterior lobes and areas of bronchiolitis obliterans. Gastroesophageal reflux was determined in the scintigraphy. The cranial MRI was normal. The karyotype revealed a partial trisomy of chromosome 2p and was noted as 46,XX,inv dup(2)(p23p25.2). The parents had normal karyotypes. According to the clinical picture and the karyotype, the patient was considered to be a novel case of partial trisomy 2p and fluorescence in situ hybridization (FISH) and array comparative genomic hybridisation (aCGH) studies were planned for revealing the exact breakpoints.

P01.306

Clinicopathological study of a Infantile Systemic Hyalinosis case with a novel mutation in the CMG2 gene

B. Demeer¹, M. M. Viprey-Thouvard², M. Ramirez³, N. Bednarek², M. Doco-Fenzy¹, M. Abely², J. Martignetti³, D. Gaillard¹;

¹Department of Genetics, Reims Hospital, reims, France, ²Department of Pediatrics, American Memorial Hospital, reims, France, ³Department of Human Genetics, Mount Sinai School of Medicine, NY, United States.

Infantile Systemic Hyalinosis (ISH) is an autosomal recessive disorder, belonging to the wide and heterogeneous group of genetic fibromatosis, characterized by widespread deposition of hyaline material in the skin, gastrointestinal tract, muscles and glands. Mutations in the capillary morphogenesis gene-2 (CMG2), coding for a transmembrane protein with important roles in cell-cell adhesion and cell-extracellular matrix interactions, have been shown to cause ISH. We report on a patient with a severe form of ISH, confirmed by clinical and histological findings, who also displayed clear evidence of early muscle involvement, and enteropathy. Novel mutation of CMG2 gene has been found and review of the literature will be made.

P01.307

Maternal uniparental isodisomy 20 : clinical report

C. Vincent-Delorme^{1,2}, E. Pipiras³, S. Drunat⁴, C. Dupont⁵, A. Delahaye³, I. Guilloto⁶, S. Manouvrier⁶, B. Benzacken³;

¹UF de génétique CH Arras, ²Service de Génétique clinique CHRU Lille, Arras, France, ³Centre de référence maladies rares pour les syndromes malformatifs et anomalies de développement Nord de France, Lille, France, ⁴UF de cytogénétique Service HEC-BDR Hôpital Jean Verdier AP-HP, Bondy, France, ⁵UF de Biologie moléculaire Département de Génétique Hôpital Robert Debré AP-HP, Paris, France, ⁶Service de Médecine Néonatale CH Arras, Arras, France, ⁷Service de Génétique clinique CHRU Lille. Centre de référence maladies rares pour les syndromes malformatifs et anomalies du développement Nord de France, Lille, France.

We report on a young child, presenting with intractable feeding difficulties, and severe post-natal growth retardation required enteral tube feeding,

He was the second child, from non-consanguineous Caucasian healthy parents, born at 39 weeks of gestation and delivery was uneventful. Birth measurements were normal.

Nucal translucency was detected during first trimester of pregnancy and prenatal investigation in amniotic fluid was performed.

Chromosome studies using standard R banding showed a tiny marker in all cells; parents refused complementary investigations.

Prenatal ultrason examination revealed moderate pyelectasy. Post-natal examination showed posterior urethral valves.

Post-natal cytogenetic analysis revealed that the marker was from chromosome 20 and contained only centromere and pericentromeric segments.

The combination of cytogenetic findings and severe feeding difficulties made we speculate that it could be a maternal UPD 20 confirmed by molecular analysis.

Phenotype, in our case, is less severe (specially mental retardation) than those of the paternal 20q13.2-q13.3 deletions, even though major characteristic are present.

At 3 years, measurements are -5SD for length and weight, and -0,5SD for OFC. He says only a few words and walks with help.

This report demonstrates interpretation's difficulties when excedentary marker is found and allows us to be careful, and to look for UPD for markers derived from imprinted chromosomes.

P01.308

Hypomelanosis of Ito - report of two patients

M. P. Martins, R. P. Leite, M. Souto, E. Ribeiro;

Centro Hospitalar Trás-os-Montes e Alto Douro, Vila Real, Portugal.

Hypomelanosis of Ito syndrome (HI - MIM* 300337), is characterized by the presence of whorled hypochromic skin lesions often associated with systemic manifestations.

To date, epidemiological data on HI are limited. It appears to be the third most common neurocutaneous disease, second only to neurofibromatosis and tuberous sclerosis. Approximately three fourths of the patients with typical skin lesions have systemic manifestations. Typical skin lesions are initially demonstrated during the first year of life in as many as 70% of patients; they are noticeable at birth in 54% of patients. Prognosis depends on the patient's manifestations and complications of the disease. Patients with chromosomal anomalies are at risk for tumors.

We report two children, a 6 years female and a 5 years old male, with typical HI lesions and systemic nondermatological abnormalities (eg, mental retardation and epilepsy). Blood karyotyping was normal on both; skin biopsy revealed normal fibroblast karyotype in the girl and mosaicism for chromosome abnormality in the boy.

Despite recent advances, the genetic substrate for HI syndrome is far from homogenous and is not completely understood. Although several chromosomal abnormalities have been reported in HI the etiology remains elusive. The pattern of chromosomal aberrations and the polymorphic nature of this disease have led some to believe that HI syndrome is a descriptive term rather than a true syndrome.

Most cases are a de novo occurrence although very rare cases of familial HI following a dominant pattern have been described in the literature.

P01.309

Misdiagnosis in patients with Joubert Syndrome

C. Marzocchi¹, K. Ludwig¹, L. Salvati¹, S. Sartor², R. Tenconi¹;

¹Servizio di Genetica Clinica, Padova, Italy, ²Dipartimento di Pediatria, Padova, Italy.

We report a 18 month-old boy born to a Moroccan non-consanguineous couple referred to our center for the presence of a Dandy-Walker-Malformation (DWM) with hydrocephalus and intracranial hypertension, mental retardation, and cranio-facial dysmorphisms.

About a year after the birth of the proband, a second pregnancy of the couple was terminated at 20 weeks of gestation after ultrasound detection of DWM, cleft-lip and -palate and nasal root hypoplasia

The initial diagnosis of DWM in the proband and in the fetus was put into question. A control MRI performed after placement of a ventriculoperitoneal shunt at twenty months of age showed the classical "molar tooth sign", allowing us to hypothesise the diagnosis of Joubert syndrome.

Genetic testing is currently being performed.

These results indicate that in the presence of intracranial hypertension it might be difficult to diagnose the underlying brain malformation. Therefore the recurrence of DWM, especially if diagnosed only by fetal brain ultrasound, should take to rule out Joubert syndrome.

P01.310

Novel mutation in the keratin 3 gene in an asymptomatic family with Meesmann corneal dystrophy suggests genotype-phenotype correlation

M. Oldak¹, J. P. Szaflik², A. Pollak³, R. B. Maksym¹, M. Udziela², R. Płoski⁴, J. Szaflik²;

¹Department of Histology and Embryology, Center of Biostructure Research, Medical University of Warsaw, Warsaw, Poland, ²Department of Ophthalmology, Medical University of Warsaw, Warsaw, Poland, ³Institute of Physiology and Pathology of Hearing, Warsaw, Poland, ⁴Department of Medical Genetics, Center of Biostructure Research, Warsaw Medical University, Warsaw, Poland.

Meesmann corneal dystrophy (MCD, OMIM #122100) is a dominantly inherited disorder characterized by fragility of the anterior corneal epithelium and intraepithelial microcysts formation. Although the disease is generally mild and affected individuals are often asymptomatic, some suffer from recurrent erosions leading to lacrimation, photophobia and deterioration in visual acuity. MCD is caused by mutations in keratin 3 (*KRT3*) or 12 (*KRT12*) genes encoding cornea-specific cytoskeletal proteins. Seventeen mutations in *KRT12* and only two in *KRT3* have been described so far. In this study we report on a three-generation Polish family with MCD. Epithelial lesions characteristic for MCD were visualized with slit-lamp examination and confirmed by *in vivo* confocal microscopy. In the proband a direct sequencing of the PCR amplified coding regions of *KRT3* and *KRT12* revealed a novel 1493A>T heterozygous missense mutation in exon 7 of *KRT3*, which predicts the substitution of glutamic acid for valine at codon 498 (E498V). By a PCR-RFLP test the mutation was demonstrated to segregate with disease (four affected members, three non-affected) and to be absent in 100 controls from Polish population indicating that it is not a common polymorphism. Location of the E498V mutation emphasizes the functional relevance of the highly conserved boundary motifs at the C-terminus of the alpha-helical rod domain in *KRT3*.

P01.311

A molecular diagnostic service for lacrimoauriculodentodigital (LADD) syndrome

T. Lester¹, L. J. Williams¹, J. N. Berg², D. Goudie², H. Lord¹, A. O. M. Wilkie³, A. Seller¹;

¹Clinical Molecular Genetics Laboratory, Churchill Hospital, Headington, Oxford, United Kingdom, ²Clinical Genetics, Ninewells Hospital, Dundee, United Kingdom, ³Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Headington, Oxford, United Kingdom.

Lacrimoauriculodentodigital (LADD) syndrome (Levy-Hollister syndrome) is a rare autosomal dominant condition characterised by multiple congenital abnormalities mainly affecting the lacrimal glands and ducts, salivary glands and ducts, ears, teeth and distal limb segments. In addition there may be mild facial dysmorphism, malformation of the kidney and respiratory system and abnormal genitalia. The phenotype of LADD syndrome is highly variable and can range from congenital renal disease causing death in the neonatal period, to aplasia of the

lacrimal and salivary glands (ALSG) only. This variability in phenotype has been seen within families with the same mutation.

LADD syndrome is a genetically heterogeneous disorder caused by heterozygous mutations in the *FGF10*, *FGFR2* and *FGFR3* genes. As the Oxford Molecular Genetics Laboratory already offers *FGFR2* and *FGFR3* gene testing as part of the Craniofacial service, testing for LADD syndrome was introduced in 2007.

Testing is done using bi-directional sequencing of the coding region and exon/ intron boundaries of the *FGF10* gene, and bi-directional sequencing of exon 16 of the *FGFR2* gene and exon 13 of the *FGFR3* gene. This screening strategy is expected to pick up all known point mutations in *FGFR2*, *FGFR3* and *FGF10*, but not exonic deletions. An exonic deletion of *FGF10* has been reported.

Three cases have been analysed to date. The presented case has a maternally inherited c.1942G>A (p.A648T) mutation in *FGFR2* exon 16. Both mother and son have classical facial features, cup-shaped ears, variable nail dysplasia and lacrimal duct obstruction. The proband also had unilateral renal agenesis.

P01.312

Limb Body Wall Complex in a Monochorial Mono-amniotic Twin

M. M. G. Biervliet¹, J. van den Ende², N. Van der Aa²;

¹Center of Medical Genetics, Atwerp, Belgium, ²Center of Medical Genetics, Antwerp, Belgium.

The limb-body wall complex (LBWC) or body stalk anomaly is a variable group of congenital defects characterized by a combination of anterior body wall defects, limb defects and/or encephalocele or exencephaly. There are often additional structural defects such as urogenital anomalies and abnormalities of the cloaca.

Three pathogenic mechanisms have been proposed for this anomaly: a mechanical origin by early amnion rupture, a vascular disruption during embryonal development and an embryonic origin due to a mutation in a developmental gene.

We report of a monochorial mono-amniotic twin pregnancy with ultrasound abnormalities seen in the 13-th week. The pregnancy was terminated. Post mortem examination on the first foetus showed only one kidney, a megabladder and anal atresia. The second foetus had a severe hydrops, anal atresia, a large abdominal wall defect and absence of the external genitalia.

In our case we presume that the body stalk anomaly in both foetuses results from a mutation in a developmental gene.

This case supports the hypothesis of a possible embryonal origin of limb-body wall complex.

P01.313

Novel LMNA mutation seen in a patient with leanness, severe insulin resistance and facial dysmorphisms

F. Lombardi¹, M. R. D'Apice¹, S. Latini¹, M. D'Adamo², P. Sbraccia², S. Servide³, G. Novelli^{1,4};

¹Departments of Biopathology and Diagnostic Imaging, University of Rome Tor Vergata, Rome, Italy, ²Departments of Internal Medicine University of Rome Tor Vergata, Rome, Italy, ³Department of Neuroscience, Catholic University, Rome, Italy, ⁴University of Arkansas for Medical Sciences, Little Rock, AR, United States.

Here we describe a novel LMNA gene mutation in a 27-year-old woman with a complex disorder characterized by extreme leanness, severe insulin resistance, mixed calcific valvulopathy involving both mitral and aortic valves, slight facial dysmorphism, low femoral bone mass. The patient is the 2nd child of non consanguineous parents. Physical examination showed: extreme leanness (BMI 15.6 kg/m²), especially at the legs, craniofacial dysmorphisms with sharp nose, small chin and small mouth, narrow palate and tongue hypoplasia, micrognathia and slight dental overcrowding; she has subtle and sparse hair. Surprisingly, whole body DEXA scan showed normal total fat mass (25.8%) and distribution, whereas MRI showed no alteration of both subcutaneous and visceral adipose tissue depots. Metabolic alterations includes hyperinsulinemia both basal and 2 hours after OGTT (respectively 57.2 and 982.4 µU/ml), insulin resistance assessed by glucose clamp (M=2.3 mg/kg/min). LMNA sequencing evidenced a novel heterozygous missense mutation in exon 4 that replaces well-conserved residue glutamic acid at position 262 to lysine (p.E262K, c.784 G→A). Her parents were negative for the same mutation, suggesting that this mutation has *de novo* origin. Sequence analysis of 100 healthy normal controls did

not reveal this sequence alteration, indicating that this mutation is not a common variation. Genetic screening of additional genes mutated in laminopathic or lipodystrophic disorders (*ZMPSTE24*, *PPARγ*, *BSCL2*) showed a wild type sequence. This study extends the large phenotypic spectrum of laminopathies and may lead us better understanding molecular basis of this group of disease.

P01.314

Serendipitous detection of ENG haploinsufficiency in a girl with nail-patella syndrome and a 9q33.3-q34.11 microdeletion

E. Lapi¹, E. Andreucci¹, R. Ciccone², S. Guarducci¹, U. Ricci¹, O. Zuffard³, M. Genuardi⁴;

¹AOU Meyer, Florence, Italy, ²Institute of General Biology and Medical Genetics - University of Pavia - Italy, Pavia, Italy, ³Institute of General Biology and Medical Genetics - IRCCS San Matteo Hospital - University of Pavia - Italy, Pavia, Italy, ⁴AOU Meyer - University of Florence, Florence, Italy.

We describe the first case of a microdeletion syndrome with concurrent loss of the *LMX1B* and *ENG* genes on 9q33.3-q34.11. The probanda, first-born of healthy non-consanguineous parents, was born at term of a pregnancy complicated by hypertensive gestosis and IUGR. She had a severe psychomotor delay and, during infancy, myoclonic epilepsy and generalized seizures. Nail-patella syndrome was diagnosed upon physical and radiological examination. She had occasional nose-bleeding episodes since the age of 6 years. No ocular neither renal function alteration have been detected until the current age of 14 years. Precocious puberty was blocked with triptorelin treatment until the age of 12 yrs: regular menses began six months after therapy withdrawal.

aCGH was performed to look for a common cause of the phenotypic manifestations. A *de novo* 1.7 Mb deletion in 9q33.3-q34.11 was detected. Microsatellite analysis revealed that the deletion was of maternal origin. The deleted region includes the *LMX1B* and *ENG* genes. Deletion of *LMX1B* is responsible for manifestations of the nail-patella syndrome displayed by the patient. *ENG* haploinsufficiency causes hereditary hemorrhagic teleangiectasia (HHT). At present, the only clinical manifestation of HHT present in the patient is nose bleeding.

This observation underscores the predictive power of aCGH. This technique does not only allow to clarify the origin of existing clinical manifestations but may also lead to the identification of haploinsufficiency for genes causing adult-onset conditions with implementation of appropriate surveillance.

P01.315

Discordant monozygotic twins suggests that macrocephaly-capillary malformation is a post-zygotic event

D. J. P. Lederer^{1,2}, O. Battisti³, C. Verellen-Dumoulin¹;

¹Center For Human Genetic, IPG, Charleroi (Gosselies), Belgium, ²UCL-Saint-Luc, Bruxelles, Belgium, ³Clinique Saint-Vincent, Rocourt, Belgium.

Macrocephaly-Capillary Malformation (M-CM) is the new name for Macrocephaly-cutis marmorata telangiectatica congenita.

We describe a 17 month old girl with M-CM. She has a healthy monozygotic twin. She is the fourth of five girls from second degree consanguineous Turkish parents.

The proband was born at 35 weeks of gestation by caesarean-section for foetal distress. Birth weight was 2,47 kg (P50), birth length 46 cm (P25) and occipito-frontal circumference (OFC) 35,5 cm (>P90). During the neonatal period profound hypoglycaemias were noted. Clinical examination shows: frontal bossing, nasal and frontal angiomas, strabismus of right eye (inconstant), hypertelorism, right epicanthus, ogival palate, abnormal palmar crease, gap between first and second toes, axial and peripheral hypotonia, cutis marmorata, thick subcutaneous tissue. She has psychomotor retardation and macrocephaly. The cerebral MRI at 7 months showed cerebellar tonsillar herniation with hydrocephaly and signs of cerebral hypertension. She had ventricular shunting at 11 months of age with improvement of macrocephaly and psychomotor retardation. Thermoregulation trouble appeared after one year of age with usual temperature between 38-39°C.

The karyotype and X-inactivation pattern are normal. Twin zygosity testing performed on buccal smear DNA proved monozygosity.

There are about 100 published cases of M-CM. Detailed clinical findings and cerebral imaging of our case are similar to those reported before. Thermoregulation trouble has never been described in M-CM. All the cases of M-CM are sporadic. Our patient is a unique case of M-

CM in monozygotic twins where only one is affected, suggesting that M-CM is due to a post-zygotic event.

P01.316

Study of the aortic risk associated with *FBN1* mutations from an international study of 1013 patients with Marfan syndrome or related type I fibrillinopathy

L. Faivre¹, G. Collod-Berouf², B. Loeys³, A. Child⁴, C. Binquet⁵, E. Gautier⁶, B. Callaewer⁷, E. Arbustin⁸, K. Mayer⁹, M. Arslan-Kirchner⁶, C. Berouf⁸, M. Claustres⁹, C. Bonithon-Kopp⁵, L. Ades¹⁰, J. De Backer³, P. Coucke³, U. Francke¹¹, A. De Paepe³, C. Boileau¹², G. Jondeau¹³;

¹Departement de Genetique, Dijon, France, ²INSERM, U827, Montpellier, France, ³Center for Medical Genetics, Ghent, Belgium, ⁴Department of Cardiological Sciences, St. George's Hospital, London, United Kingdom, ⁵Centre d'investigation clinique – épidémiologie clinique/essais cliniques, Dijon, France, ⁶Molecular Diagnostic Unit, Policlinico San Matteo, Pavia, Italy, ⁷Center for Human Genetics and Laboratory Medicine, Martinsried, Germany, ⁸Institut für Humangenetik, Hannover, Germany, ⁹Laboratoire de Génétique Moléculaire, Hôpital Arnault de Villeneuve, Montpellier, France, ¹⁰Marfan Research Group, The Children's Hospital at Westmead, Sidney, Australia, ¹¹Departments of Genetics and Pediatrics, Stanford, CA, United States, ¹²Laboratoire de Génétique moléculaire, Hôpital Ambroise Paré, Boulogne, France, ¹³Centre de Référence Maladie de Marfan, Hôpital Bichat, Paris, France.

In order to better describe the aortic risk associated with mutations in the *FBN1* gene, we took advantage of a series of 1013 genotyped probands carrying Marfan syndrome or another type I fibrillinopathy, recruited for a genotype-phenotype correlation study. At 40 years of age, the cumulative probability of presenting an ascending aortic dilatation (AAD) was 75% (95%-CI=72%-78%), 26% (95%-CI=22%-31%) for ascending aortic dissection and 41% (95%-CI=36%-46%) for cardiac surgery. The cumulative probability of presenting AAD was higher in males than in females (80% [95%-CI=76%-83%] at 40 years of age in males versus 70% [95%-CI=65%-75%] in females; $p=0.0036$). An higher risk of aortic surgery was also observed in males (46% [95%-CI=39%-52%] versus 34% [95%-CI=27%-42%] in females; $p=0.0002$). The study of the paediatric cohort ($n=320$) showed that aortic complications remained an exception, with a 1% risk of aortic dissection and a 5% risk of aortic surgery at 10 years of age. Adult patients diagnosed during childhood had a higher risk of developing AAD (81% [95%-CI=73%-88%] at 40 years of age) than patients diagnosed in adulthood (65% [95%-CI=60%-69%], $p<0.0001$). They also had a higher risk of aortic surgery (64% [95%-CI=52%-77%] at 40 years of age compared to 35% [95%-CI=30%-40%], $p<0.0001$). The search for clinical factors associated with the occurrence of ascending aortic dilatation over time revealed that patients with mitral valve prolapse (HR=5.86; IC-95%=3.08-11.18) or ectopia lentis (HR=2.17; IC-95%=1.55-3.05) had a higher risk of developing AAD.

P01.317

Case report: a boy with mild mental retardation, hypogenitalism and karyotype 46,XY,add(8)(q24.3) de novo

N. A. Gladkova¹, M. O. Mkhaidze², M. V. Prozorova¹;

¹Municipal Centre of Medical Genetics, St.Petersburg, Russian Federation,

²Medical Academy for postgraduate study, St.Petersburg, Russian Federation.

We report on 27-month-old boy with abnormal karyotype. He was born premature at 35-36 weeks of the fifth gestation as the first child of healthy non-consanguineous parents. At birth, the mother was 31 years old and the father was 59 years old. They both had a professional contact with industrial hazards. Being married first time, the mother had three miscarriages. In her second marriage, she had a pregnancy ended as spontaneous abortion at six weeks of gestation. The fifth pregnancy was complicated with anemia, pyelonephritis, threatened miscarriage at 12 weeks of gestation. Results of prenatal ultrasound and biochemical screening were normal. The proband presented with a birthweight of 2350g, length of 44 cm, at 12 months his weight was 10200g, length 81cm. Findings at 27 months included mild mental retardation, speech and developmental delay, asthenic stature, telecanthus, strabismus alternating, flat nasal bridge, geographical tongue, unilateral simian crease, broad hallux, flat-valgus feet, moderate hypotonia and hyperflexibility of the distal parts of the hands and feet, diastasis of rectum abdominal muscles, small testes (<1 ml), hypoplastic penis. The chorionic gonadotrophin test showed testosterone increased (initial level=2.2nmol/l, after ChG-27, normal range 8-38). TSH

level was 3.56 microME/ml (normal range 0.1-3.5), FT₄-9.2 picomol/l (normal range 9-28). Cytogenetic testing revealed the proband to be a carrier of 46,XY,add(8)(q24.3) while his parents had normal karyotype in the blood. For uncovering the origin of the additional region on chromosome 8, a multi-tissue screening for the presence of mosaicism for the abnormal cell line is advisable.

P01.318

Microcephalia vera : cognitive profile and neuroradiological presentation of 9 children with ASPM gene mutations

L. Titomanlio¹, S. Passemard¹, M. Elmaleh², K. Hernandez³, T. Billette de Villemeur⁴, L. Burglen⁵, A. Afenjar⁶, S. Oden⁶, B. Isidor⁷, O. Boesflug Tanguy⁸, A. Megarbane⁹, J. Alessandri¹⁰, G. Andria¹¹, M. Abramowicz¹², B. Gerard¹³, A. Verloes¹³;

¹INSERM U676, Paris, France, ²Service de Radiologie Pédiatrique, Paris, France, ³Département de Génétique, Paris, France, ⁴Service de Neuropédiatrie, Trousseau Hospital, Paris, France, ⁵Service de Génétique, Hôpital Trousseau, Paris, France, ⁶CHU de Rennes, Rennes, France, ⁷Service de Génétique, CHU de Nantes, Nantes, France, ⁸CHU de Clermont Ferrand, Clermont Ferrand, France, ⁹Service de Génétique, Université Saint Joseph, Beyrouth, Lebanon, ¹⁰Service de Pédiatrie, CHR Saint Denis de la Réunion, Saint Denis de la Réunion, France, ¹¹Dipartimento di Pediatria, Università Federico II, Naples, Italy, ¹²Service de Génétique, Université Libre, Bruxelles, Belgium, ¹³Service de Génétique, R. Debré Hospital, Paris, France.

Primary microcephaly (MIM 251200) is a neurodevelopmental condition in which there is a global reduction in cerebral cortex volume. Abnormal neuronal and glial proliferation lead to microcephalia vera (MV) and microcephaly with simplified gyral pattern (MSG). Patients affected by MV or MSG show mental retardation. The MCPH5 locus for MV patients on 1q31 corresponds to the *ASPM* gene, a human ortholog of the *Drosophila melanogaster* 'abnormal spindle' gene (*asp*), identified by homozygosity mapping and found responsible of roughly 1/2 of the MV cases in all ethnic backgrounds.

We report on clinical-genetical results from a multicentric european study on MV. Nine out of 70 patients with a diagnosis of MV or MSG (based on clinical and neuroradiological studies) showed mutations in the coding sequence of *ASPM*. Patients' IQ ranged from 35 to 70. One third of them had MSG, one an unilateral polymicrogyria. We observed that MR was more severe in patients who presented a more severe microcephaly and a MSG rather than MV. Furthermore, memory was better preserved than attention or fine motor functions. MV and MSG represent the phenotypical spectrum of *ASPM* gene mutations.

P01.319

Multiple minor congenital defects associated with autism spectrum disorders

D. Stoicanescu¹, M. Cevef, E. Sirbu²;

¹University of Medicine and Pharmacy "Victor Babes", Timisoara, Romania,

²University of Oradea, Oradea, Romania, ³West University of Timișoara, Timișoara, Romania.

Autism spectrum disorders represent a wide spectrum of conditions characterized by abnormalities of social interactions and communication, severely restricted interests and highly repetitive behavior. They have multiple genetic and nongenetic causes. In order to ascertain the cause and the onset of the disorder, establishing a positive correlation with some markers would be useful. Minor congenital defects result from either genetic or environmental causes that act during pregnancy and are an indirect measure of abnormal embryo and fetal development. The purpose of the study was to see if patients with autism spectrum disorders have more minor congenital defects than healthy individuals and if so, if this finding correlates with the history of the patients. The incidence and media of minor congenital defects were determined in 76 patients with autism spectrum disorders and in unrelated control subjects matched by age and sex. The frequency of minor anomalies was not significantly different in the two groups, 14.47% in autistic children and teenagers, compared to 14.80% in healthy controls. The mean number of minor congenital anomalies was significantly higher in the autistic group, 3±0.70 minor defects/patient, compared to 1.43±0.36 minor defects/patient in controls. None of the control subjects had three or more minor anomalies. These results support the idea that minor defects, especially multiple ones, may represent markers of early prenatal factors that contribute to the adverse outcome.

P01.320**Gene Copy Number analysis using semi-quantitative multiplex PCR-based assay on capillary electrophoresis systems**

S. Jankowski, E. Currie-Fraser, L. Xu;

Applied Biosystems, Foster City, CA, United States.

Deletions and duplications in genomic DNA have been implicated as pathogenic mutations in many diseases. Traditionally, detection of these types of mutations is done using southern blot hybridization or Fluorescence in situ hybridization, techniques which can be laborious, time-consuming and require high quantities of starting material. In this study we present analysis of a semi-quantitative multiplex PCR-based method that uses relative quantitation of fluorescently-labeled fragments. Fragments from BRCA1, BRCA2, 9p21 and MMR (MSH2) regions were tested using labeled probes from DNA that had been isolated from blood. Amplified samples were then run on an Applied Biosystems capillary electrophoresis platform and the data was analyzed in GeneMapper® software v4.0. After signal normalization, loci regions that had undergone deletions or duplications were identified using the GeneMapper® software v4.0 report manager feature and verified using the dye scale functionality. Our results will highlight an easy to use, optimal workflow and analysis that can be used for both small and large-scale studies.

P01.321**A severe form of the X-linked microphthalmia with linear skin defects syndrome (MLS) in a female newborn - expansion of the clinical spectrum**E. Steichen-Gersdorf¹, F. Pientka², D. Kotzot³, I. Wimplinger², E. Griesmaier¹, K. Kutsche²;¹Medical University of Innsbruck, Innsbruck, Austria, ²Institute for Human Genetics, Hamburg, Germany, ³Department of Medical Genetics, Innsbruck, Austria.

The microphthalmia with linear skin defects syndrome (MLS/MIDAS) is an X-linked disorder with male lethality, mostly associated with segmental monosomy of the Xp22 region. MLS is characterized by unilateral or bilateral microphthalmia and linear skin defects limited to the face and neck. We report a female newborn with a severe phenotype of MLS syndrome. She presents with the typical MLS signs, such as bilateral microphthalmia, primary persistent vitreous and sclerocornea, and a linear erythematous skin defect on her cheek. Additional features include agenesis of the corpus callosum, left-sided diaphragmatic hernia, an ileal duplication cyst, imperforate anus with a rectoperineal fistula, a hamartoma at the right liver lobe, and partial duplication of the uterus.

A terminal deletion of the short arm of one of her X chromosomes was confirmed by fluorescence *in situ* hybridization using various BAC clones mapping in Xp22.3-p22.2. The breakpoint was localized in Xp22.2 and the size of the deletion was estimated to cover ~11 Mb, including the *HCCS* gene. Mutations in *HCCS*, encoding the mitochondrial holocytochrome *c*-type synthase, have recently been identified in patients with MLS and normal karyotype. Midline defects, as imperforate anus and duplication of the uterus, have rarely been described in patients with MLS. However, anal atresia is a frequent feature in male patients with X-linked Opitz G/BBB syndrome carrying a mutation in *MID1*. We hypothesize that deletion of both *MID1* and *HCCS* as well as skewed XCI might have contributed to the complex disease phenotype of our patient.

P01.322**Corpus Callosum Agenesis In Three Patients With Moebius Syndrome**

S. Basaran Yilmaz, E. Karaca, G. Yesil, A. Yuksel;

Istanbul University, Cerrahpasa Medical Faculty, Department Of Medical Genetics, Istanbul, Turkey.

Moebius Syndrome is a rare disease which is defined as congenital facial palsy with impairment of ocular abduction. The facial nerve(7) and abducens nerve(6) are most frequently involved, but other cranial nerves may be involved as well. Other variable features include orofacial dysmorphism, limb malformations, mental retardation, external ear defects. The most accepted hypothesis with regard to pathogenesis is that disruption of the primitive subclavian arteries and their branches before establishment of a sufficient blood supply to the brain stem leads to the symptoms of Moebius sequence. Up to date congenital anomalies of the posterior fossa, including Arnold-Chiari malformation,

pineal cyst, hypoplastic hemisphericum, asymmetric lateral ventricles, anomalies of cranial nerves nuclei had been described.

We describe here 3 cases with Moebius Syndrome in two of whom corpus callosum agenesis were detected.

The patients referred to our clinic with facial asymmetry and additional dysmorphic features. Cranial MRI revealed corpus callosum agenesis in two of the patients.

To our knowledge, these are the first patients with Moebius Syndrome who are reported presenting corpus callosum agenesis.

P01.323**MOMO syndrome without macrosomia - alternative definition of the obesity syndrome**N. Tyshchenko¹, T. Neuhann¹, E. Schrock¹, A. Huebner², S. Tinschert¹;¹Institute of Clinical Genetics, Dresden, Germany, ²Children's Hospital, Technical University, Dresden, Germany.

Two unrelated patients with a combination of macrosomia, macrocephaly, obesity and ocular abnormalities (retinal coloboma and nystagmus) were described by Moretti-Ferreira et al. (1993). Thereafter, the new syndrome - called MOMO syndrome (Macrosomia, Obesity, Macrocephaly, and Ocular abnormalities) - was categorized as an overgrowth syndrome. However, since a third patient, published in 2000, was of short stature, overgrowth was discussed as non-mandatory for the diagnosis.

We report a further patient with proposed diagnosis MOMO syndrome. At the age of 5 years and 7 months the girl presented with overweight, macrocephaly and borderline short stature. She showed a prominent forehead, deep-set eyes, a flat nasal bridge, anteverted nares, a cupid bow upper lip, low-set posteriorly rotated ears and tapering fingers. She had hypotonia, recurrent febrile convulsions and developmental delay. A hand radiogram showed delayed bone age. Ophthalmological examination revealed a choroid coloboma in her left eye. Metabolic tests and chromosomal examinations including Array-CGH analysis with the 44k Operon chip were normal. On the basis of the general obesity, macrocephaly, coloboma of the choroid and mental retardation the diagnosis of MOMO syndrome was made. The comparison of these four patients showed that a combination of obesity, macrocephaly, ocular coloboma (especially coloboma of the retina or choroid) and mental retardation is specific for MOMO syndrome. Due to variability of stature anomalies we propose to form the acronym "MOMO" from Macrocephaly, Obesity, Mental retardation and Ocular abnormalities, excluding macrosomy from the syndrome name.

P01.324**Mosaic trisomy 22: report of two patients and review of the literature**

M. Rio, S. Noel-Couillard, M. Le Merrer, M. de Blois, O. Raoul, V. Malan, A. Munnich, M. Vekemans;

Department of genetic, Paris, France.

Non-mosaic trisomy 22 is commonly seen in spontaneous abortions and is incompatible with life. Conversely, mosaic trisomy 22 is observed in newborns and is compatible with long survival. The clinical presentation of mosaic trisomy 22 is variable. It includes growth retardation, mental retardation, limb malformation, congenital heart defect and dysmorphic features. Here we report two unrelated patients with mosaic trisomy 22.

Both patients were referred for genetic evaluation due to developmental delay and failure to thrive. Patient 1 had intrauterine and postnatal growth retardation, microcephaly, complex heart defect, severe developmental delay, facial dysmorphism, deafness, skin pigmentation anomalies, brachydactyly, short toes with syndactyly. Interestingly, patient 2 had an overlapping phenotype including postnatal growth retardation, non-compaction of left ventricle, developmental delay, deafness, and skin pigmentation anomalies. Facial dysmorphism, hand and feet anomalies were also similar to the one observed in patient 1. Routine chromosome analysis on lymphocytes showed normal karyotype in both patients. Chromosome analysis of fibroblasts showed a mosaic trisomy 22: 47,XY,+22[12]/46,XY [15] in patient 1, 47,XX,+22[17]/46,XX[2]. These findings were confirmed by *in situ* hybridization. The phenotypic spectrum observed in both patients is compared to previously reported cases.

P01.325

Mowat-Wilson syndrome in a patient with severe eye anomaliesA. Medeira¹, G. Black², E. Seabright², I. Cordeiro¹;¹Serviço de Genética Médica, Hospital de Santa Maria, Lisboa, Portugal,²Department of Clinical Genetics, St. Mary's Hospital, Manchester, United Kingdom.

Mowat-Wilson Syndrome (MWS) is a mental retardation syndrome associated with distinctive facial features, frequent microcephaly and epilepsy, and a variable spectrum of congenital anomalies, including Hirschprung disease (HSCR), corpus callosum agenesis, genitourinary and heart defects. Eye anomalies such as strabismus, microphthalmia, colobomas, have been reported in a few patients.

Heterozygous mutations or deletions involving the zinc finger homeobox 1B gene (ZFX1B) cause MWS

We report a 5 years old female patient with severe psychomotor delay, epilepsy, microcephaly, deep set eyes, left eye anophthalmia, right eye severe microphthalmia with retinal and optic nerve colobomas, broad nose with long columella, short nasolabial distance, large mouth, prominent chin, large ears with fleshy uplifted lobes, septo-optic dysplasia, corpus callosum hypoplasia, HSCR, ventricular septal defect. Mutation analysis of ZFX1B gene identified a truncating mutation c.2083C>T[p.Arg695X].

MWS was originally reported as a syndromic form of HSCR. It is now known that it frequently occurs without HSCR and can be recognized by a consistent facial phenotype associated with severe mental retardation. MWS and Goldberg-Shprintzen may overlap features but faces are distinct. Some MWS patients have an ataxic gait and smiling personality suggesting Angelman, but the characteristic facial features of MWS and the presence of other congenital anomalies usually distinguish these conditions. The patient that we report presents the main manifestations described in MWS including facial phenotype. Eye anomalies have been reported in MWS, but not as severe as in our patient. As far as we are aware this is the only MWS patient with anophthalmia.

P01.326

Recurrence of Mowat-Wilson syndrome in two siblings carrying a novel mutation in the ZEB2 geneM. Cecconi¹, F. Forzano¹, L. Garavelli², M. Grasso¹, E. Di Maria^{1,3}, F. Faravelli¹;¹Galliera Hospital, Genova, Italy, ²Clinical Genetics Unit, S. Maria Nuova Hospital, Reggio Emilia, Italy, ³Dept. of Neuroscience, Ophthalmology and Genetics, University of Genova, Genova, Italy.

The eponym Mowat-Wilson syndrome (MWS, OMIM #235730) designates a multisystem congenital disease caused by heterozygous mutations in the ZEB2 gene. Molecular diagnosis has helped to delineate the cardinal signs (facial gestalt and delayed psychomotor development) as well as several variously associated congenital disorders. To date, literature describes approximately 180 patients with MWS. Only three cases of recurrence in siblings were reported.

We describe two sisters with clinical features of MWS. Antenatal scanning in the first sibling had revealed corpus callosum agenesis. Hypotonia and feeding difficulties were present in the neonatal period. The psychomotor development was delayed. US scans of the heart and abdomen were normal. At our evaluation (5 years of age), facial dysmorphisms strongly suggestive of MWS were noted. The second born had a congenital complex heart disease. The surgical interventions on heart defects were complicated by renal failure, airways infection, denutrition and a cardiac arrest. At our evaluation (3 yrs.), she presented microcephaly and facial dysmorphisms, and with the sequelae of cerebral anoxia.

Direct sequencing of ZEB2 revealed in both patients a novel heterozygous c.310C>T transition, resulting in a stop codon (p.Q104X). The nucleotide substitution was not found in both parents, as well as in 94 unrelated control individuals. No evidence of somatic mosaicism was found in the parents.

In light of this and previous reports, the recurrence risk provided to families with an isolated MWS case should be frequently revisited. Genetic counselling should consider intrinsic clinical variability, risk of complications and still inaccurate empiric risk of recurrence.

P01.327

The placenta as the main clue to the diagnosis in a patient with recurrent nonimmune hydrops fetalisA. Moresco¹, N. Mazzitelli², N. Ronaldo³, D. Caceres³;¹Centro Nacional de Genética Médica, Buenos Aires, Argentina, ²Unidad de Patología. Hospital Materno Infantil Ramón Sardá, Buenos Aires, Argentina,³Servicio de Neonatología. Hospital Materno Infantil Ramón Sardá, Buenos Aires, Argentina.

Introduction: Nonimmune hydrops fetalis (NIHF) usually carries a poor prognosis and can have diverse causes. Lysosomal storage diseases (LSD) are among the causes of NIHF.

Objective: Report a case of recurrent NIHF where the placental histology lead to the investigation of Mucopolysaccharidosis VII (MPS VII). Materials and methods: Histopathological examination of the placenta and serum beta-glucuronidase (GUSB) activity were performed.

Case report: In the second pregnancy of non-consanguineous parents fetal hydrops was detected by an ultrasound scan at 22 weeks of gestation. An earlier pregnancy resulted also in a hydropic fetus. There was no evidence of immune hydrops, congenital infection or cardiovascular abnormalities and a normal karyotype (46,XY) was obtained. The pregnancy resulted in a depressed, hydropic infant, which despite of intensive care died at 3 days of age.

The histopathological examination of the placenta, presented vacuolated Hofbauer cells, which were positive stained with Alcian Blue and negative to PAS reaction. A normal appearance of the cytotrophoblast was noted. The electron microscopic reflected the empty appearance of the vacuoles. This features suggested a LSD with accumulation of an acid mucopolysaccharide probably MPS- VII. The diagnosis was confirmed GUSB activity that was negligible.

Conclusion: The placental histopathological examination performed in this case of recurrent NIHF led to the suspicion of MPS-VII. The diagnosis necessary had to be confirmed with the quantification of enzyme activity. The placental proved to be an useful tool, in order to limit the diagnostic resources. The accurate diagnosis is important for adequate genetic counselling.

P01.328

Novel mutation in epithelial sodium channel alfa subunit (SCNN1A) in a patient with a cystic fibrosis-like syndrome.M. Bernal¹, F. Mora¹, J. F. Rodríguez-Gutiérrez¹, N. Hernández-Trujillo², J. A. Brieva¹, A. Sampalo¹, A. Nieto¹;¹Laboratorio de Diagnostico Molecular. Hospital Puerta del Mar, Cádiz, Spain,²Servicio de Pediatría. Hospital Puerta del Mar, Cádiz, Spain.

A six months old girl clinically diagnosed of cystic fibrosis was admitted for molecular study of CFTR gene. No mutations were detected using Inno-Lipa CFTR19 and CFTR17+Tn kits. A subsequent complete screening using DGGE and SSCP/HD was also negative (detection level of 97%). In the search for an alternative diagnosis, an extremely high aldosterone and renin activity levels were found suggesting the diagnosis of a multisystem primary type I pseudohypoaldosteronism. This is a rare autosomal recessive disease that results from mutations in the genes encoding epithelial sodium channel subunits (alfa, beta, gamma). Most mutations have been described in the alfa subunit gene (SCNN1A). This gene was sequenced in the patient and her parents. A C>A substitution at position 301 resulting in a change of glutamine for lysine at amino acid 101 (Q101K) was found. The patient was homozygous for the mutation while parents were both heterozygous. This mutation has not been reported to date. Residue 101 is at the first membrane-spanning segment of the channel inside a structural motif that has been shown to be essential to proper channel folding or assembly. In addition the 101Q residue is highly evolutionarily conserved. This data strongly suggest that Q101K mutation affects channel function and support the diagnosis of multisystem primary pseudohypoaldosteronism in this patient.

P01.329

Mulvihill-Smith Syndrome - Case Report

L. Caba, C. Rusu, A. Sireteanu, M. Covic;

University of Medicine and Pharmacy - Department of Medical Genetics, Iasi, Romania.

Mulvihill-Smith syndrome is a very rare autosomal dominant disorder, defined by low birth weight, dwarfism, a prematurely aged facial appearance, pigmented naevi, hearing impairment and mental retardation.

We report a case in order to illustrate the clinical features of this progeroid disease. The proband is a 13 years old male that presents: short stature (-2.3 SD) and microcephaly (-3.7 SD; without bulging sutures). Clinical examination also reveals: poorly muscled build with lipoatrophy, thin skin with pigmented naevi, small prematurely aged face with pointed chin and retrognathia, small mouth and total anodontia (confirmed by radiologic examination). The patient has mild mental retardation, speech defect and hoarse voice. Family history is positive for anodontia (the mother has no teeth).

We made differential diagnosis with Leopard syndrome and other progeroid syndromes.

In conclusion, we present a male with Mulvihill-Smith syndrome in order to illustrate a rare disorder and to discuss the importance of clinical features like dwarfism, anodontia and pigmented naevi for diagnosis.

P01.330

Nail patella-syndrome: Phenotype and genotype correlation

B. Çolak¹, N. H. Elçioglu¹, B. Eroğ¹, S. Yalçın²;

¹Department of Pediatric Genetics, Marmara University Hospital, Istanbul, Turkey, ²Department of Orthopaedics, Marmara University Hospital, Istanbul, Turkey.

Nail patella-syndrome (OMIM: 161200) is a rare autosomal dominant connective tissue disorder with a prevalence 1 in 50 000. The phenotype is associated with multiple deformities affecting the nails, skeletal system, kidneys, and eyes. Skeletal features include absent or hypoplastic patellae, patella dislocations, scoliosis, elbow abnormalities, talipes and iliac horns. Inter- and intrafamilial clinical variability are common in this disorder particularly for skeletal abnormalities, presence and severity of nephropathy and ocular anomalies like glaucoma. Mutations in the gene encoding the Lim Homeo Box Transcription Factor-1 (LMXB1), mapped on chromosome 9 (9q34), are responsible for the clinical phenotype of NPS. No clear genotype-phenotype association have been found to date by the published cases.

We present here the phenotype and genotype of two different NPS Families. First family presented an isolated case and the second one a dominantly inherited three generations NPS family with multiple affected family members. The main clinical symptoms were lower limbs disabilities and nail dysplasia with remarkable inter- and intrafamilial variability. Neither nephropathy nor ocular problems were found in our all examined cases. Molecular analysis of the LMXB1 showed a de novo wide deletion in intron 2 by the first family and an inherited heterozygous deletion in exon 3 (430delG) in the second Family.

Genetic counseling and follow-up regarding the different manifestations are important for all family members who have inherited the disease but could have a milder phenotype and remain underdiagnosed.

P01.331

Clinical characterisation of NBIA patients with and without mutation in PANK2 gene (PKAN)

M. Hempel¹, T. Kmiec², M. Hartig¹, H. Prokisch³, T. Meitinger³;

¹Institute of Human Genetics, Munich, Germany, ²Memorial Children's Health Institute, Warsaw, Poland, ³Helmholtz Zentrum München, Munich, Germany.

Neurodegeneration with Brain Iron Accumulation (NBIA) is a heterogeneous group of disorders sharing the underlying and by MR imaging detectable feature of iron accumulation in the basal ganglia. A substantial part of these patients have mutations in PANK2 (Patathenase Kinase-Associated Neurodegeneration, PKAN). NBIA patients with and without PANK2 gene mutations share common clinical symptoms like dystonia, parkinsonism, pyramidal signs, cognitive deficits and dysarthria. Analysis of clinical symptoms of NBIA patients is often difficult because of the small patient numbers and several different investigators involved. We took advantage of a large collection of 43 NBIA patients characterized by a single investigator (T. K.). Screening PLA2G6 not mutations were found, in 24 patients two mutations have been identified in PANK2. The eye of the tiger sign were found in the majority of patients (21 out of 24) with PANK2 mutation. The group of patients with PANK2 mutations can be distinguished from the group without mutation by age of onset, loss of gait, the occurrence of generalized dystonia, parkinsonism, cognitive deficits, oromandibular dystonia and dysarthria.

Cytogenetic and molecular analysis of patients with Nijmegen breakage syndrome in Serbia

S. S. Cirkovic¹, M. Guc-Scekic^{1,2}, S. Pasic¹, D. Radivojevic¹, A. Jovanovic¹;

¹Mother and Child Health Care Institute of Serbia "Dr Vukan Cupic", Belgrade, Serbia, ²Faculty of Biology, University of Belgrade, Belgrade, Serbia.

Nijmegen breakage syndrome (NBS) is a rare autosomal recessive chromosome instability disorder, characterized by microcephaly, growth retardation and elevated risk of cancer. Cells cultured from NBS patients exhibit an increased cellular hypersensitivity to specific mutagenic agents such as bleomycin (BLE). It was shown that patients with NBS have mutations in the *NBN* gene, which is involved in the sensing and repair of DNA double strand breaks. Most of the known NBS patients so far are of Slavic origin and share the founder *NBN* mutation, 657del5.

Here we report on five Serbian children with NBS, diagnosed and treated at the Mother and Child Health Care Institute of Serbia from July 2005 to September 2007. Cytogenetic analyses were performed on control and BLE (1µg/ml) - treated, peripheral blood cultures using standard procedure. Metaphases were examined for chromosome breaks and aberrations. Three cultures were successfully established revealing increased chromosome breaks (0.27-0.81 vs. 0.02-0.05 breaks/cell) and various aberrations including chromosomes 7 and 14, with significant difference as compared to their control counterparts. Molecular analysis for the presence of the 657del5 mutation was carried out in five patients on DNA samples extracted from peripheral blood, using modified PCR method and heteroduplex analysis on PAGE gel. Homozygosity for the 657del5 mutation was detected in all analyzed NBS children.

Patients described here are the first Serbian NBS patients reported so far. Considering that NBS patients are extremely sensitive to ionizing radiation an early and precise cytogenetic and molecular diagnosis is very important for the management of the disease in case of malignancy.

P01.333

Recurrent severe pulmonary manifestations in 6 patients with nodular periventricular heterotopia associated and FLNA mutation

A. Masurel-Paulet¹, C. Goizef², E. M. Thompson³, A. Taš⁴, D. Kennedy⁵, E. Haan⁶, E. Landre⁶, N. Mejean⁶, A. Houze⁶, N. Bahi-Buisson⁷, C. Thauvin-Robinet⁸, F. Hue⁹, S. Roberston⁹, L. Favier¹;

¹Centre de Génétique, Hôpital d'Enfants, Dijon, France, ²Département de Génétique, Hôpital Pellegrin, Bordeaux, France, ³Clinical Genetics Service, Women's and Children's Hospital, Adelaide, Australia, ⁴Service de Neurochirurgie, Hôpital St Anne, Paris, France, ⁵Radiologie pédiatrique, Hôpital d'Enfants, Dijon, France, ⁶Pédiatrie, Hôpital d'Enfants, Dijon, France, ⁷Neurologie pédiatrique, Hôpital Necker-Enfants Malades, Paris, France, ⁸Paediatric Genetics, University of Otago, Dunedin, New Zealand.

Nodular periventricular heterotopia is an X linked dominant neuronal migration disorder caused by mutations in the filamin A (FLNA) gene. FLNA is an actin-binding protein and has a role in the modulation of cell shape and migration. A high phenotypic diversity has been described in association with FLNA mutations, from nodular periventricular heterotopia to otopalatodigital syndrome and frontometaphysal dysplasia. Extra neurological features have sometimes been described in patients with nodular periventricular heterotopia, including patent ductus arteriosus, coagulopathy, or Ehlers Danlos phenotype. In this study, we reported on 6 females aged 2 to 48 years, presenting with nodular periventricular heterotopia, FLNA gene mutation and notable lung manifestations. The median age of onset of lung manifestations was 4.5 months (1.5-240). Manifestations included recurrent early-onset pneumopathies in 5/6 patients, recurrent bronchiolitis in 4/6 patients and asthma in 4/6 patients. 5/6 patients had to be hospitalized at least once for lung involvement, including one-year cumulative length of hospitalisation in one child and hospitalisation in intensive care in another. Long-term oxygen dependence was described in 2 patients. The symptomatology appears to improve with age. We believe that such lung phenotype can be a recurrent manifestation in patients with nodular periventricular heterotopia, consequence of the mutation in the FLNA gene. This hypothesis is supported by the recent demonstration of interaction between FLNA and CFTR, the ubiquitous distribution of FLNA and its role in the cytoskeleton.

P01.334

Identification of a novel NOTCH1 mutation in patient with bicuspid aortic valve disease and thoracic aortic aneurysm

M. Diegoli¹, M. Grasso², N. Marziliano², A. Serio², A. Pilotto², M. Pasotti², E. Serafini², E. Porcu², P. Cassini², A. Brega³, E. Arbustini²;

¹University of Pavia, PAVIA, Italy, ²IRCCS Policlinico San Matteo, PAVIA, Italy, ³University of Milano, MILANO, Italy.

The bicuspid aortic valve (BAV) (MIM#109730) is the most common congenital cardiac malformation, occurring in 1-2% of the population. This condition is associated with a significantly increased risk of developing thoracic aortic aneurysms and acute aortic dissection. The valve calcification often observed in BAV is a result of inappropriate activation of osteoblast-specific gene expression. Recently, an association between mutations in NOTCH1 gene and aortic valve disease has been described. NOTCH1 encodes for a transmembrane protein that activates a signaling pathway with an active role in cardiac embryogenesis, including aortic and pulmonary valve development.

A 52-year old male was referred to our attention for suspected Marfan Syndrome. The patient did not fulfil Ghent criteria for Marfan Syndrome. He presented dilatation of the aortic root, the ascending aorta, and bicuspid and calcified aortic valve.

The family history was positive for autosomal dominant aneurysm of the ascending aorta not associated with other syndromic features.

The candidate gene NOTCH1 was screened by DHPLC and sequencing of heteroduplex amplicons.

A novel c.C4104T transition predicting the missense p.Ala1343Val mutation was identified in exon 25.

This result brings the attention of clinical geneticists to evaluate the NOTCH1 gene in patients with early onset of calcific and bicuspid aortic valve as plausible causative gene in the light of preventive surgery for carriers of gene defects and mild to severe aortic root dilation. Furthermore, this gene should be carefully evaluated in patients with thoracic aneurysm dissection without syndromic features previously genotyped for TGFBR1 and TGFBR2 genes with negative results.

P01.335

R229Q and A284 mutations of NPHS2 gene likely cause of steroid resistant nephrotic syndrome

A. Zuniga, S. Sanchez, S. Ferrando, A. Guerrero;
Hospital de la Ribera, Alzira (Valencia), Spain.

The idiopathic nephrotic syndrome is a clinical pathologic entity occurring mainly in children and is characterized by massive proteinuria, hypoalbuminemia, hyperlipidemia, edema, and minimal glomerular changes. In some instances, renal biopsy may show focal segmental glomerulosclerosis (FSGS) or diffuse mesangial proliferation. In contrast to 2 types of hereditary nephrotic syndrome previously identified, congenital nephrosis of the Finnish type (OMIM 256300) and diffuse mesangial sclerosis (OMIM 256370), idiopathic nephrotic syndrome was generally regarded as a sporadic disease although a few familial cases had been reported. Most patients with idiopathic nephrotic syndrome respond to steroid therapy and show a favorable outcome. However, 20% are steroid-resistant, with progression to end-stage renal failure in many cases. The nephrotic syndrome may recur after renal transplantation in such cases. NPHS2 mutations will be found in sporadic cases of steroid-resistant idiopathic nephrotic syndrome, which represents an important cause of childhood end-stage renal disease. The detection of NPHS2 mutations is of clinical utility as it would prescribe against unnecessary immunosuppressive therapy.

A 12-year-old girl was referred to our laboratory with a diagnosis of steroid-resistant nephrotic syndrome from pediatric nephrology department. We have analyzed PCR amplicons of each of the eight exons of NPHS2 by direct sequencing and we have found that she was carrier of two mutations: R229Q and A284V. The R229Q mutation alone is insufficient to cause FSGS but the presence of a second A284V NPHS2 mutation on the other allele suggests that compound heterozygosity for these sequence changes is the likely cause of disease.

Background: OFCD syndrome is characterized by ocular defects (congenital cataract, microphthalmia), facial dysmorphism, congenital cardiac defects, dental irregularities (radiculomegaly, oligodontia) and skeletal deformities. It results from mutations in BCOR gene localized on Xp11.4. All affected individuals are females and the few reported mutations are either deletions or generate premature stop codons. A single missense variant was identified within BCOR in a family with Lenz microphthalmia syndrome. OFCD syndrome has been shown to encompass defects of laterality, including the heart and other viscera. Methods: We analyzed BCOR gene in 26 female patients diagnosed with OFCD syndrome, 21 males with Lenz microphthalmia, 96 patients with isolated microphthalmia and 96 patients with cardiac laterality defects.

Results: Mutations were identified for the 26 patients with OFCD syndrome, and one patient with "isolated" microphthalmia. The same previously reported missense variant was identified in a boy with Lenz microphthalmia syndrome. No mutation was identified in the other patients tested. We report somatic mosaicism of BCOR anomalies in two families with OFCD syndrome. In both families, the mothers had 50% mosaicism in leucocytes, and their daughters carried the mother's mutation homogeneously. In the first family the mother, her monozygotic twin sister and her daughter were affected. In the second family, the daughter was affected but not her mother.

Conclusion: We report 27 novel patients with OFCD syndrome and mutations in BCOR gene. Cataract and radiculomegaly seem to be the two constant clinical signs in OFCD syndrome. Mosaicism in two of our families advocates cautiousness in genetic counselling.

P01.337

Clinical heterogeneity in cases of oral clefts with multiple congenital anomalies

E. Preiksaitienė¹, A. Matulevičienė^{1,2}, A. Utkus^{1,2}, V. Kučinskas^{1,2};

¹Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania, ²Centre for Medical Genetics at Vilnius University Hospital Santariškių Klinikos, Vilnius, Lithuania.

The causes of oral clefts (OCs) are multiple and complex, but the first step in the search of genetic basis should be epidemiological and clinical data. Although cleft palate (CP) is usually regarded as distinct defect from cleft lip with or without cleft palate, there is still an open question if the latter should be considered as variants of the same defect or should be divided into groups of cleft lip only (CL) and cleft lip with cleft palate (CLP). In the retrospective study of multiple congenital anomalies (MCA) of unknown origin in cases of oral clefts in Lithuania the incidence of anomalies associated with OCs was calculated among all three groups: CL, CP and CLP. There were 434 associated anomalies in 143 cases of OCs with MCA. Most frequently affected was the musculoskeletal system (31.6%, 137 anomalies), followed by cardiovascular (21.7%, 94), but a more detailed analysis of CL and CLP cases revealed some differences in the incidence and type of associated anomalies. Cardiovascular anomalies were the most common associated anomalies (30.1%), followed by musculoskeletal (23.8%) and congenital anomalies of ear, face and neck (20.6%) in

the CL group, while the most common associated anomalies in the CLP group were musculoskeletal (32.9%), cardiovascular anomalies (22.7%) and anomalies of central nervous system (10.2%). There are also some differences in pairs of associated anomalies with OCs. The results indicate that CL and CLP could be genetically distinct entities and should be analyzed separately when possible.

P01.338

Phenotypic diversity of oral-facial-digital syndrome

E. Sukarova-Angelovska, M. Kocova, N. Angelkova, S. Palcevska-Kocevska, L. Kojic;

Pediatric Clinic, Skopje, The former Yugoslav Republic of Macedonia.

The oral-facial-digital syndromes (OFDS) are variable group of disorders characterized by malformations in oral cavity, face and digits on hands and feet. Nine different subgroups are described depending on the severity of the above mentioned anomalies as well as on the additional anomalies of the brain, kidneys, limbs, eyes and other organs. However, overlap between groups occurs frequently in described cases.

Four patients with different type of oral-facial-digital syndrome (OFD) have been described. The patients showed variable anomalies on oral structures, tongue and digits on hands and feet. Anomalies of other organs and systems were noticed, including brain (1 patient), heart (1 patient) and kidneys (1 patient). The diagnosis of OFD types I, IV, and VI (two patients) has been established. Severity of the disease varied in all of them.

Minor facial anomalies, digital malformations, as well as the existence of additional malformations of other organs enable classification of the patients in subgroups. Although there are attempts for classification according to specific criteria, the diagnosis of the subtype is not always easy and clear. Many doubtful cases have been reported. The similarity and diversity of the clinical findings of the above described cases points out the difficulty in delineation of the subtypes of OFD syndrome because of the overlapping features between them and with related syndromes.

P01.339

Randomized dose comparison of pamidronate in children with types III and IV Osteogenesis imperfecta: 3 vs 6 month cycles

J. C. Marini¹, A. A. Obafermi^{1,2}, M. K. Abukhaled¹, H. L. Cintas³, J. F. Troendle⁴, A. D. Letocha¹, J. C. Reynolds⁵, S. Pau⁶;

¹National Institute of Child Health and Human Development, Bethesda, MD, United States, ²Clinical Research Training Program-Foundation for NIH and Pfizer Inc. grant research support, Bethesda, MD, United States, ³Rehabilitation Medicine, NIH Clinical Center, Bethesda, MD, United States, ⁴Biometry and Mathematical Statistics Branch, NICHD, NIH, Bethesda, MD, United States, ⁵Nuclear Medicine, NIH Clinical Center, Bethesda, MD, United States.

Aim: To determine whether the vertebral benefits of q3m infusion cycles can be attained on q6m cycles, with a lower cumulative dose.

Methods: Twenty-seven children with types III and IV OI were randomly assigned to receive 1mg/kg/3d IV pamidronate in q3 or q6 month cycles. All patients had spine radiographs, L1-L4 DXA, and musculoskeletal and function testing.

Results: L1-L4 DEXA increased significantly after 1 year of q3m cycles, with average change in z-score =+1.41 SD, but did not improve significantly with further treatment. In the q6m group, the average change in DEXA was not significant. Repeated measures analysis of DEXA z-scores yielded a z-score rate change of 0.064 SD/m for q3 vs 0.036 SD/m for q6 group (p=0.13). T12-L4 vertebral area and central height were determined from radiographs. Repeated measures analysis revealed significant improvement of q6m group average L1-L4 and T12-L2 vertebral height (p=0.05, 0.01) and area (p=0.002, 0.006). The rate of improvement of the q3m and q6m groups did not differ for L1-L4 area or height (p=0.52, 0.86) or T12-L2 area or height (p=0.28, 0.77). The OI children had no significant improvement in fracture incidence, manual muscle testing or BAMF motor scores in either group. Noteworthy, response to treatment was highly variable in each treatment group; improvement in vertebral area did not correlate with change in DEXA z-score.

Conclusions: Equivalent gains in vertebral height and area are obtained with q6m and q3m pamidronate cycles. For individual OI children, gain in DEXA does not correlate with extent of vertebral response.

P01.340

Osteoporosis-Pseudoglioma syndrome in two sisters

G. O. Cetin¹, F. Duzcan¹, E. Tepeli¹, F. S. Kirac²;

¹Pamukkale University School of Medicine, Department of Medical Biology, Denizli, Turkey, ²Pamukkale University School of Medicine, Department of Nuclear Medicine, Denizli, Turkey.

Osteoporosis-Pseudoglioma Syndrome (OPPG) is an autosomal recessive disorder characterized by congenital blindness and severe individuals often have deformed bones due to fractures. The ophthalmologic findings may include phthisis bulbi, microphthalmia, and some vitreoretinal changes. The OPPG locus is mapped to 11q12-13 and mutations that cause OPPG were identified in the LRP5 gene. LRP5 is a member of low density lipoprotein receptors (LDLR) family and a component of the Wnt pathway. Here, we report two sisters diagnosed as OPPG who were referred to genetic service with osteogenesis imperfecta, bilateral congenital nystagmus and microphthalmia. Their parents were phenotypically normal first cousins. The older sister was 18 years and the younger was 14 years old. They had congenital blindness and both had operations due to long bone fractures resulting in inability to walk. Physical examination findings included microphthalmia, scleral opacity and skeletal deformities especially in the lower limbs of both sisters. Tc-99m MDP whole-body scintigraphy showed deformation and asymmetry of the lower limbs and axial bones of the older sister while the younger one had normal scintigraphic findings. Dual-energy X-ray absorptiometry measurements revealed osteoporosis of both cases. According to these findings OPPG was prediagnosed and LRP5 gene mutation screening is planned.

P01.341

Overgrowth and X chromosome imbalance: Study of two unrelated females

M. P. Ribate¹, J. del Valle², I. Bueno³, B. Puisac¹, M. Arnedo¹, M. C. Gil¹, J. C. de Karam¹, J. Pie¹, L. A. Pérez-Jurado², F. J. Ramos^{1,3};

¹University of Zaragoza Medical School, Zaragoza, Spain, ²University Pompeu i Fabra, Barcelona, Spain, ³Hospital Clínico Universitario, Zaragoza, Spain.

In humans, partial X chromosome duplications/deletions are relatively rare chromosome rearrangements, described predominantly in males with mental retardation and generally associated with phenotype anomalies. Nevertheless affected females have also been reported although most of them do not show abnormal clinical findings, probably due to skewed, preferential inactivation of dup/del(X) chromosomes, and subsequent selection against cells with an active abnormal X in carrier females. However, some females with dup/del(X) chromosomes and random X-inactivation also exhibit developmental anomalies. Therefore, females with two X chromosomes and an active duplicated/deleted segment are functionally disomic/monosomic for genes that are normally subject to X-inactivation and functionally trisomic/disomic for those genes that escape X inactivation.

Here, we report on two unrelated females with overgrowth, Sotos-like phenotype, mental retardation, normal sexual development and de novo X chromosome anomalies, both originated in the paternal X chromosome and showed random X-inactivation. Diagnosis was confirmed by array-CGH and MLPA, and completed by X-inactivation and microsatellite studies. The first case, a 14 year-old girl with epilepsy carried a 20.2 Mb Xp duplication (p11.3 → p21.3). The second, a 17 year-old female was found to have a 26 Mb Xq deletion (q24-qter) and she had idiopathic thrombocytopenic purpura (ITP). These findings indicate that a gross functional imbalance in the cells with functional disomy/monosomy due to an active dup(Xp)/del(Xq) chromosome respectively, may have caused the same effect on prenatal and postnatal growth in both patients.

P01.342

Vitamin A deficiency in a neonate with PAGOD syndrome

D. Babovic-Vuksanovic, R. Gavrilova, S. Kirmani, A. N. Lteif, T. M. Olson; Mayo Clinic, Rochester, MN, United States.

PAGOD syndrome is a rare condition characterized by multiple congenital anomalies. These include pulmonary artery and lung hypoplasia, agonadism, diaphragmatic abnormalities and congenital cardiac defects. Omphalocele, various degrees of genital anomalies, cleft palate and optic nerve hypoplasia have also been described in affected patients. The etiology of this condition is still unknown. The spectrum of

birth defects is similar to developmental anomalies that are observed in an animal model with vitamin A or retinoic acid deficiency. We describe an infant with hypoplastic left heart, right pulmonary artery and lung hypoplasia, eversion of right hemidiaphragm, complete hypospadias and absent gonads. The karyotype was normal (46,XY) and FISH for SRY locus was present. Endocrine evaluations were suggestive of primary hypogonadism. Low testosterone, AMH (anti mullerian hormone) and Inhibin B values along with absence of visualized testicular tissue and Mullerian structures by imaging studies, indicated a defect in early embryogenesis. Interestingly, the level of plasma free retinol was low, consistent with severe vitamin A deficiency, supporting the hypothesis that a defect in vitamin A metabolism may have an etiological role in this syndrome with multiple congenital anomalies.

P01.343

Perrault Syndrome: Report of Four New Cases, Review and Exclusion of Candidate Genes

S. Marlin^{1,2}, **D. Lacombe**³, **L. Jonard**⁴, **N. Leboulanger**⁴, **D. Bonneau**⁵, **C. Goiset**⁶, **T. Billette de Villemeur**⁷, **S. Cabrol**⁸, **M. Houang**⁴, **D. Feldmann**⁴, **F. Denoyelle**⁴;

¹Hôpital Armand Trousseau, Paris, France, ²INSERM U587, Centre de référence des surdités génétiques, Paris, France, ³Hôpital Pellegrin, Bordeaux, France, ⁴Hôpital Armand Trousseau, Paris, France, ⁵CHU, Angers, France.

Sensorineural hearing impairment and ovarian dysgenesis are the main clinical signs of the Perrault syndrome. This syndrome was first described by Perrault et al in 1951. Since this first report, about 30 cases were described. More recently, some authors have reported neurologic abnormalities in Perrault syndrome, in particular progressive cerebellar ataxia and mental retardation. We present here on three sporadic and two familial new cases of Perrault syndrome. Only two of them present with neurological defect. We analyse the clinical features of this five patients and review the published cases in order to evaluate the frequency of the neurological defect in this syndrome. Moreover, we exclude *GBG2*, *POLG* and *FOXL2* as candidate genes in Perrault syndrome.

P01.344

Susceptibility markers for PFAPA disease

R. Gershoni-Baruch^{1,2}, **E. Dagan**^{1,3}, **K. Ihab**⁴, **A. Mori**¹, **N. Amar**¹, **R. Brik**^{4,5};

¹Rambam Health Care Campus, Institute of Human Genetics, Haifa, Israel,

²The Ruth and Bruce Rappaport Faculty of Medicine, Technion-Institute of Technology, Haifa, Israel, ³Department of Nursing, University of Haifa, Haifa, Israel, ⁴Rambam Health Care Campus, Department of Pediatrics, Haifa, Israel.

Periodic fever syndrome (PFAPA) is characterized by aphthous stomatitis, pharyngitis and cervical adenitis. The periodic fever and auto-inflammatory syndromes constitute a group of diseases characterized by repeated febrile illnesses associated with various other symptoms. Except for PFAPA, the genetic basis of each of these diseases is known. Predominant mutations in *MEFV*, *TNF1A* and *CARD15/NOD2* were analyzed in 57 children diagnosed with PFAPA.

Children with PFAPA were carefully selected based on clinical signs and symptoms. All patients were recruited at the Department of Pediatrics, Meyer Hospital of Children, Rambam-Health Care Campus during 2006-2007. Parents were invited to include their PFAPA diagnosed children in the study and to sign informed consent forms as customary. Clinical information was complemented during physicians-parents encounter and a blood sample was drawn for molecular testing. PCR and RFLPs for the predominant mutations in *MEFV*, *TNF1A* and *CARD15/NOD2* genes were performed.

The cohort consisted of 57 children with PFAPA [33 (58%) boys; 24 (42%) girls]. The mean age at diagnosis was 30.64±16.4 months, boys were diagnosed earlier than girls (26.18±13.83 and 36.41±18.32 months, respectively, p=0.05). Predominant mutations in the *MEFV* genes were found in 16 (28.1%) children, mutations in *TNF1A* were found in 3 (5.2%) children and mutations in *CARD15* also in 3 (5.2%) children. The clinical symptoms (e.g. pharyngitis, aphthous stomatitis, abdominal pain and cervical adenitis) were equally manifested between carriers and non-carriers.

In Israeli children diagnosed with PFAPA a higher frequency of mutations in *MEFV* gene were found compared to that observed in the general population.

²National Institute for Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran, ³National Institute for Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran, ⁴Shahed university, Tehran, Islamic Republic of Iran, ⁵Science and Research Islamic Azad University, Tehran, Islamic Republic of Iran, ⁶Special Medical center, Tehran, Islamic Republic of Iran.

Multiple sclerosis (MS) is an autoimmune multifactorial disease that usually develops in susceptible young adults. A possible involvement of mitochondria in MS has been postulated because of a higher rate transmission of the disease from mother to child than from father to child. Also association between Leber's Hereditary Optic Neuropathy a mitochondrial disease and MS is another evidence. Fatigue is a common problem of the MS patients which is related to the energy production difficulty by the mitochondria. To investigate further the relationship between MS and mitochondria we analysed the gene encoding for polymerase G (POLG). Among the nearly 50 disease mutations in the gene for the catalytic subunit of POLG, The A467T mutant enzyme possesses only 4% of wild-type DNA polymerase activity.

Polymerase gene (pol G) is a two-subunit complex consisting of a 140-kDa catalytic and a 55-kDa accessory subunit (p55the Nterminal-catalytic subunit contains a trinucleotide CAG repeat encoding a polyglutamine tract near the amino-terminus of the protein. Expansions of similar polyglutamine-encoding CAG microsatellite repeats in other genes are known to cause neurodegenerative disorders.

Total genomic DNA was extracted from 60 idiopathic Ms Patients and 40 controls. Primers were designed to amplify the 4 hot exons and CAG repeat length of the gene following by sequencing. The distribution of the POLG CAG repeat length in the control samples matched the distribution reported for control samples by others. The analysis of our sample shows no difference between the CAG repeat length distribution of control and ms disease samples analysis of exon 7, 8, 9, and 13 of POLG gene from 60 DNA samples of MS patients showed no mutation. However this does not exclude the association of the gene in MS but it needs more investigation. Also it is necessary to test the other exons of the gene.

Background: Pitt-Hopkins syndrome (PHS) is a syndromic mental retardation disorder marked by hyperventilation episodes and characteristic dysmorphism (large beaked nose, wide mouth, fleshy lips, and clubbed fingertips). PHS has been shown to be caused by de novo heterozygous mutations of the *TCF4* gene, located in 18q21. To expand the phenotypic spectrum of mutations and deletions of the *TCF4* gene, we studied 30 hitherto unexplored patients whose phenotype overlapped with PHS.

Methods: The *TCF4* gene was analysed by QMF-PCR, followed by sequencing. Large deletions were characterised by CGH array. All patients were karyotyped.

Results: In three patients, 18q21.1-q22.2 deletions were revealed by

karyotyping. QMF-PCR permitted to detect one large deletion and six small deletions generating premature stop codons.

The patients with small deletions had characteristic dysmorphic features. All patients had severe developmental delay, late (after 5 years) or absent walking, no speech, and microcephaly. We found a high incidence of myopia in all patients who had undergone eye testing. We frequently observed a happy disposition, stereotypic movements and strabismus. In contrast, hyperventilation, epilepsy, constipation were inconstant, and none of them had Hirschsprung disease or visceral malformation.

Conclusion: We report 10 novel *TCF4* deletions, in patients whose phenotype strongly overlapped with PHS. However, we observed phenotypic variations between the small deletions and the large genomic deletions, which may lay the basis for further genotype-phenotype correlations at the *TCF4* locus. Owing to the large number of deletions and microdeletions/insertions in *TCF4* we would address to start the molecular study by a QMF-PCR analysis.

Medical and auxological outcome in seventy 2-year-old singletons born after embryo biopsy applied in preimplantation genetic diagnosis or preimplantation genetic screening

S. Desmyttere¹, J. De Schepper², J. Nekkebroeck³, A. De Vos⁴, M. De Rijcke¹, C. Staessen¹, I. Liebaers¹, M. Bonduelle¹;

¹UZBrussel, Centre for Medical Genetics, Brussels, Belgium, ²UZBrussel, Department of Pediatric Endocrinology, Brussels, Belgium, ³VUB, Department of Developmental- and Lifespan Psychology, Brussels, Belgium, ⁴UZBrussel, Centre for Reproductive Medicine, Brussels, Belgium.

Introduction: Limited data are available on the growth and clinical outcome of children born after embryo biopsy. Embryo biopsy is an invasive procedure to perform preimplantation genetic diagnosis (PGD) or screening (PGS). The objective was to determine if embryo biopsy might cause prenatal and/or postnatal growth restriction and induce congenital malformations.

Materials and methods: In this study we compared growth and physical findings between seventy 2-year-old singletons born after PGD/PGS compared to intracytoplasmic sperm injection (ICSI) and spontaneous conception (SC). Children were matched for gender, maternal educational level, mother tongue and birth order.

Results: No differences were found regarding weight, height and head-circumference standard deviation scores at birth and at age two years. Body Mass Index standard deviation score in PGD/PGS children at age two years was lower compared to SC children ($p = 0.05$). PGD/PGS children were more frequently born after caesarian section but had no more congenital malformations, hospital admissions and surgical interventions. Growth parameters within the PGD/PGS group of children born after biopsy of one or two blastomeres were comparable.

Conclusions: Singleton children born after embryo biopsy applied in PGD/PGS present a similar prenatal and early postnatal linear growth compared to ICSI children and SC children. PGD/PGS singletons appear not at higher risk for congenital malformations and surgical interventions. Body Mass Index standard deviation score was slightly lower in PGD/PGS children compared to SC children. There are no observable detrimental effects of the PGD/PGS procedure on children during the first years of life.

P01.348

Primary hyperoxaluria in Italy

A. Robbiano¹, G. Mandrile¹, M. Petrarulo², D. Pirulli³, C. Zadro³, D. Giachino¹, M. Marangella², A. Amoroso⁴, M. De Marchi¹;

¹Medical Genetics, University of Torino, Torino, Italy, ²Renal Stone Centre, Maurizioano Hosp., Torino, Italy, ³University of Trieste, Trieste, Italy, ⁴Dept. of Genetics, Biology and Biochemistry, University of Torino, Torino, Italy.

Primary Hyperoxaluria (PH) is a rare autosomal recessive disease with impaired hepatic detoxification of glyoxylate, due to AGT (PHI) or GRHPR (PHII) enzyme deficiency. Oxalate overproduction in turn causes nephrolithiasis, end-stage renal failure, systemic oxalosis and multi-tissue damage. In responsive subjects an early biochemical and genetic diagnosis can address to treatment with vitamin B6 (the AGT cofactor). In many cases liver or combined liver/kidney transplant is necessary to correct the metabolic defect.

In a cohort of 47 PHI and 2 PHII Italian patients we identified the pathogenic mutation of 90/94 PHI and 4/4 PHII alleles (96% mutation detec-

tion) using DHPLC and DNA sequencing.

Age at presentation varied from 1 month to 49 years (median 6 y). AGT residual activity in liver biopsies is available for 34 subjects. In 33 it was possible to define B6 responsiveness by comparing plasma oxalate before and after oral supplementation.

23 different mutations were found (6 unpublished); missense mutations affect evolutionary conserved residues and are absent in 160 chromosomes of healthy ethnically matched controls.

Genotype-phenotype correlations show an important role of non-genetic factors as diet or delayed diagnosis, and confirm in our population that the most frequent mutation G170R, causing mitochondrial mistargeting, is associated with a mild phenotype (residual enzymatic activity, late onset and responsiveness to B6). For missense (G116R) and *insdel inframe* (c.283dupGAG) mutations we presume an *antimorphic* effect as they were found only in patients with a severe phenotype despite the presence of a mild mutation on the other allele.

Wiedemann-Rautenstrauch syndrome: case report

A. Laku (Babameto)¹, V. Mokin¹, L. Grimci²;

¹University Hospital Center "Mother Theresa", Service of Medical Genetics, Tirana, Albania, ²University Hospital Center "Mother Theresa", Service of Pediatric Endocrinology, Tirana, Albania.

Wiedemann-Rautenstrauch syndrome or neonatal progeroid syndrome is a rare autosomal recessive disorder, with few published case reports. WRS is characterized by progeroid appearance at birth, lipoatrophy, slow growth.

We report a 8 months old female, the fourth child of a healthy nonconsanguineous couple. The pregnancy was unremarkable. The birth was at term with prenatal hypoplasia and aged signs present at birth. (BW 2500 g, BL 47 cm). At age of 8 months old progeroid appearance became more pronounced. The patient showed growth delay ($W=3,9\text{kg}$; $L=60\text{cm}$), muscle hypotrophy, psychomotor retardation and typical progeroid features; senile-appearing triangular face, beak-shaped nose, microstomia, micrognathia, congenital incisors, hydrocephaloid cranium, widened fontanelles and sutures, prominent veins on scalp, hypotrichosis, relatively large fingers and toes, wrinkled skin, lipoatrophy with scleroderma-like changes of skin on the buttocks. She had feeding problems.

Congenital cataract and glaucoma were revealed. Ultrasound examination of brain, heart and abdomen did not reveal any abnormalities. Chromosomal and biochemical analyses were normal. Clinical features of our patient were compared with published data of WR syndrome, other premature aging syndromes, nonclassified progeroid conditions. We have established "neonatal progeroid Wiedemann-Rautenstrauch syndrome" based on association of characteristic aging appearance present at birth, failure to thrive, deficient growth and development, hypotrichosis, signs of generalized lipoatrophy, scleroderma-like changes of skin on the buttocks and congenital incisors. The parents were informed about the genetic risk of recurrence.

P01.350

A case report of proteus syndrome

I. Chelly, F. Maazoul, L. Kraoua, I. Ouertani, M. Chaabouni, L. Ben Jemaa, R. Mrad, H. Chaabouni;

department of hereditary and congenital disorders, Tunis, Tunisia.

Proteus Syndrome (PS) was initially described in 1979 by Cohen and Hayden and assigned its name several years later in 1983 by Wiedemann. This is a relatively recently delineated syndrome, probably because it is so rare and because it overlaps with a number of other asymmetric overgrowth syndromes.

The disorder primarily manifests as postnatal overgrowth, with irregular, distorting and progressive overgrowth that can include many tissues essentially connective tissue, bone, skin, central nervous system, and the eye.

The overgrowth of PS is progressive and can be difficult to manage. It can cause severe orthopaedic complications.

One of the most common complications in patients with PS is deep venous thrombosis and pulmonary embolism, which can cause premature death.

The management of this syndrome requires knowledge of the wide array of manifestations and complications and a multidisciplinary approach. Patients with PS have an increased risk of developing tumours.

The cause of this disorder is unknown. All cases have been sporadic events in the otherwise normal families. It is most likely caused by a somatic mutation of a gene that is lethal when occurring in the non-mosaic state.

We report on a sporadic case of two years old boy in which Proteus Syndrome is diagnosis because of a large haemangioma in the right hemi chest and the upper limb. He has also a macrodactyly of the left thumb, hemihypertrophie. He has also a multiple soft subcutaneous swellings over the chest and the abdomen.

Identification of *PSEN1Δ9* mutation in mexican families with spastic paraparesis and presenil dementia

G. Castañeda-Cisneros^{1,2}, **D. García-Cruz**³, **C. Moran-Moguel**¹, **S. Gutiérrez-Rubio**¹, **M. López-Cardona**³, **I. Dávalos-Rodríguez**⁴, **R. Rosales-Gómez**¹, **F. Jiménez-GiF**, **P. Nava-Rodríguez**⁴, **M. Macías**⁵, **J. Sánchez-Corona**¹;

¹División de Medicina Molecular, Centro de Investigación Biomédica de Occidente, Instituto Mexicano del Seguro Social, Guadalajara, Mexico, ²Departamento de Neurocirugía, Hospital de Especialidades, Instituto Mexicano del Seguro Social, Guadalajara, Mexico, ³Instituto de Genética Humana, Universidad de Guadalajara, Guadalajara, Mexico, ⁴División de Genética, Centro de Investigación Biomédica de Occidente, Instituto Mexicano del Seguro Social, Guadalajara, Mexico, ⁵Departamento de Neurología, Hospital de Especialidades, Instituto Mexicano del Seguro Social, Guadalajara, Mexico.

Spastic paraparesis and early-onset dementia (also known as early-onset familial Alzheimer disease-3) is rare, and 26 families have been worldwide described; in most of them several mutations in *PSEN1* included point mutations (exons 3, 4, 7, 8 y 12), insertions (exon 3) and deletions (exons 4, 9, 12) that have been identified. Our aim is to detect the *PSEN1Δ9* mutation related with high frequency and severity. In Mexico there are not familial reports with this disease, therefore it is unknown if previously described mutations are present in these families.

In this study we described eight families with clinical signs that correlated with spastic paraparesis and early-onset dementia. They showed an autosomal dominant inheritance with variable expressivity. Affected subjects per family are 2 to 6 with mean onset age of 45.1 years and sex ratio of 1/0.76.

Molecular analysis demonstrated a *PSEN1Δ9* mutation in eight affected subjects and in two non-affected (33 and 36 years old), 34.78% and 6.06% of total amount respectively. At least it was identified in one affected subject out of six studied families. It was not possible to conclude that *PSEN1Δ9* mutation itself explains the presence of this phenotype in Mexican families.

P01.352

Primary pulmonary vein stenosis and lymphatic anomalies: a new syndrome?

I. van de Laar, **I. Frohn-Mulder**, **M. Dalinghaus**, **R. de Krijger**, **M. Husen-Ebbinge**, **A. M. Bertoli-Avella**, **M. Wessels**;

Erasmus Medical Center, Rotterdam, The Netherlands.

Primary pulmonary vein stenosis is a rare congenital vascular malformation with a high mortality rate. It is characterized by obstruction of one or multiple pulmonary veins. Most patients present in the first year(s) of life with failure to thrive, dyspnoea, and recurrent pneumonias. Later pulmonary hypertension, pulmonary oedema and haemoptysis develop. Most patients die during infancy since there are no adequate therapeutic options. So far only sporadic cases have been described. The aetiology of the disease is unknown and many possible underlying pathologic mechanisms have been described.

We present a consanguineous Turkish family with four affected siblings (three males and one female) of healthy parents. The first child died at 16 months due to progressive pulmonary vein stenosis. The following two sibs presented prenatally with cystic hygroma and mild skin oedema. Chromosome analysis was normal. At birth cardiac evaluation was normal but both developed severe and progressive stenosis of the pulmonary veins in the following months of life. Both died before the age of 8 months due to restenosis of the pulmonary veins after surgical intervention. The fourth pregnancy was terminated due to cystic hygroma and severe hydrops.

These data provide evidence for an autosomal recessive form of primary pulmonary vein stenosis associated with lymphatic anomalies and hydrops. We are performing genome wide linkage studies in this

family to locate the gene for primary pulmonary vein stenosis. This syndrome might be underdiagnosed due to post- and prenatal lethality.

P01.353

Quadrupedal Locomotion and Cerebellar Hypoplasia Caused by Mutations in the Very Low Density Lipoprotein Receptor (VLDLR) Gene

S. Türkmen¹, **K. Hofmann**¹, **D. Aruoba**², **N. Humphrey**³, **S. Mundlos**^{1,4};

¹Charité Virchow-Klinikum, Berlin, Germany, ²Valikonogi Nisantasi, Istanbul, Turkey, ³Centre for Philosophy of Natural and Social Science, London School of Economics, London, United Kingdom, ⁴Max Planck Institut für Molekulare Genetik, Berlin, Germany.

The cerebellum is the primary motor coordination centre of the central nervous system. Lesions or congenital defects of the cerebellum cause incoordination of the muscles resulting in irregular gait and falling. Recently, we reported a large family with cerebellum hypoplasia and quadrupedal locomotion as a recessive trait, which we mapped to chromosome 17p13.

We identified one additional family with the same condition and mapped the underlying gene to a 14-centimorgan interval on chromosome 9p11 using a genome wide linkage approach. Sequencing of candidate genes identified a homozygous frameshift mutation in the Very Low Density Lipoprotein Receptor (VLDLR) gene in all affected individuals. The association of cerebellar hypoplasia with mutations in VLDLR has been reported previously in the Hutterite population and in a family from Iran. However, quadrupedal locomotion was never observed indicating that environmental factors play a major role in the pathogenesis of this form of locomotion.

P01.354

Old Iranian Scientists conception about reproduction and Genetics were almost similar to Modern Facts

M. H. Kariminejad;

Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Islamic Republic of Iran.

The oldest scientific hypothesis in this regards is attributed to Hippocrates, which denotes, that "man's water (semen) is an extract from the whole body and contains all the characteristics of the man".

Aristotle believed that the semen originated from blood and gave life to the clotted menstrual blood. In general, the scientists believed that all characteristics were inherited only from the father. This belief persisted for about 2000 years, until William Harvey, showed that there were no traces of blood clots in the uterus of the pregnant hunted gazelles.

C.E. Wolf in the late 17th century showed that the embryo is a product of the fertilization of ovum by spermatozoid. It is surprising that based on the Zoroastrian law the right of women and men were equal in all respects.

The Zoroastrian priests, would pass, this important position to their offspring regardless of the sex. Eight hundred years before Wolfs' discovery the sage Ferdowsi describes the royal characteristic of Kaykhosrow, the grand son of the kings Kaykavos and Afrasyab: "He, the pure bred, has inherited from two races".

More interesting, in the book written in the first half of the thirteenth century, characteristics of the spermatozoid have been described in an appealing way almost same as what we know today. Despite this brilliant history, there was a big gap in this field between our country and the developed world.

In spite of a long standstill, recently, we have moved to the front line with our outstanding advancements in diagnosis, prevention and treatment of hereditary diseases, particularly application of embryonic cells in production and restoration of body organs and cloning of "Royana", which with all rewarding advancements, have placed our country among pioneers and leaders of this caravan.

Mitochondriopathy presenting with immune disorder

I. Karačić¹, **A. Gagro**², **R. Horvath**³, **M. Čuk**¹, **V. Sarnavka**⁴, **G. Tešović**⁵, **H.**

Lochmuller⁶, **N. Barišić**^{1,4}, **M. Novak**⁴, **S. Galić**⁴, **M. Cvitković**⁴, **M. Jelušić**^{1,4}, **M.**

Vidović⁴, **D. Begović**^{1,4}, **L. Tambić-Bukovac**⁴, **I. Barić**^{1,4};

¹Zagreb University School of Medicine, Zagreb, Croatia, ²Institute of Immunology, Zagreb, Croatia, ³Mitochondrial Research Group, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom, ⁴Department of Pediatrics,

University Hospital Center Zagreb, Zagreb, Croatia, ⁵University Hospital for Infectious Diseases Dr. Fran Mihaljević, Zagreb, Croatia, ⁶Institute of Human Genetics, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom.

Due to ubiquitous nature of oxidative phosphorylation and dual genetic origin of respiratory chain enzymes (nuclear and mitochondrial DNA) their deficiencies can produce any symptom in any organ. However, the involvement of the immune system in mitochondriopathies is rare. We report a girl aged 20 months with combined respiratory chain defect and immunologic impairment that includes T-cell immunodeficiency and autoimmune reactions. Main clinical findings were generalized hypotonia, rotatory nystagmus, failure to thrive and respiratory deficiency due to persistent lung infections. In trachea a large spectrum of bacteria and fungi (mostly *Aspergillus fumigatus*) has been detected. Cytomegalovirus infection was permanent with up to 240,000 copies of CMV DNA/ml of blood despite one year ganciclovir treatment. She had crises with fever, tachycardia and facial blushing. Laboratory findings pointed to autoimmune processes (positive anticardiolipin antibodies, positive direct and indirect Coombs test and positive antiplatelet antibodies, hypergammaglobulinemia) and immunodeficiency. The clinical impression of an immunodeficiency was supported by repeatedly increased CD4/CD8 ratio (6.3; normal 0.97-2.3) with significant decrease of CD8 T cells (9%). Flow cytometric analysis of intracellular staining of IFN-gamma and IL-4 in CD4 and CD8 T cells showed three times very low IFN-gamma in CD8 T cells (0.5-1%; reference range 2-7%).

The severely reduced activity of respiratory chain complexes I (3.0 U/gNCP; normal 15.8-42.8) and IV (53.6 U/gNCP; normal 112-351) in skeletal muscle suggested mitochondrial etiology. Sequencing of the mtDNA tRNA genes did not reveal pathogenic mutations and mtDNA depletion was excluded by real-time PCR suggesting a mitochondrial translation defect.

P01.356

Horizontal gaze palsy with progressive scoliosis can result from new missens mutation in *ROBO3* gene in Russian family

V. A. Galkina, A. Kalygina, O. A. Schagina, A. V. Polyakov;
Research Centre for Medical Genetics, Moscow, Russian Federation.

Horizontal gaze palsy with progressive scoliosis (HGPPS) is an autosomal recessive disorder characterized by congenital absence of horizontal gaze, progressive scoliosis, and failure of the corticospinal and somatosensory axon tracts to decussate in the medulla. The reasons of disease are various homozygous or compound heterozygous mutations in the axon guidance molecule *ROBO3*.

Two sisters seven and ten years old from Armenian family with short stature non-proportional because of spine deformity were examined by us. Both of them has progressive scoliosis (the oldest sister has right-sided scoliosis and younger has left-sided one). Now both girls have severe thorakolumbar scoliosis. Two girls have congenital external ophthalmoplegia, horizontal gaze palsy, which at birth onset.

DNA was extracted from a blood sample from each participant using a standard protocol, and the coding exons of *ROBO3* were amplified and sequenced.

Two sibs with horizontal progressive external ophthalmoplegia unique and scoliosis have c.290G>C (Trp97Ser) mutation in homozygous state in *ROBO3* gene. Each of their parents was the heterozygotic carrier of this mutation. This mutation was not previously described.

P01.357

An unusual case of sirenómelia and a review of the casuistic of the Perinatal Genetic Program, UNICAMP, Brazil

D. P. Cavalcanti¹, P. L. P. Rojas^{1,2};

¹UNICAMP, Campinas, Brazil, ²Universidade Javeriana, Bogotá, Colombia.

Sirenómelia sequence is a rare and etiologically unknown anomaly, which is considered as a primary defect of the blastogenesis. The purposes of this presentation is, first, reporting a case of sirenómelia associated with a unique constellation of malformations, and, second, exploring the casuistic of this anomaly in the Perinatal Genetic Program during a twenty years period. The case reported is the product of the first gestation of young and non consanguineous parents. Family history was unremarkable. Gestational period was also uneventful, except for prenatal ultrasonographic evaluation that revealed bilateral renal agenesis, absence of the left lower limb and the right fibula, and

vertebra malformations. At birth, besides the findings of sirenómelia sequence with footless, the fetus also presented bilateral anotia, an unusual cleft palate, and also an unusual phallic structure on the genital region. The review of 7 cases occurring at the same hospital showed a high prevalence (1.2 cases per 10,000 births) of sirenómelia, probably, due to the prenatal diagnosis. All are single cases. The maternal diseases referred by these respective mothers were hypotiroidism, depression and arterial hypertension. The main medicines used by them were l-thyroxine, fluoxetine, captopril, and amphetamines. Although the sonographic evaluation performed at the first trimester has been made in two cases, sirenómelia was never referred at prenatal time. In conclusion, besides the case with a rare pattern of sirenómelia associated with other no related defects, the review of seven new cases shows the inability of sonographers to make diagnosis of sirenómelia.

P01.358

Sirenómelia sequence: clinical, radiological and postmortem findings

S. Balci¹, G. Altinok²;

¹Hacettepe University, Department of Pediatrics, Clinical Genetics (Emeritus Member), Ankara, Turkey, ²Hacettepe University, Department of Pathology, Ankara, Turkey.

Sirenómelia is a Greco-Roman mythical creature with the tail of a fish and a human upper body. Similarly, Sirenómelia Sequence is characterised by fusion and reduction of lower extremities; renal and sacral agenesis; imperforate anus; absence of rectum and bladder. It is indeed an "orphan" malformation since it is not even recognised as a separate entity in the OMIM catalogue. Here, we report a total of five cases, including a pair of twin sibs, who were classified according to Stocker classification as type I, VI and VII (N=1 each) and type II (N=2). All patients had a single umbilical artery; imperforate anus, oligo hydramnion; Potter facies; congenital heart diseases; gastrointestinal and genitourinary abnormalities. One of the twins had full blown expression of Sirenómelia, whereas the other had imperforate anus only (Clinical Dysmorphology 2000; 9:227). Maternal diabetes was associated with Sirenómelia in one patient (Turkish Journal of Pediatrics 1996; 38: 393). The earliest age of prenatal diagnosis was fourteen weeks based on the observation of severe oligohydramnion and a single lower extremity at ultrasonography. Postmortem findings of this case revealed a blind end of the abdominal aorta, a single femur and hypoplastic fused tibiae, renal agenesis, a dysplastic kidney, a hypoplastic bladder, genital organ agenesis, colon abnormalities, hypoplasia of the cerebellum and the posterior fossa. Severe maternal B12 and Folic Acid deficiency were present in this case. These etiological factors have not been reported previously although various teratogenic events have frequently been associated with Sirenómelia.

P01.359

Sirenómelia with a *de novo* balanced translocation 46,XX,t(X;16)(p11.3;p12.3)

K. Kurosawa, M. Takei, N. Furuya, H. Yoshihashi, M. Yamanaoka;
Kanagawa Children's Medical Center, Yokohama, Japan.

Sirenómelia is a rare developmental abnormality, characterized by the fused lower limbs, and abnormalities in the caudal abdomen and pelvis. Most cases are sporadic and specific causes and early pathogenic events leading to sirenómelia are unknown. We report a singleton female fetus with sirenómelia with 46,XX t(X;16)(p11.3;p12.3)dn. The pregnancy was electively terminated at 21 weeks gestation after prenatal ultrasound examination. The birth weight was 294g, and length 25.5cm. The external genitalia was ambiguous and anal atresia was noted. At autopsy, anatomical findings included absence of bilateral kidney and bladder, hypoplastic or absence of renal artery and inferior mesenteric artery. Unfortunately the results of karyotype were revealed after autopsy. The cytogenetic analysis of breakpoints was so limited. FISH experiments with BACs were employed for narrowing of the breakpoint regions. On chromosome 16, the breakpoint was mapped between RP11-347K10 (16p12.3, 17.55Mb from pter) and RP11-167K14 (16p12.2, 20.87Mb from pter). On chromosome X, the breakpoint was mapped between RP11-245M24 (Xp11.3, 45.36Mb from pter) and RP11-416B14 (Xp11.23, 48.46 Mb from pter). Abnormal phenotype, present in balanced translocation, was caused by deletion or breakage of dosage-sensitive genes of breakpoint, or disruption of an imprinted gene. In addition, cases with balanced translocations

were assumed to be at risk for UPD. To date, only one case with abnormal karyotype involving maternal UPD16 was reported as body stalk anomaly [Chan et al., 2000]. Although the parental origin of normal 16 and der(16) remained to be determined, this case will provide insight into consideration of pathogenetic mechanism of sirenomelia.

P01.360

Hereditary spastic paraplegia, type 4, in Russian families

G. E. Rudenskaya, I. S. Sermyagina, A. Kalygina, S. Kazakova, A. V. Polyakov;

Research Centre for Medical Genetics, Moscow, Russian Federation.

Hereditary spastic paraplegia (HSP), type 4, or SPG4, caused by various mutations in spastin gene (*SPAST*) is the most common disorder in a heterogeneous group of autosomal dominant HSP's. We performed a search of *SPAST* mutations by routine methods (SSCP and subsequent direct sequencing of fragments with modified electrophoretic mobility) in a sample of 26 families with autosomal dominant HSP from different Russian regions. In six families, five of Russian and one of Tatar ethnicity, different *SPAST* mutations were detected. Three of them, Arg431Stop, 839-840 delAG, and Asn386Ser, were already reported; the remaining three, Asp555Tyr, 1107A>G, and Asn184Thr, were novel. One more large family showed a linkage to SPG4 locus (lod score 1.51) but mutation was not found. This may be due to atypical *SPAST* mutations (partial deletions etc) undetectable by routine methods of DNA analysis. Including this family, the proportion of SPG4 in the sample is 27%, which is less than average world data (40-50%). Most of our patients presented relatively late-onset "uncomplicated" HSP, which is typical for SPG4. Though, in some families additional features were reported, epilepsy among them. One of our patients had very early-onset HSP and concomitant epilepsy while his mother had typical SPG4 presentation. All pedigrees showed complete penetrance though some patients, women particularly, had mild signs of the disease, even late in life. Another relatively frequent autosomal dominant HSP is SPG3 caused by mutations of atlastin gene (6-10%). We plan to perform a search of atlastin mutation in families without *SPAST* mutations.

P01.361

Glaucoma, short stature, mental retardation and ischemic stroke: A new autosomal-recessive syndrome mapping to Chromosome 20q11-12

F. Rutsch¹, C. George¹, M. Frosch¹, C. Becker², G. Nürnberg², P. Nürnberg²;

¹University Children's Hospital, Muenster, Germany, ²Cologne Center for Genomics, Cologne, Germany.

We report on a family with multiple affected siblings of both sexes presenting with a novel combination of anomalies including cerebrovascular insults. The four affected probands were born to consanguineous Turkish parents, there are six non-affected siblings. All four probands have a short stature. The eldest male had congenital left sided glaucoma, presented with a stroke at the age of 6 months and showed a severe developmental delay. He died at 40 years of age. The second proband suffered from right-sided congenital glaucoma and recurrent strokes starting at the age of one year. He was wheel-chair dependent and developed multiple joint contractions. He died of an intracranial hemorrhage at the age of 28 years. The third proband had bilateral congenital glaucoma. She is only mildly developmentally retarded, but also developed multiple joint contractions. The youngest proband also suffers from congenital left sided glaucoma and severe developmental delay. She was never able to walk and showed precocious puberty. At the age of 14 years, she had an ischemic stroke of the left arteria cerebri media. MRI angiography showed total occlusion of the internal carotid arteries bilaterally and of the left arteria cerebri media. Homozygosity mapping in this family, using a high density SNP array, identified a candidate locus of 7.3cM on chromosome 20q11-12. The familial association of congenital glaucoma, mental retardation, short stature and ischemic stroke is a hitherto unreported entity. This autosomal-recessive syndrome is mapping to chromosome 20q11-12.

P01.362

Screening of telomeric regions by MLPA in more than 470 patients with mental retardation and fetuses with malformations

R. L. Touraine¹, A. Combes¹, M. Gilet¹, M. Tiff¹, D. Sanlaville², P. Eder², P. Jouk³, V. Herbepin-Granados¹, F. Prieur¹;

¹CHU de Saint Etienne, Saint etienne, France, ²CHU de Lyon, Lyon, France,

³CHU de Grenoble, Grenoble, France.

Cryptic telomeric rearrangements are frequent causes of mental retardation and/or malformation syndromes. We used for more than 2 years, a systematic screening of all subtelomeric regions using MLPA with two commercial kits from MRC Holland.

We studied more than 470 patients, including 44 fetuses with malformations. Except for these fetuses, all the patients had mental retardation, associated for most of them with some malformation or dysmorphic features. In every cases, but four, standard karyotype analysis was normal.

Only one fetus (2,5 %) is probably positive. This case is likely a 15q deletion, but FISH analysis was not possible to confirm it.

Among our postnatal cases, 15 anomalies, not suspected on karyotype analysis were confirmed (3,5%) and 4 suspected anomalies were further analyzed.

In addition some anomalies with only one MLPA kit were identified in an unaffected parent and therefore considered as polymorphism. On the opposite, true anomalies were sometimes detected with only one MLPA kit.

Unexpectedly, 5 anomalies implied M9p, including 3 «pure» subtelomeric monosomies. One case was familial, inherited from the mother (with border-line mental retardation).

In conclusion, MLPA technique for telomeric screening is interesting and not very expensive. Furthermore, some of the anomalies we detected here, were almost «non-syndromic», favoring a non-specific all-telomeres screening approach in mental retardation.

At last, further molecular analysis, including CGH-array, of our M9pter cases is in progress to refine phenotype/genotype correlations.

P01.363

Testicular dysgenesis syndrome: more common after assisted reproduction?

S. Funke, E. Flach, Z. Mánfai, T. Ertl;

University of Pécs, Pécs, Hungary.

Recent reports have demonstrated a decline in human male reproduction health: increasing prevalence of cryptorchidism, hypospadias, poor semen quality, rising incidence of testis cancer and growing demand for assisted reproduction. It is supposed that these are symptoms of one underlying entity, the testicular dysgenesis syndrome (TDS). The rapid rise in the prevalence of TDS may be linked to endocrine disruptors affecting genetically susceptible individuals. Genetic aberrations or polymorphisms may predispose to augmented effects by environmental factors. Meta-analysis of in vitro fertilization (IVF) studies revealed that hypospadias is more common after assisted reproduction (AR). In Hungary about 2000 infants are born following IVF yearly. In our study we investigated the incidence of congenital abnormalities after AR. At the Department of Obstetric and Gynaecology, Medical School, University of Pécs 712 newborn infants were born after IVF between January 1st, 1999 and December 31th, 2006, 319 singletons and 178 sets of twins. The mean gestational age was 35.6±2.1 weeks, the mean birthweight 2520±630 grams. The incidence of congenital abnormalities in infants born after conventional IVF was compared to newborns born after intracytoplasmic sperm injection (ICSI). In regard to major congenital abnormalities we did not find any significant differences between the two groups (5.8% vs 3.2%, p=0.056). Infants born after ICSI significantly more often suffered from minor anomalies [p=0.004, OR:1.9478 (95%CI:1.1916-3.1841)], especially from genital abnormalities, hypospadias, cryptorchidism, hydrocele testis [p=0.031, OR:2.48 (95% CI:0.9949-6.1594)]. Further investigations will be needed to confirm the supposition that children born after IVF/ICSI are at higher risk to develop TDS.

P01.364

Familial hypodontia associated with taurodontism

E. Severin, C. Albu, D. Stanciu, D. F. Albu;

"Carol Davila" Univ Med Pharm, Bucharest, Romania.

Tooth agenesis and taurodontism are developmental dental anomalies. Some studies support the hypothesis that isolated taurodontism is associated with tooth agenesis, as it shows a higher prevalence in families with missing teeth than in general population, and, therefore, may share a common genetic cause. We report a case of a mother and her two daughters affected of tooth agenesis. Mother and daughters exhibited different clinical manifestation of missing teeth. Simultaneous occurrence of taurodontism and tooth agenesis was detected only in mother. Evaluation included clinical, radiographic and genetic examinations. The affected members of the family did not show features of syndrome tooth agenesis. No specific correlation between missing teeth and taurodontism was noted.

P01.365

A de novo microdeletion of 774 kb including the entire TP53 gene - Li-Fraumeni-plus as a contiguous gene syndrome?T. Schwarzbraun¹, A. C. Obenaus¹, A. Langmann², U. Gruber-Sedlmayr³, K. Wagner¹, M. R. Speicher¹, P. M. Kroisel¹;*¹Institute of Human Genetics/Medical University of Graz, Graz, Austria, ²Department of Ophthalmology/Medical University of Graz, Graz, Austria, ³Department of Pediatrics/Medical University of Graz, Graz, Austria.*

Li-Fraumeni syndrome (LFS) is a rare genetic disorder usually characterized by familial occurrence of various malignancies with early onset. LFS is clinically and genetically heterogeneous. The inheritance of LFS follows an autosomal dominant mode with high penetrance and mutation rate in germ cells is very low. In most cases LFS is due to a constitutional mutation of one copy of the *TP53* tumor suppressor gene in affected family members and somatic mutations in the second copy of that gene in the process of malignant transformation. The *TP53* gene at chromosome 17p13.1 is the most frequent target for genetic alterations in human cancer.

Here we describe the first case of a de novo constitutional chromosomal microdeletion including the entire *TP53* gene as well as several closely linked genes. The phenotype of the patient is striking and includes severe psychomotor retardation, a Dandy-Walker anomaly, Leber congenital amaurosis (LCA), seizures and dysmorphic features. Chromosomal breakpoints (BP) were mapped by high resolution array comparative genome hybridization (aCGH) followed by quantitative real time PCR analysis down to base pair level. The distal BP disrupts the *ACADVL* gene and the proximal BP is located about 6.5 kb upstream of the *GUCY2D* gene disrupting its upstream regulatory sequences. SNP analysis revealed monoallelic expression of *GUCY2D* which would explain the LCA of the patient. More than 40 genes have been mapped to the 774 kb deletion interval including the *FXR2* gene which is an autosomal homolog of the *FMR1* gene.

P01.366

Hypogonadism and Novel Craniofacial Findings in a Case of Treacher-Collins Syndrome with a Pathogenic Mutation and a Missense Variant in the TCOF1 Gene

C. Li;

McMaster University Medical Centre, Hamilton, ON, Canada.

A severe case of Treacher-Collins syndrome with novel findings in a newborn boy is presented here. Craniofacial features include bilateral atretic internal auditory canals, macrocephaly with remnant lobules of the external ears, absence of external auditory canals, missing ossicles with hypoplastic middle ear cavities. The nasal cavities were filled with a soft tissue mass that may represent an encephalocele. The eye cavities were extremely underdeveloped. The inferior wall was absent, the zygomatic arches were absent. There was severe micrognathia and concurrent narrowing of the pharyngeal space, resulting in markedly narrowed upper airway. Moreover, the baby was found to have widely spaced nipples, hypoplastic scrotum, bilateral cryptorchidism and micropenis. Molecular testing revealed a pathogenic mutation and a novel missense change. The mother carries the same missense change and is clinically and radiographically normal. The potential significance of these findings is discussed.

P01.367

Coexistence of Unverricht-Lundborg disease and congenital deafness in one Serbian familyM. M. Kecmanovic¹, A. Ristic², D. Sokic², M. Keckarevic-Markovic¹, D. Keckarevic¹, S. Romac¹;*¹Faculty of Biology, Belgrade, Serbia, ²Institute of Neurology, Belgrade, Serbia.*

Unverricht-Lundborg disease (ULD) is an autosomal recessive disorder caused by mutations in cysteine B (*CSTB*) gene located on chromosome 21q22.3. Majority of the ULD chromosomes carry expansion of dodecamer repeats in promoter region of the *CSTB* gene. The location of *TMPRSS3* gene, in which mutations cause nonsyndromic recessive deafness, is in proximity of *CSTB* gene, on chromosome 21q22.3.

Here we present a complex syndrome in one Serbian family in which three out of four siblings of healthy parents have inborn deafness. Action and stimulus sensitive myoclonus appeared in two individuals (II-1 and II-3) in 12-13 year of life (individual II-1 was not available for this analysis). Except congenital deafness, individual II-2 is otherwise healthy, while the individual II-4 has none of two mentioned disorders. Molecular diagnostics confirmed suspected ULD in sibling with progressive myoclonic epilepsy and innate deafness, while the sibling with isolated inborn deafness was heterozygote for expansion in the *CSTB*. One could exclude coexistence of *CSTB* and *TMPRSS3* mutations in this pedigree due to assumed joint transmission. For that reason we performed haplotype analysis, genotyping seven microsatellites flanking *TMPRSS3* and *CSTB*. Haplotype analysis showed that absence of homozygous expansion in the individual II-2 is due to a recombination event that occurred ahead of *CSTB*, what was the strong indication that homozygous mutation in the *TMPRSS3* is responsible for deafness. Following sequencing of the *TMPRSS3* revealed 207delC mutation in fourth exon.

To our best knowledge this is the first genetically confirmed case of coexistence of mentioned two mutations.

P01.368

Central Nervous System involvement in patients with vascular cutaneous anomalies

C. Mellado, M. Sahin;

Neurology Department, Children's Hospital Boston, Harvard Medical School, Boston, MA, United States.

Vascular cutaneous anomalies could be related to an underlying systemic disease and/or involve other systems. One of these could be the Central Nervous System, leading to a various neurological complications. The purpose of this study is to describe brain anomalies among individuals affected with some of these syndromes, including PHACE, Macrocephaly and Cutis Marmorata Telangiectasia Congenita (M-CMTC), Sturge Weber (SW) and Klippel Trenaunay (KT).

We reviewed 216 clinical records of patients seen at Children's Hospital Boston, between 2000 and 2007, with the diagnoses mentioned above. Brain imaging information was obtained. In 11/11 PHACE syndrome cases, beside vascular anomalies, neuroimaging showed hypoplastic corpus callosum (2), cerebellar involvement (3), asymmetric ventricles (1), retro cerebellar cyst (1), moyamoya phenomenon (1). 8/10 M-CMTC cases have images, showing hemimegalencephaly (4), Chiari I malformation (4), asymmetric/large ventricles (4), white matter changes (3), cortical dysplasia (2), periventricular heterotopias (1), brain atrophy (1), periventricular leukomalacia (1). 36/55 SW cases have images, that showed leptomeningeal enhancement in almost all cases, normal brain structures (5), cerebral atrophy (18), prominent choroid plexus (17), calcifications (5), venous anomalies (5), white matter anomaly (5), Chiari I malformation (1), asymmetric ventricles (1), mega cisterna magna (1). 20/140 KT cases have images that showed normal brain images (9), white matter changes (5), Chiari I malformation (3), calcifications (2), venous anomalies (2), asymmetric brain hemispheres (1), cerebral atrophy (1), thick corpus callosum (1).

Brain imaging is important in these syndromes to define the pathologic entity, help in the diagnosis, management and prognosis in children at risk.

P01.369

Three novel mutations in FRMD7 in X-linked congenital motor nystagmus in Russian families

S. Gudzenko¹, V. Fedotov², R. Zinchenko¹, A. Polyakov¹;¹Research Centre for Medical Genetics, Moscow, Russian Federation, ²Regional Clinical Diagnostic Centre, Voronezh, Russian Federation.

X-linked congenital motor nystagmus is a common inherited oculomotor disorder characterized by repetitive uncontrollable ocular oscillations, unassociated with a number of ocular or neurological diseases with onset typically at birth. The loci for X-linked CMN have been mapped to Xp11.3-p11.4 and Xq26-q27 (NYS1). Three more loci have been described for autosomal-recessive and autosomal-dominant form of CMN without any gene identification. The molecular characterization of NYS1 has been solved by Tarpey et al., who identified mutations in *FRMD7*, a gene with unknown function.

The aim of our research was searching for *FRMD7* mutations in three Russian families with X-linked CMN, who had already shown the linkage with Xq26-q27 locus. Sequencing analysis of all exons and intron-exon junctions of *FRMD7* was performed in affected males from these families. We identified three novel, previously unreported mutations in *FRMD7*: missense mutation c. 47T>C (Phe16Ser), nonsense mutation c. 1524G>A (Trp508Stop) and small deletion c. 1492delT. Thus the results of our study confirm the role of *FRMD7* in the pathogenesis of X-linked CMN.

P01.370

Diagnostic and prognostic implications of nuclear and mitochondrial mutations in couples opting for ART

R. Dada, R. Kumar, M. B. Shamsi, S. Venkatesh;

Laboratory for Molecular Reproduction and Genetics, Dept. of Anatomy, All India Institute of Medical Sciences, New Delhi, India.

Microdeletion on the long arm of the Y chromosome and mutations in mitochondrial genes regulating oxidative phosphorylation may severely impair spermatogenesis. Thus it was planned to analyze cases (n = 580) with idiopathic male infertility opted for ART by cytogenetic, Yq microdeletion and mitochondrial mutation analysis.

In cytogenetically normal cases microdeletion analysis was done using EAA guidelines. Mitochondrial genome was amplified and sequenced using a set of 24 primers in 33 OAT cases. The mutations were compared in blood and sperm DNA. 8.2% and 10.1% cases harboured Yq microdeletion in blood and semen respectively. Results of mitochondrial mutation analysis showed G to A transition in ND4 gene at nucleotide position 11719 in sperm DNA of 19 cases and only in 14 cases from blood DNA. Though this is a non-synonymous change, the amino acid remains the same. The polymorphism A750G, A4769G and A8860G was found in all the semen as well blood DNA of the cases but only in 12 controls. A750G, A4769G are non-synonymous changes but A8860G polymorphism in ATPase 6 gene changes amino acid threonine to alanine.

As majority of these infertile couples opt for ART/ICSI, it is very important to distinguish cases with Yq microdeletions and mitochondrial mutations as former are iatrogenically transmitted to the offspring through these techniques. Thus a thorough genetic analysis is a must in all infertile couples to provide comprehensive counseling and most adapted therapeutics.

Screening for subtelomeric aberrations using multiplex ligation dependent probe amplification (MLPA)

D. Gomez, M. Fernandez, L. Aparicio, F. Cuevillas, H. Vidiella, E. Cusó, J. V. Martinez, C. Mordillo;

Balagué Center S.A., Hospitalet de Llobregat, Spain.

Subtelomeric rearrangements are believed to be a common cause of mental retardation. New molecular techniques allow their identification, their frequency and significance are still unknown.

METHODS: We screened 30 patients with idiopathic mental retardation and/or phenotypic malformations making use of the multiplex ligation-dependent probe amplification (MLPA, SALSA kits P036D and P070). The parents of those patients with subtelomeric aberrations were also tested for the origin (see table 1). All rearrangements were confirmed by FISH or by the SALSA MLPA KIT P096-MR2.

RESULTS: We identified a total of 7 subtelomeric aberrations (23,3%). Four were deletions, two were duplications and one case showed one deletion and one duplication (See table 1).

Table 1.

Case	MLPA aberration	Confirmation	Origin
1	del 4p	+ Wolf-Hirschhorn with P096 KIT - FISH with WHSC1 probe	de novo
2	del 20p	FISH in process	unknown
3	del 4p	+ Wolf-Hirschhorn with P096 KIT + FISH with WHSC1 probe	de novo
4	del 1p	+ FISH 1p36	de novo
5	dup Xq/Yq	FISH in process	unknown
6	del Xq/Yq, dup Xp/Yp	46,X, der(Y)	de novo
7	dup Xp/Yp	FISH in process MLPA positive in mother and brother	maternal

CONCLUSIONS: The high frequency of subtelomeric aberrations detected confirmed the important role played by these rearrangements in the aetiology of Mental retardation. *De novo* aberrations are likely related to the clinical presentation of the patient while inherited aberrations probably are not the cause of the patient phenotype. MLPA has demonstrated to be a very useful method that can be offered to all mentally retarded patients in order to approach to genetic diagnosis.

P02.002

Unusual 17p subtelomeric micro-duplication

S. Garcia-Minaur¹, C. Serra^{1,2}, I. Cusco², A. Plaja¹, L. Pérez Jurado^{1,2};¹Programa de Medicina Molecular y Genética, Hospital Vall d'Hebron, Barcelona, Spain, ²Unidad de Genética, Universidad Pompeu Fabra, U-735 CIBERER, Barcelona, Spain.

We report a 5 ½ year-old girl with developmental delay, microcephaly, cardiomyopathy and distinctive facial features. Additional brain MRI findings include a hypoplastic corpus callosum and enlarged cisterna magna. Standard karyotype was normal. MLPA assay with commercial probe kits to detect subtelomeric rearrangements identified a *de novo* 17p micro-duplication. Microarray analysis with a custom made chip, which contains 1905 BAC clones covering subtelomeric and pericentromeric regions of each chromosome and regions related to known syndromes, confirmed the presence of a duplication of > 6.2 Mb confined to 17p13. Interestingly, the duplicated fragment is not continuous but interrupted by a 0.45-1.1 Mb segment that is not duplicated, suggesting a more complex rearrangement, possibly mediated by a balanced rearrangement in one of the parents. Although partial 17p trisomy has been found in association with other rearrangements, to our knowledge only one other case has been reported with a 17p13 duplication exclusively and clinical features overlapping those of our patient. Further studies on this child and her parents are currently under way and the results will be presented.

P02.003

Subtelomeric study of 109 patients with developmental delay, dysmorphism and/or congenital anomalies of unexplained etiology - case presentations

M. Krajewska-Walasek, A. Gutkowska, A. Marczak, M. Gajdulewicz, K. Spodar, A. Jezela-Stanek, M. Kugaudo, M. Bialecka, K. Chrzanowska, E. Popowska;

The Children's Memorial Health Institute, Warsaw, Poland.

Background: Subtelomeric chromosome aberrations are acknowledged as one of the significant causes of mental retardation (MR). Their prevalence is about 5.2%, ranging from 0 to 16% (depending on the preselection criteria and the expertise of the examining clinician). Because of either their small size and/or similarity of involved segments, these aberrations are undetectable by conventional binding techniques. Hence, they can be screened for by other methods, most frequently by FISH with a complete set of subtelomeric probes or by multiplex ligation-dependent probe amplification (MLPA). We report the diagnostic yield in a series of 109 patients with an unexplained combination of mental retardation with dysmorphism and/or congenital anomalies.

Methods: Patients were evaluated for subtelomeric rearrangements using commercially available total subtelomeric FISH (TS). All had normal results of GTG-banded chromosomes at the 550-band level and were referred for TS based on clinical indications suggestive for

chromosomal aberration. In some cases, for identification or confirmation of detected abnormalities, specific microdeletion and telomeric probes were used.

Results: Twelve subtelomeric chromosomal aberrations were recognized, which corresponds to a diagnostic yield of about 10%. Identified rearrangements were: del(1p36); der(1)t(1;3)(q44;p25)pat; der(1)t(1;22)(p36.1;q11.23)mat; del(2q37) in two cases; del(4p); der(6)t(6;7)(q27;q36)mat and der(7)t(6;7)(q27;q36)mat; der(9)t(9;20)(pter-;pter+)pat; del(9qter); del(12pter); del(22q13).

Conclusions: Since there is still limited knowledge of the phenotype of many subtelomeric aberrations, we believe that our study gives insight into the etiology of mental retardation by clinical delineation of subtelomeric aberrations.

The work was supported in part by grant KBN 2P05A 161 28

P02.004

Telomeric Submicroscopic Deletion of Chromosome 1

E. Gean¹, V. Catala², I. Plensa³, C. Garrido², A. Garcia-Cazorla¹, Y. Jordan¹, D. Velasco¹, P. Poo¹;

¹Hospital sant Joan de Deu, Esplugues. Barcelona, Spain, ²Prenatal Genetics, Barcelona, Spain, ³Hospital Sant Joan de Deu, Esplugues. Barcelona, Spain.

Submicroscopic deletion 1ptel the most common telomeric deletion with an incidence of 1:5000 live births. Patients carrying this deletion tend to have similar phenotypes. We describe 3 patients with 1ptel deletion.

Case 1: Female, 3 years old, is an only child born to healthy unrelated parents. Pregnancy was normal. Clinical examination: dystrophic appearance. Microcephaly. Synophrys and dull face. General hirsutism and severe developmental delay.

Case 2: Female, 13 year old, first child of healthy and non consanguineous parents.

Growth retardation and early puberty, pulmonary stenosis, sensorineural hearing loss and moderate mental retardation. Facies was characteristic of 1ptel deletion.

Case 3: Male, 2 month old, with congenital cardiac anomaly and facial dysmorphic features: facial hirsutism, short palpebral fissures and developmental delay.

In all the patients FISH analysis showed deletion 1p36.3

The 1qter microdeletion is often reported in the literature as a part of complex chromosome rearrangement. No particular feature is specifically unique. Next, we describe 2 patients with isolated 1qter deletion

Case 1: Female, 5 years old, is an only child born to healthy unrelated parents.

Proportioned growth retardation, congenital cardiac anomaly, pelvic horseshoe kidney, and duodenal diaphragm. Seizures. Severe developmental delay with facial dysmorphic features.

Case 2: Male, 8 year old, is an only child born to healthy unrelated parents.

Clinical features: Low birth weight. New born with hypotonia and microcephaly. Cerebellar vermis hypoplasia. Right kidney agenesis. Peripheral pulmonary stenosis. Cryptorchid testes. Seizures and severe mental retardation. Stereotopy. Dysmorphic features.

In both cases FISH studies showed deletion 1qter.

P02.005

Presentation of four new cases with chromosome 2q terminal deletion

M. Elena^{1,2}, M. Palomares^{1,2}, P. Lapunzina^{1,2}, B. Fernández¹, I. Martínez¹, P. Lago¹, J. Arcos³, A. Delicado^{1,2};

¹Servicio de Genética.Hospital Universitario la Paz, Madrid, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Madrid, Spain, ³Servicio de Neurología Infantil.Hospital Universitario la Paz, Madrid, Spain.

Terminal deletions of chromosome 2 may be found commonly among patients, with idiopathic mental retardation, referred for subtelomeric screening. Chromosome 2q terminal deletion (2q37) is characterized by mild to moderate mental retardation, behaviour manifestations on autism spectrum, facial dimorphism (prominent forehead, thin, highly arched eyebrows, depressed nasal bridge, and hypoplasia nasal alae, prominent columella and thin upper lip) and other major congenital malformations. Patients with most distal deletion present phenotypic features which mimic Albright hereditary osteodystrophy (AHO), including brachymetaphalangia in nearly half of all patients.

We report four patients including for subtelomeric screening. In all the patients a high resolution G-band Karyotype and subtelomeric screening using MLPA were performed. Result were confirmed by fluorescence in situ hybridization (FISH). The four cases presented a "de novo" terminal deletion at or within band 2q37, ranging from cytogenetically visible abnormalities (patient 1 and 2) to cryptic subtelomeric deletions (patient 3 and 4). Molecular characterization of the breakpoints were performed by STRs. The size of the deleted segments ranged from 2 Mb to 7 Mb.

The patient 4 showed of approximately 2Mb terminal deletion. He has limbs abnormalities with short fourth and fifth metacarpals on the left hand and short first, third and fourth metacarpals on the right hand. These findings are consistent with previous observations to narrow the brachydactyly critical region as the terminal 3 Mb region.

We observed no clear relationship between clinical features and the size of the monosomic region; this represents a significant difficulty in predicting phenotype for this deletion.

P02.006

High resolution SNP-array and MLPA analyses of patients with atypical 9q34 subtelomeric deletions

E. Van Binsbergen¹, T. Kleefstra², N. Verbeek¹, M. Poot¹, W. Nillesen², J. C. Giltay¹, M. Nelen¹;

¹University Medical Hospital, Utrecht, The Netherlands, ²Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Recently patients with deletions of the 9q34 region were proposed to have a recognizable syndrome with a combination of mental retardation, recognizable facial phenotype, hypotonia, brachy(micro)cephaly and other congenital anomalies, mostly heart defects in up to 50% of the cases. The *EHMT1* gene has been proposed as the prime candidate gene to be responsible for these features. In a diagnostic survey of patients with mental retardation/multiple congenital abnormalities, HumanHap300 illumina SNP arrays and Multiplex Ligation-mediated Probe Amplification revealed two patients with *de novo* deletions in the 9q34 region which did not include the *EHMT1* gene. A patient with moderate mental retardation and facial dysmorphologies that are also seen in the "9q34 subtelomeric deletion syndrome" showed hemizygosity for *PNPLA7*, *MRPL41*, *WDR85*, *ZMYND19*, *ARRDC4*. A second patient with mild hydrocephalus, a heart defect (VSD) and hypospadias but without mental retardation at the age of 5 years showed an interstitial deletion with a maximal size of exon 3 up to 14 of the *CACNA1B* gene (i.e. exon 1, 2 and 15 until 25 were not affected). Our data (1) emphasize the need for high resolution molecular cytogenetic analysis to elucidate the underlying genome rearrangements in patients with mental retardation or multiple congenital abnormalities (2) show that *EHMT1* is not the major candidate gene in all patients with a deletion in the 9q34 subtelomeric region (3) allow further analysis of genotype vs phenotype in larger 9q34 deletions.

P02.007

Subtelomeric deletion of 1p36 detected by HR-CGH could not be confirmed by FISH

A. Escalona¹, M. Santos¹, A. González-Meneses², C. Fuster¹;

¹Universitat Autònoma de Barcelona, Bellaterra, Spain, ²Hospital Virgen del Rocío, Sevilla, Spain.

Background Molecular High Resolution Comparative Genome Hybridization (HR-CGH) is applied to detect an imbalance in whole genome. This technique is especially successful in detecting small genomic abnormalities in patients with unexplained mental retardation and/or congenital malformations.

Objective To detect and identify the existence of any chromosome alteration in two unrelated girls with mental retardation and multiple congenital clinical features.

Methodology G-banding, HR-CGH and FISH.

Results Conventional GTG-banded chromosome analyses revealed a normal karyotype in both cases. Analysis by HR-CGH demonstrated a loss in 1p36 in two patients. However, FISH with a specific subtelomeric 1p probe detected 1pter deletion in only one patient.

Conclusion Our results showed that a combination of both CGH and FISH should always be used in the identification of 1p36 microdeletion, which is difficult or impossible by banding techniques alone

ACKNOWLEDGMENTS: This work was supported by MCYT (SAF 2003-03894) and CIRIT (2005, SGR-00495).

P02.008**Reconfirmation of terminal deletions and derivative chromosomes by MLPA subtelomeric screening**

K. Wakui^{1,2}, Y. Furuji³, K. Shinogi³, T. Fukui³, R. Kawamura¹, Y. Kinoshita¹, T. Koshio^{1,2}, T. Wada^{1,2}, H. Ohashi⁴, N. Gondo³, S. Yokoyama³, H. Higashi⁴, Y. Fukushima^{1,2};

¹Dept Med Genet, Shinshu Univ Sch Med, Matsumoto, Japan, ²Div Clinical and Mol Genet, Shinshu Univ Hosp, Matsumoto, Japan, ³Biomedical Business Div. FALCO biosystems Ltd, Kyoto, Japan, ⁴Div Clinical Genet, Saitama Children's Hospital, Saitama, Japan.

Multiplex Ligation-dependent Probe Amplification (MLPA) has come into wide use for subtelomeric screening as a new molecular cytogenetic technique. We used 2 kinds of MLPA® Kits (SALSA MLPA KIT HUMAN TELOMER, P036B and P070, MRC-Holland) for analyzing 21 subjects of known subtelomeric imbalances which have been already detected by G-banding. Of the 12 cases detected as additional materials of unknown origin at one of the chromosomal end by G-banding, 9 had loss of the subtelomere of the derivative chromosome and gain of the subtelomere of the other chromosome by MLPA, as we suspected. But, in the rest of 3 cases, MLPA showed only gain of the subtelomere of the other chromosomal end, but no loss of the subtelomere of the derivative chromosome. Of the 9 cases detected as terminal deletion by G-banding, 6 cases had only loss of the targeted subtelomere, as we suspected. But the other 3 cases had been detected not only loss of the targeted chromosomal end, but also gain of the other subtelomere by MLPA. We performed the metaphase FISH analysis to confirm the results of MLPA for the cases having discrepancies of the results between G-banding and MLPA. When a distal part of chromosomal arm looks smaller than the normal chromosome by G-banding, the abnormal chromosome is often interpreted as terminal deletion. But, it is noteworthy even shorter chromosome may be derived from familial balanced translocation. MLPA subtelomeric screening is useful for the precise diagnosis of structural chromosomal abnormality, and necessary for providing genetic counseling.

P02.009**A terminal 7,1 Mb chromosome 18p deletion flanked by a 2,3 Mb duplication in a phenotypically normal mother and her microcephalic and mentally retarded son**

K. H. Ørstavik^{1,2}, D. Miscio³, H. Lybæk⁴, E. Frengen³, G. Houge⁴;

¹Department of Medical Genetics, Rikshospitalet University Hospital, Oslo, Norway, ²Faculty Division Rikshospitalet, University of Oslo, Oslo, Norway, ³Institute of Medical Genetics, University of Oslo, Oslo, Norway, ⁴Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway.

Deletions of chromosome 18p are frequent and associated with broad phenotypic variability. We report an identical and cytogenetically visible terminal deletion in a mentally retarded microcephalic boy and his normocephalic cognitively normal mother.

The patient was a 13 year old boy with head circumference 1.5 cm below the 2.5th centile. Height was at the 10th centile and weight between the 25th and 50th centile. Early motor milestones were unremarkable. However, he has needed extra help at school because of problems with concentration, behaviour, and activities requiring fine motor skills. On examination, he had a single right palmar crease. He was microcephalic but not otherwise dysmorphic. His mother was of normal intelligence. She was 172 cm tall with a normal head circumference and no dysmorphic features.

G-banded chromosome analysis revealed a terminal 18p deletion, removing band 18p11.3. Array CGH analysis on Agilent 44K arrays indicated a 7,1 Mb terminal deletion flanked by a 2,3 Mb duplication; arr cgh 18p11.32p11.23(RP11-76H24->RP11-42J5)x1,18p11.23p11.22(RP11-207E16->RP11-784M9)x3. Work is under way to determine if the duplication is inverted. Inversion would lead to generation of a new 18p terminus. The mother's karyotype was identical. The maternal grandmother had normal chromosomes. The maternal grandfather was deceased.

Inheritance of an 18p deletion has been reported previously in seven families. In all cases the deletion was inherited from the mother, possibly indicating that males with 18p deletions are more likely to express adverse phenotypic effects of this genomic imbalance. This is the first reported family in which the mother had a normal phenotype.

P02.010**FISH analysis of replication timing of human subtelomeric regions**

I. Petković;

University Children's Hospital Zagreb, Zagreb, Croatia.

Recent studies have shown that DNA replication timing is correlated with transcriptional activity of genes. Synchronous replication of alleles was demonstrated for genes with a biallelic and asynchronous replication for those with a monoallelic mode of expression. Alteration of replication order has been associated with aneuploidy and genetic instability, while asynchronous replication with the formation of a deletion. No data on replication timing of subtelomeric regions (SR) are available so far. SRs are highly unstable and rearrangements have been reported in ~7% of patients with mental retardation.

The objective of this study was to determine the replication timing of human SR. The replication pattern of SR of chromosomes 5, 7, 8 and 20 was investigated using FISH method in lymphocytes of 4 healthy donors. At least 200 cells per probe per person were studied. The replication status of a locus was classified as unreplicated ("s"-single signal) and replicated ("d"-doubled signal).

The results showed that each SR had a characteristic timing of replication, and that 20q (ss: 47.8±3.1%; dd: 18±1.8%) was the first of examined SRs to replicate, whereas 5q (ss: 75.9±1.8%; dd: 4.3±0.5%) was the last (p<0.001). The analysis revealed variable level of replication synchrony of homologous SR. The frequency of sd cells hybridized with the probes for the 5p, 7p, 8q, 20q (30.1±2.6%) was significantly higher (p<0.02) compared to 5q, 7q, 8p, 20p (20.6±2.0%).

These results suggest that replication pattern might contribute to the non-random involvement of specific SR in the aetiology of mental retardation.

P02.011**Human herpesvirus 6 always integrates at the telomere region**

A. Virgili¹, D. Brazma¹, K. N. Ward¹, P. Hubacek², D. A. Clark², M. J. Dyer¹, E. P. Nacheva¹;

¹Academic Haematology, Royal Free & UCL Medical School, London, United Kingdom, ²Centre for Virology, Department of Infection, Royal Free & UCL Medical School, London, United Kingdom, ³Department of Paediatric Haematology and Oncology, Motol University Hospital, Prague, Czech Republic, ⁴MRC Toxicology Unit, University of Leicester, Leicester, United Kingdom.

Human Herpesvirus 6 (HHV-6) has the unique ability amongst the human herpesviruses of integrating its genome in a persistent latent state into a chromosome of the individual infected. We used fluorescent in situ hybridization (FISH) to investigate the HHV-6 chromosomal integration sites in 7 unrelated individuals with high levels of HHV-6 viral load, which is indicative of HHV-6 chromosomal integration. A cocktail of 8 non-overlapping plasmids containing between 9Kb-16Kb inserts of the HHV-6 genome was used as a HHV-6 specific probe (Clark DA et al., 2006). FISH proved HHV-6 chromosomal integration in all 7 individuals, either in phytohemagglutinin-stimulated peripheral blood (PB) leukocytes or in Epstein-Barr virus-transformed lymphoblastoid cell lines derived from PB lymphocytes. HHV-6 was found in all 50 cells analyzed and 6 different chromosomal integration sites were identified. Two of the sites had already been reported: 17p13.3 and 22q13; while the remaining four, 9q34.3, 18p11.3, 18q23 and 19q13, had not been previously described. HHV-6 was found at one genome location per individual and always affecting only one chromosome homologue. The HHV-6 signals were always found in the vicinity of the telomeric region. For 9q34.3, the site of integration was further mapped using the BAC clone RP11-424E7, which locates at the end of 9q34.3 (genome address: 140,005,384-140,207,236). Both RP11-424E7 and HHV-6 signals co-localised in metaphase and interphase cells. HHV-6 also co-localised with a pan-telomeric probe. In summary, our study identifies four novel chromosomal integration sites and most importantly localises preferential site of HHV-6 integration at the chromosome telomere region.

P02.012**High resolution oligonucleotide aCGH in a Jacobsen syndrome patient with an atypically small 6.5 Mb terminal 11q deletion supports FLI1 as an important mediator of thrombocytopenia**D. H. Tegyay^{1,2}, H. V. Toriello³, G. Parsons³, E. Hatchwell³:¹New York College of Osteopathic Medicine, Old Westbury, NY, United States,²Stony Brook University Medical Center, Stony Brook, NY, United States,³Spectrum Health, Grand Rapids, MI, United States.

Jacobsen syndrome (JBS; OMIM#147791) is a MCA/MR syndrome clinically characterized by growth and mental retardation, thrombocytopenia, congenital heart defects, trigonencephaly and dysmorphic facial features including telecanthus, downslanting palpebral fissures, a broad nasal bridge and a “carp” shaped mouth. The vast majority of reported cases are due to ~7-15 Mb de novo terminal 11q deletions typically extending from chromosome band 11q23 to 11qter. With the advent of high-resolution molecular karyotyping by microarray comparative genomic hybridization (aCGH) smaller deletions are now frequently uncovered allowing further refinement of genotype-phenotype correlations. Here we report the case of a 5-year-old girl with clinical features of Jacobsen syndrome including growth and mental retardation, thrombocytopenia, and classical facial dysmorphism as well as unilateral optic nerve hypoplasia, multicystic kidneys, aortic valve regurgitation and a tethered spinal cord. This patient was found by high-density whole-genome oligonucleotide aCGH to have a small ~6.5 Mb chromosome 11q24.3-qter deletion. This deletion starts just proximal to FLI1 (friend leukemia virus integration 1) and provides additional evidence supporting FLI1 as the important mediator of thrombocytopenia in JBS.

P02.013**19ptel (p13.3) duplication**C. Garrido¹, E. Gear², V. Català¹, L. Vila¹, P. Poo², C. Fons², E. Cuatrecasas¹, M. Pérez², A. Serés¹;¹Prenatal Genetics, Barcelona, Spain, ²Hospital Sant Joan de Déu, Barcelona, Spain.

Submicroscopic rearrangements involving chromosome 19 are very uncommon, there are very few reports in the literature of patients with partial trisomy of distal 19p. We describe two cases with 19p duplication.

Karyotype were normal in both patients but the availability of subtelomere specific FISH probes has made identification of cryptic subtelomeric rearrangements possible.

Case 1: Male, second child born to healthy unrelated parents, intrauterine grow retardation (IUGR) detected in third trimester and low weight at birth. Severe developmental delay and seizures, normal hands and feet, and very dysmorphic face.

Duplication of 19ptel using Totelvysion panel (Vysis) was observed. The extra 19ptel signal was detected at p arm of an acrocentric chromosome of group G.

Parents were studied and showed normal hybridization results. Duplication of 19ptel was “de novo” in the proband.

Case 2: Male, first child from non consanguineous parents, IUGR detected in the third trimester and low birth weight. Severe developmental delay, epilepsy and gastroesophageal reflux.

FISH studies showed a duplication of 19ptel and a deletion of 17qtel. The extra signal 19ptel is contained within the terminal long arm of the deleted chromosome 17q.

Parents' studies have to be done.

P02.014**Screening for subtelomeric rearrangements in mental retardation. Description of two new cases: dup16qter and del19qter**N. Baena¹, L. Comadran¹, I. Crespo¹, E. Gabau¹, M. Roselló², M. Guitart¹;¹Corporacio Sanitaria Parc Tauli, Sabadell, Spain, ²Hospital Universitario La Fe, Valencia, Spain.

Copy number changes of subtelomeric chromosomal regions are responsible for 5-10% of all mentally retarded (MR) patients. Multiplex-Ligation Probe Amplification (MLPA) is a technology used to detect microdeletion and microduplication syndromes.

In the current study we determined the frequency of subtelomeric changes in a series of 108 patients showing MR and dysmorphic features in which G banded karyotype at a 600- band level were normal.

Subtelomeric assay using MLPA with SALSA P036B/C and P070 kits, and FISH in some cases were performed.

MLPA revealed subtelomeric changes in 9 out of 108 MR patients (8.3%), 7 deletions: 1p, 1q(2), 18p, 19q, 22q(2), one duplication 16q, all of them *de novo* abnormalities, and one case with a concurrent duplication and deletion 6q/3p inherited from a parental translocation. Among these imbalances we report two rare cases. 1.-Duplication of chromosome 16q in a 2 -year-old girl with a psychomotor delay, who showed intrauterine growth retardation and ventriculomegaly in prenatal examination; plagiocephaly, delayed clousure fontanel, hypertelorism, epicanthus, small nose and mouth, tapering fingers and hypotonia. 2.-Deletion of chromosome 19q in a 5-year-old boy with speech impairment and behaviour disorder, high palate and narrow palpebral fissures.

Comparing clinical features, only one case of dup(16)(qter) (Ahn, 2007), and one case with del(19)(qter) (EUCARUCA database) reported, both phenotypes are different from described in our patients. These two new cases could contribute to a better clinical characterization of these subtelomeric imbalances but more cases are necessary. Supported by the grant from Fundació Parc Tauli of Sabadell.

P02.015**MLPA as screening method for the detection of cryptic subtelomeric rearrangements in patients with idiopathic mental retardation**L. Morozin Pohovski¹, I. Sansović¹, I. Barišić¹;

Children's University Hospital Zagreb, Zagreb, Croatia.

Background: Submicroscopic chromosomal rearrangements involving the subtelomere regions are considered to be a significant cause of idiopathic mental retardation (MR). The Multiplex Ligation dependent Probe Amplification (MLPA) analysis has increasingly been used as an adjunct to routine cytogenetic testing and a relatively low cost and high throughput screening for the detection of small rearrangements. Objective: To screen for submicroscopic subtelomeric aberrations by MLPA method. Results: We have studied a series of 50 unselected patients with mental retardation and negative chromosomal analysis. The MLPA with SALSA P036C and SALSA P070 probe mixes was performed for subtelomere screening. Unbalanced chromosomal rearrangements detected by MLPA were confirmed by quantitative fluorescent-PCR (QF-PCR). The MLPA screening revealed chromosome aberrations in two (4%) cases: one patient with terminal deletion in the long arm of chromosome 22 and one case with double subtelomeric aberration consisting of a 12p deletion associated with 22q duplication. Conclusion: MLPA screening is a fast, sensitive and cost-effective technique for screening idiopathic mentally retarded patients with normal karyotype. Validation by another cytogenetic or molecular method is still needed for use in routine diagnostics.

P02.016**Array-CGH analysis in 48 patients with complex syndromic phenotypes**E. F. Belligni¹, J. Messa², A. Vetro², C. Migliaccio¹, N. Chiesa¹, C. Molinatto¹, G. A. Delmonaco¹, G. B. Ferrero¹, O. Zuffard², M. Cirillo Silengo¹;¹Department of Paediatrics, Torino, Italy, ²Department of Genetics - University of Pavia, Pavia, Italy.

Array comparative genomic hybridization (array-CGH) detects DNA copy number variations, allowing to identify genetic imbalances in human genetic disorders. We present the results of array-CGH analysis in 48 children affected by mental retardation, congenital malformations, and dysmorphic features. Standard karyotype was normal in all cases but 3, array-CGH analysis detected a chromosomal imbalance in 19 patients: 7 deletions, 3 duplication, 1 tetrasomy, 2 double deletion, 1 double duplication and 5 more complex chromosomal rearrangements. In a patient affected by a complex PEHO-like syndrome, characterized by severe developmental delay, severe seizures, hyporegenerative anemia, hypoalbuminemia and specific facial dysmorphisms, a de novo duplication of 22q11.23 has been identified, allowing to define a putative critical region for this complex developmental disorder. The analysis confirmed the clinical diagnosis of five genomic syndromes (Smith-Magenis, del1p36.33, del9q34.3, X-linked ichthyosis, Pallister-Killian), and in 3 patients it identified a complex chromosomal rearrangement previously described as a simple chromosomal anomaly by standard karyotype. Rouling out the four cases in which the chro-

mosomal rearrangement could theoretically be performed by region specific FISH, array-CGH detected 15 rearrangements in 44 patients, with a high detection rate (34,09%), allowing to propose a new critical region for a complex syndromic PEHO-like phenotype.

P02.017

Defining a new checklist of sensitive clinical signs in mental retardation, useful to select patients for array-CGH and to validate array-CGH results

M. Zollino¹, G. Marangi¹, D. Orteschi¹, R. Lecce¹, M. Murdolo¹, M. E. Grimaldi¹, A. Orrico², O. Zuffardi³, G. Neri¹;

¹Institute of Medical Genetics, Università Cattolica del Sacro Cuore, Roma, Italy, ²Clinical Genetics, UOC Molecular Medicine, Azienda Ospedaliera Universitaria Senese, Siena, Italy, ³Biologia Generale e Genetica Medica, University of Pavia, Pavia, Italy.

Cryptic chromosomal rearrangements are responsible of about 1-25% of cases of idiopathic mental retardation.

We studied 325 subjects with mental retardation/developmental delay by the means of subtelomeric FISH (300 patients) and array-CGH analysis (70 patients) using BAC-array with an average resolution of 1 Mb.

Cryptic chromosomal rearrangements were detected in 29 cases (10%) by subtelomeric FISH. A total of 70 patients with normal telomeres underwent array-CGH, that disclosed an interstitial cryptic abnormality in 17 (24%). Adapting this percentage to all cases with normal telomeres, detection rate for cryptic chromosome abnormality was 30% in the present cohort of patients. It represents the highest detection rate of cryptic chromosome abnormalities in idiopathic mental retardation reported so far by molecular karyotyping.

Detailed clinical analysis of all positive cases and of 50 negative patients allowed us to develop a new checklist of the clinical signs sensitive for chromosomal abnormalities. It includes 5 categories: 1) postnatal growth abnormalities, 2) disproportion between growth parameters, 3) minor facial anomalies, 4) hands and feet abnormalities and 5) major malformations. A 0-2 score was assigned to each category, with a maximum of 10. Cut-off value resulted to be 4 in our series. Interestingly, familial MR and IUGR were not sensitive signs. Genotype-phenotype correlations represent a great problem during array-CGH analysis.

We propose this checklist as a useful tool for clinical validation of the chromosomal unbalances detected by array-CGH.

P02.018

Identification of cryptic chromosomal rearrangements in patients with multiple anomaly syndromes and mental retardation using oligo-based array-CGH

V. Vranova^{1,2}, P. Kuglik^{1,2}, I. Slamova², E. Zrnova¹, A. Oltova², R. Gaillyova²;

¹Masaryk University, Institute of Experimental Biology, Department of Genetics and Molecular Biology, Brno, Czech Republic, ²University Hospital Brno, Department of Medical Genetics, Brno, Czech Republic.

Chromosomal abnormalities are the major cause of mental retardation (MR), growth and developmental delay and dysmorphic features. Many of these imbalances are caused by submicroscopic deletions or duplications not detected by conventional cytogenetic methods. Array-CGH is an innovative high-resolution technology that detects and maps submicroscopic DNA copy number alterations, improving the diagnostic detection rate of subtle copy number changes.

From 67 patients with mental disability, congenital anomalies, dysmorphic features and unknown underlying cause investigated by G-banding, FISH, SKY and high-resolution CGH (HR-CGH) were chosen 4 that were also screened using 60-mer oligonucleotide-based array-CGH (Agilent). Two interstitial and two terminal imbalances were identified. In patient 1 and 2, both with normal karyotype, *de novo* interstitial deletion was found at 6q15 and 11q13, respectively. Both abnormalities arose *de novo* and were previously detected using HR-CGH. Array-CGH studies not only confirmed these aberrations but specified their position and size. In patient 3 with no cytogenetic finding, array-CGH revealed deletion of terminal part of 1p include 1p36. The deletion was *de novo* and was confirmed by FISH and MLPA methods. The last patient had karyotype 46,XY,der(4p), but no evident cytogenetic imbalance. Using array-CGH, not only deletion of telomeric region of 4p, but additional duplication of terminal part of 8p was revealed. Both imbalances were also detected by MLPA, but duplication at 8p was

negative by FISH.

We conclude that oligonucleotide based array-CGH can be used as excellent diagnostic tool for genome-wide screening and identification of cryptic chromosomal imbalances not evident by routine cytogenetic analysis.

P02.019

High resolution Agilent 244K oligoarray CGH analysis for screening of patients with congenital eye malformations

I. Balikova, T. de Ravel, K. Devriendt, J. Fryns, J. R. Vermeesch;
Center for Human Genetics, Leuven, Belgium.

Hereditary diseases of the eyes are a frequent cause for blindness in early childhood with complex etiology. The exact frequency of chromosomal deletions and duplications causing congenital eye abnormalities is unknown. Summarising results from conventional karyotyping showed that around 1/8 segmental chromosomal duplications and 1/6 deletions are associated with eye malformations. Considering the high frequency of microscopically visible imbalances associated with eye disorders we hypothesize that patients with idiopathic eye anomalies may carry submicroscopic imbalances.

Compared with conventional cytogenetics methods - karyotyping and fluorescent *in situ* hybridization [FISH], array Comparative Genomic Hybridization [array CGH] provides the advantage of full genome scan with significantly higher resolution to detect deletions or duplications. Agilent 244K oligoarrays allow to perform a genomic screen with a theoretical resolution higher than 50kb.

We screened patients with congenital eye malformations and associated abnormalities and their both parents on 244K array. The project aims to identify novel genes involved in the development of the eye and to improve the diagnosis in these patients. We will present results from the analyses.

P02.020

Inherited not polymorphic CNV in mental retardation patients: implications in clinical practice

E. Katzaki, M. A. Mencarelli, F. T. Papa, R. Caselli, V. Uliana, M. Pollazzon, K. Sampieri, I. Longo, F. Ariani, I. Meloni, F. Mari, A. Renieri;
Medical Genetics, Siena, Italy.

Mental retardation is a common disorder, affecting 1-3% of the population. In spite of all diagnostic tools available, the etiology can still not be established in half of the cases. The introduction of array-CGH analysis has improved the identification of novel genomic disorders. However, this high-resolution new technique open novel diagnostic challenges when inherited private CNVs of unclear clinical significance are found. The analysis of 84 patients with mild to severe mental retardation associated to facial dysmorphism and/or congenital anomalies revealed 10 private CNVs inherited from a healthy parent. Three were deletions (7q31, 14q21.1, Xq25) and 7 duplications (12p11.22, 12q31.31, 13q31.1, 17q12, Xp22.31, Xq28) ranging between 0.1 and 3.8 Mb. Three small rearrangements were gene desert. The remaining 7 had a mean gene content of 5 (ranging from 1 to 18). None of the rearranged genes is known to be imprinted. Three disease-genes were found in three different cases: *KAL1* in dupXp22.31, *STS* gene in another dupXp22.31 and *TCF2* gene in dup17q12. The patient carrying the last duplication presents, among others, sex reversal, Peters' anomaly and renal cysts and the duplication is located 4Mb apart of the *HSD17B1* gene, coding a key enzyme of testosterone biosynthesis. We suggest that at least in this case low penetrance instead of no pathogenesis, should be taken into account. We discuss on the final interpretation that should be given in the clinical practice and the opportunity to report such rearrangements in the family reports.

P02.021

Description of two new cases of microdeletions detected by array-CGH in carriers of apparently cytogenetically balanced chromosome rearrangements associated with phenotypic abnormalities

I. Mademont-Soler¹, C. Morales², L. Armengo³, E. Margari^{2,4}, A. Soler^{2,4}, X. Estivill³, A. Sánchez^{2,4};

¹CIBERER, Barcelona, Spain, ²Servei de Bioquímica i Genètica Molecular, Hospital Clínic, Barcelona, Spain, ³CRG, Barcelona, Spain, ⁴IDIBAPS, Barce-

Iona, Spain.

Cytogenetically balanced chromosome rearrangements constitute chromosome abnormalities that may be associated with mental retardation and dysmorphic features, suggesting possible cryptic imbalances in the breakpoint. Due to the limited resolution of conventional cytogenetics, new molecular techniques are required for their detection, such as array-CGH.

We present two patients with phenotypic abnormalities and *de novo* cytogenetically balanced rearrangements. After analysing them by 1 Mb array-CGH, imbalances were observed in both cases (just one case involving the breakpoints).

In patient 1, who presented deafness, hydrocephaly and coloboma, the karyotype was 46,XX,t(6;13)(q23;q31)dn. Array-CGH detected a 13q32.2 deletion, 13q33.1 duplication, 1q44 duplication and 16q21-22 deletion. The last one is the only confirmed abnormality by FISH for the time being (BACs RP11-89O14 and RP11-468F3), but it has been described as a polymorphism.

Patient 2, with a Silver-Russell-like phenotype, showed the karyotype 46,XX,inv(7)(q21.12q34)dn. Array-CGH did not show any deletion in the breakpoints, but highlighted a *de novo* microdeletion of 5Mb at 3p12.3-3p13, confirmed by FISH (BACs RP11-781E19 and RP11-59O5).

In relation to patient 2, the only confirmed case for now, a review of similar reported cases has been performed. Although none of them has an identical microdeletion, common features have been observed, ranging from minor anomalies to growth and mental retardation, and brain, heart and lung malformations. Many genes of 3p12.3-3p13 region remain still unknown, making it difficult to establish a good genotype-phenotype correlation.

These results underline the importance of the use of molecular cytogenetics in patients with apparently cytogenetically balanced chromosome rearrangements associated with phenotypic abnormalities.

P02.022

Oligonucleotide array-CGH in postnatal cytogenetics

H. Tönnies¹, A. Caliebe¹, I. Martin-Subero¹, S. Gesk¹, N. Husemeyer¹, I. Stefanova², G. Gillissen-Kaesbach², K. Bruhn³, U. Stephani³, G. Krüger⁴, M. Kautza⁵, J. Weimer⁶, R. Siebert¹;

¹Institut für Humangenetik, Kiel, Germany, ²Institut für Humangenetik, Lübeck, Germany, ³Klinik für Neuropädiatrie, Kiel, Germany, ⁴Abteilung für Medizinische Genetik, Rostock, Germany, ⁵Praxis für Humangenetik, Kiel, Germany, ⁶Onkologisches Labor der Klinik für Gynäkologie und Geburtshilfe, Kiel, Germany.

High-resolution array-CGH (aCGH) allows the detection of small, sub-microscopic imbalances in euchromatic chromosomal segments. We have performed aCGH for the detection of constitutional imbalances in 129 patients with normal karyotype and developmental delay and/or various malformations, dysmorphisms, or complicated epilepsy of unknown etiology using 44K, 105K, and 244K oligonucleotide arrays (Agilent). In 22 of 129 patients euchromatic imbalances have been detected (~17%) by aCGH and verified by FISH analyses. In seven out of 18 cases where parental samples were available for verification analyses, it could be shown that the euchromatic imbalance (3 deletions: 0.4 Mb-1.9 Mb; 4 duplications: 1.3 Mb-5.3 Mb) has been transmitted from a phenotypically normal parent. Overall, in 14 of 129 patients (~11%) a *de novo* aberration has been detected; some of those representing well known, others recently established microdeletion and microduplication syndromes. In addition to the 129 patients, 19 patient samples were analyzed to further characterize a chromosomal aberration detected initially by conventional cytogenetics. In eleven of these cases (~58%) including complex translocations and ring chromosomes, the imbalance(s) could be characterized successfully in more detail using aCGH. Hybridization of microdissected chromosome material of a supernumerary ring chromosome 19 onto a 105 K array allowed the high resolution mapping of the nonlinear euchromatic content. However, in eight preselected cytogenetic samples no euchromatic imbalance could be detected by aCGH using whole genomic DNA. In summary, aCGH and array-hybridization of microdissected chromosomes are highly informative methods for the detection and characterization of chromosomal imbalances in postnatal cytogenetics.

P02.023

Array CGH detection of genomic imbalances in 370 patients with unresolved retardation syndrome

U. Koehler, E. Holinski-Feder, E. Holinski-Feder;
Medizinisch Genetisches Zentrum, Munich, Germany.

Genomic imbalances are a major cause of mental retardation and developmental delay in patients with congenital and developmental abnormalities. With the advent of whole genome array-CGH analysis, the number especially of interstitial genomic imbalances increased dramatically. Here we present our results of array-CGH investigations in 370 cases of patients with retardation syndromes and dysmorphic features using the Cytochip v2 BAC array (BlueGnome, Cambridge). Among these cases we found 55 genomic imbalances (15%). Seven (2,1%) of the genomic imbalances were telomeric (3 deletions, 4 duplications) and 48 interstitial (12,9%, 28 deletions, 12 duplications). Of these interstitial imbalances 28 were >1 Mb in size (average 3,5) whereas 20 were smaller or equal to 1 Mb in size. Four aberrations included terminal deletion/duplication events (three *de novo*, one inherited from a balanced father). 8 cases (2,4%) were patients with known microdeletion or microduplication syndromes (two microdeletions 22q11.2, two microdeletions 17p11.2, two microdeletions 15q11.2q13, two microduplications 17p11.2). FISH has not been performed prior to the array CGH, as no obvious indication of the referrals existed. All of the detected gains and losses have been confirmed by either FISH or MLPA. A small 0,8 Mb deletion in the long arm of chromosome 2 (2q22.3) lead to the molecular genetically confirmed diagnosis of Mowat-Wilson syndrome. To summarize, array CGH is a very powerful tool to detect genomic imbalances in at up to 15% of previously unresolved cases.

P02.024

Genome-wide analysis of DNA copy-number changes in subjects with mental retardation

R. Ciccone, A. Vetro, O. Zuffardi;
University of Pavia, Pavia, Italy.

During the last three years we analyzed more than 1000 individuals affected by mental retardation and/or congenital anomalies by oligo-based array-CGH. About 300 of these subjects had a known imbalance already defined by conventional cytogenetics and the genome-wide analysis helped us to better characterize these rearrangements. A group of 703 individuals with normal karyotype was investigated by using two different microarrays (Agilent 44K and 244K) which have an average resolution of about 100Kb and 20Kb respectively. Among those investigated by the 44K chip (557), 126 (22,6%) subjects were unbalanced and 82 (14,7%) had imbalances causative of their phenotype. 146 patients were investigated through the 244K chip; 46 (31,5%) were unbalanced and 22 (15%) such imbalances were pathogenic. We are not able to establish whether the remaining 66 imbalances were causative or not. In fact most of them were inherited from a normal parent whereas in few cases we could not investigate the parents. Interestingly, our study highlighted some peculiar rearrangements such as *de novo* triplications or two independent genomic disorders in the same patient. On the other hand, our study demonstrate that increasing the resolutions may improve the detection rate, although the percentage of potentially causative imbalances detected using these two platforms is not significantly different.

P02.025

Validation of BAC-array CGH using a different array CGH platform

U. Heinrich¹, L. Melanie¹, H. Tanja¹, S. Kai¹, A. Polten², R. Imma¹;
¹Centre for Human Genetics and Laboratory Medicine, Martinsried, Germany,
²Agilent, Waldbronn, Germany.

Array CGH utilizing spotted BAC/PAC clone microarrays has recently been introduced as a valuable diagnostic tool for the detection of chromosomal imbalances in patients with mental retardation and developmental delay. Since diagnostics generally requires a binding medical opinion, results from array CGH analyses need to be validated to avoid false positive results. The currently most widely used validation method is FISH of metaphase spreads using the same BAC/PAC clone that has been identified as conspicuous on the chip array. Whereas FISH is the method of choice for the validation of deletions, duplications are generally difficult to interpret. We therefore used a second, oligonucle-

otide-based array platform (244K chip, Agilent, Santa Clara, USA) on a series of 10 cases that had prior been analyzed on the CytoChip version 2.0 (BlueGnome, Cambridge, UK) and partially validated by FISH. Our findings indicate that cross validation using a second array CGH platform is a suitable approach for the validation of BAC/PAC array results that combines the advantages of other validation methods such as FISH, qPCR or MLPA. The cross validation approach is characterized by a robust protocol, a rapid work-up, no need for metaphase spreads and moderate costs.

P02.026

Characterization of balanced chromosome translocation breakpoints associated to phenotype by microdissection and aCGH

O. Villa¹, N. Kosyakova², I. Cuscó¹, M. Aragonés³, D. García-Cruz¹, F. Solé⁵, A. Plaja⁶, T. Lieh⁶, L. A. Pérez-Jurado^{1,6};

¹Unitat de Genètica, Universitat Pompeu Fabra, U735 CIBERER, Barcelona, Spain, ²Institut für Humangenetik und Anthropologie, Jena, Germany, ³Genes and disease program. Center for genomic regulation (CRG), Barcelona, Spain, ⁴Instituto de Genética Humana "Dr. Enrique Corona Rivera". Departamento de Biología Molecular y Genómica, CUCS, Universidad de Guadalajara, Guadalajara, Mexico, ⁵Laboratorio de Citogenética y Biología Molecular. Hospital del Mar, Barcelona, Spain, ⁶Programa de Medicina Molecular i Genètica, Hospital Vall d'Hebron, Barcelona, Spain.

The positional cloning of genes affected by cytogenetic anomalies associated with phenotype is one of the main methods for the identification of disease-related genes. However, mapping translocation breakpoints and rearranged chromosomal boundaries by molecular cytogenetics is labour intensive. The isolation of the aberrant chromosomes by either flow sorting or microdissection permits the specific analysis of their genomic content by high throughput technologies such as aCGH or sequencing. We have applied chromosome microdissection and aCGH to map three apparently translocation breakpoints associated with different phenotypes: 1) 46,XY,t(4;15)(q22;q26) in a chronic myelomonocytic leukaemia; 2) 46,XX,t(11;13)(q21;q14) in a patient with language and developmental delay; and 3) 46,XY,t(7;18)(p15.1;q21.1) in a male with hypogonadotropic hypogonadism. We first isolated one of the two derivative chromosomes (6-8 chromosomes), amplified the DNA by DOP-PCR, and performed reverse FISH in order to verify the appropriate cytogenetic location of the microdissected material. Then, we hybridized the DNA onto a BAC array and the Agilent 244K CGH oligoarray for precise mapping. All three translocation breakpoints have been narrowed down to regions of ~8-15 Kb in each chromosome with high reproducible signals. We are currently attempting to further define the exact breakpoints by either tiling array or direct PCR and sequencing. In summary, the manual microdissection of aberrant chromosomes is a cheap and reliable method to obtain target DNA for ulterior high throughput analysis with microarrays.

P02.027

High Resolution Comparative Genomic Hybridization analysis in patients with Idiopathic Mental Retardation

K. Nieto-Martínez, J. Duarte, C. A. Venegas, S. Kofman-Alfaro;
Facultad de Medicina, UNAM, Mexico City, Mexico.

Mental retardation (MR) and development delay (DD) occur in 2-3% of the general population and are very heterogeneous entities. Clinical characteristics observed in these patients are not always related to a specific syndromes, so different technologies must be applied to investigate the origin of MR. Conventional karyotyping has a resolution of >5 Mb and detects chromosomal alterations in >5% of individuals with unexplained MR, while Comparative Genomic Hybridization (CGH) is a molecular cytogenetic technique that can characterize unbalanced genetic material in a one-step global screening procedure. CGH analysis also provides information about the origin of gains and losses of chromosomal material and maps these imbalances to their position on the chromosome. We have used high resolution CGH to detect deletions and duplications in the range of 2-5 MB in order to find genomic imbalances in 10 patients with idiopathic mental retardation. The analysis by HR-CGH reveals 8 cases with normal profile and two showed abnormal results, one with a gain in 11p15.1 and the second one a loss in 12q21.3. These cases illustrate the value of molecular cytogenetic techniques as an important tool in the diagnosis and assessment of MR as well as a phenotype-genotype correlation.

Array-CGH diagnosis of cryptic chromosome aberrations

R. Stoeva^{1,2}, L. Grozdanova³, J. P. Fryns², J. Vermeesch², I. Ivanov¹, I. Patcheva¹, I. Stoev¹, B. Dimitrov², R. Thoeler², T. Krastev¹, M. Stefanova^{1,4};
¹Department of Pediatrics and Medical Genetics, Medical University, Plovdiv, Bulgaria, ²Center for Human Genetics, Katholieke Universiteit, Leuven, Belgium, ³Department of Medical Genetics, University Hospital, Plovdiv, Bulgaria, ⁴Center for Human Genetics, Free Flemish University Hospital, Brussels, Belgium.

Chromosome abnormalities are the most frequent cause of congenital malformations/mental retardation syndromes. Recently it was demonstrated that molecular karyotyping improves the detection rate of sub-microscopic aberrations up to 5-17%. Here we present the molecular and clinical data of three unrelated individuals with different chromosome aberrations, depicted by array-CGH analysis.

The smallest described so far deletion 1q44, only 200 kb in size, appeared *de novo* in a 4-year-old girl with clinical features inconsistent with the currently known phenotype of 1qter deletion syndrome. She presented mild mental retardation, speech delay, epilepsy, persistent foramen ovale and facial dysmorphism.

A 123 kb duplication of 8p11.1 chromosome region was detected in a severely mentally retarded 13-year-old boy with microcephaly, down-slanted palpebral fissures, midface hypoplasia, bird-like nose, long philtrum and retrognathia. Very few patients with duplications involving the same chromosome region were reported till now. Surprisingly, both the mother and healthy brother had cytogenetically balanced translocation t(9;22)(q22.1;q13.1).

Duplication of CHKAD clone (Shaikh et al., 2000) within the critical Di George region was found in an 11-month-old-boy. He was a product of twin pregnancy and had developmental delay, large fontanel, hypertelorism, depressed nasal bridge, anteverted nostrils, long philtrum, microretrognathia and inverted nipples. Few mentally retarded individuals with 22q11.2 duplication, but larger in size, approximately 3-6 Mb, were described. The phenotype was variable, characterized mainly with neurological disturbances.

The reported herein chromosome aberrations, smaller than 1 Mb, contribute to the interpretation of such anomalies in the clinical practice, an evolving issue after the routine application of array-CGH.

P02.029

De novo balanced chromosomal rearrangements in patients with mental retardation and/or multiple congenital abnormalities re-analysed by array CGH

B. Sikkema-Raddatz, N. Hanemaaijer, Y. Swart, T. Dijkhuizen, C. v. Raven-swaaij-Arts, K. Kok;

Department of Genetics, Groningen, The Netherlands.

De novo balanced chromosome rearrangements, as detected by cytogenetic banding techniques, occur in approximately one in 2500 newborns. The risk of mental retardation (MR) and/or multiple congenital abnormalities (MCA) is twice as high as in random populations. It is plausible that in approximately half of these cases the observed phenotype is caused by deletion, disruption or otherwise inactivation of a gene(s) at the breakpoint region(s). As the resolution of standard cytogenetic banding techniques is approximately 5 Mb, the unbalanced nature of some of these translocations may have escaped detection. We analyzed 19 patients with MR/ MCA and an apparently *de novo* balanced chromosome rearrangement at minimal 550 banding level, by high resolution arrayCGH using an 244K oligo array (Agilent). Eighteen patients carried a translocation, one of these patients had a complex translocation involving three chromosomes. A further patient carried an inversion. With the 244K oligo array we detected an unbalance at the breakpoint regions for four patients; at 5 out of 39 breakpoints. In addition cryptic microdeletions and duplications not located at the translocation/inversion breakpoints were seen for several patients. The *de novo* nature of these aberrations is still under investigation. The clinical relevance of our findings will be discussed.

P02.030

Investigation of cryptic chromosomal imbalances in patients with mental retardation and/or multiple congenital abnormalities using array-CGH

C. Sismani¹, G. Koumbaris¹, V. Anastasiadou², G. Stylianidou², S. Hadjiilouzou³, P. Evangelidou¹, P. C. Patsalis¹;

¹The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, ²Department of Paediatrics, Makarios Hospital, Nicosia, Cyprus, ³"Paidi" Center for Specialized Paediatrics, Nicosia, Cyprus.

Chromosomal abnormalities constitute the major cause of mental retardation (MR). Conventional chromosomal analysis still remains the most important tool for identification of genomic imbalances causing MR, however subtle aberrations smaller than 5Mb are missed by routine karyotyping. Array-CGH was recently introduced to clinical practice, significantly increasing the detection rate of chromosomal abnormalities. The aim of the current study was to investigate 70 patients with various degrees of mental retardation and/or congenital abnormalities for cryptic chromosomal imbalances. All patients were clinically examined and tested by karyotyping and FISH, in order to exclude large chromosomal abnormalities and suspected microdeletion syndromes. Array-CGH was performed using BAC microarray Cytochip platform (BlueGnome) with a median resolution of 565kb. Clinically significant submicroscopic chromosomal imbalances were detected in 4 patients (5.7%). Abnormal results were confirmed by FISH. The percentage of identified abnormalities in the current study is lower than previously reported by other studies, probably due to the fact that no specific selection criteria were applied in our patients. One deletion, one duplication, one unbalanced translocation and one mosaic case with both a deletion and duplication were identified. One of the detected abnormalities was de novo, one was familial, while the remaining two are still under investigation. Two out of the four detected abnormalities would have been identified by subtelomeric screening and two would have been missed. Array-CGH is a powerful tool for the identification of novel chromosomal syndromes and identification of new cases of known syndromes that will allow more accurate prognosis and phenotype-genotype correlations.

Modelling human microdeletion syndromes by chromosome engineering in mice

C. J. Shaw-Smith¹, M. Storer¹, D. Szumska², P. Scambler³, S. Bhattacharya¹, A. Bradley¹;

¹Wellcome Trust Sanger Institute, Cambridge, United Kingdom, ²Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom, ³Institute of Child Health, London, United Kingdom.

Array-based diagnostics and the pooling of information in databases such as DECIPHER has accelerated discovery of novel microdeletion syndromes. Examples include the recently described 17q21.31 and 22q11.2 microdeletion syndromes (refs 1 and 2). The identification of the individual genes responsible for the phenotype is facilitated by chromosomally engineered mouse models. We are using such models to analyze the chromosomal loci for recently described microdeletion syndromes (see Table).

Our strategy is to target MICER clones (ref 4) to the proximal and distal endpoints, respectively, of each deletion. Following Cre treatment, mouse ES cells are microinjected into blastocysts to generate male chimaeras. Phenotyping of offspring is carried out by MRI scanning at embryonic day 15.5. Where an appropriate phenotype is identified, a series of nested deletions is made in order to identify a candidate gene or genes. Ultimately, suitable candidates are tested by BAC rescue of the deletion. The 6.8 Mb mouse deletion at human 17q22-23 was made by this method and has a cardiac phenotype; generation of other mouse deletions is in progress..

Syndrome	Size of deletion	Syntenic mouse chromosome	Salient phenotypic features	Ref
Del 17q21.31	500 kb	11	MR, seizures, neonatal hypotonia	1
Del 22q11.2	2.1 Mb	16	Truncus arteriosus	2

Scanning copy number variations (CNV) in Angelman syndrome, mental retardation and autism

S. Villatoro¹, L. Armengol¹, I. Crespo², E. Gabau², L. Comadran², M. Col³, M. Guitart⁴, X. Estivill^{1,4};

¹Center for Genomic Regulation (CRG), Barcelona, Spain, ²Corporació Sanitària Parc Taulí, Sabadell, Spain, ³Departament de Biologia Cel·lular Universitat Autònoma de Barcelona, Bellaterra, Spain, ⁴Pompeu Fabra University, Barcelona, Spain.

Angelman syndrome (AS) is a neurodevelopmental disorder with a recognizable molecular cause in about 85% of cases. Copy number variations (CNV) are an important source of variation and genes located therein are likely to have altered expression patterns, therefore contributing to phenotypic changes. Twenty AS patients without the typical molecular alterations but with well-defined clinical features were analysed by aCGH using the 244K Agilent platform. Altered regions that contained rare CNVs (<2 findings in the literature) or not reported in the Database of Genomic Variants were selected for custom Multiple Ligation Probe Amplification (MLPA) assays. We assessed the CNV status using MLPA (52 regions) in the 20 AS family trios, and expanded the study to idiopathic mental retardation (n=220) and autism (n=100). CNV analysis by MLPA was also assessed in 450 control samples. The findings included: two de novo deletions (1p36, 1q44), one maternally inherited duplication (Xp11.23), altered regions in diseases cases but not present in controls (4q31.3, 6q21, 6q26, 7q22.1, Xp11.23, Xp22.2 and Xq28), and several inherited genomic variants (5q31.2, 9q33.1, 10p12.33, 16p13.3, 17p13.1 and 19q13.41) not found neither in other samples nor in controls. Our results support the view that a considerable proportion of genomic regions showing variability in copy number could be involved in neurodevelopmental disorders. The absence of genomic abnormalities in controls of inherited genomic changes detected in cases, suggests that even if inherited, they could be responsible for some of the clinical features perhaps uncovering recessive mutations in specific genes involved in the phenotypes.

High-density SNP array analysis reveals novel chromosomal rearrangements in human cortical malformations

G. M. S. Mancini¹, R. Schot¹, B. Dumeé², M. Y. de Wit³, R. F. de Co³, M. H. Lequin⁴, W. B. Dobyns⁵, P. van der Spek², A. J. M. H. Verkerk²;

¹Clinical Genetics ErasmusMC, Rotterdam, The Netherlands, ²Bioinformatics ErasmusMC, Rotterdam, The Netherlands, ³Child Neurology ErasmusMC, Rotterdam, The Netherlands, ⁴Radiology ErasmusMC, Rotterdam, The Netherlands, ⁵Human Genetics, Chicago, IL, United States.

Approximately 200 patients with cortical brain malformations (MCD), including simplified gyral pattern (SGP), lissencephaly (LIS), nodular heterotopia (PNH) and polymicrogyria (PMG), were recruited in 15 years at our academic hospital. An etiological diagnosis was made in 40% of the cases after systematic neuro-radiologic, clinical genetic, routine cytogenetic and molecular genetic tests (Archives of Neurology, in press). In the remaining group without etiological diagnosis we tested DNA of circa 100 patients on Affymetrix 250K SNP arrays and analysed the data using the CNAG and CNAT programs to detect submicroscopic chromosomal abnormalities. We could demonstrate 18 pathogenic changes, 17 deletions and 1 amplification) in about 20% of the tested patients. Of these, 15 had PMG and 4 PNH. Two patients had both PMG and PNH; 1 PNH and 2 PMG were associated with hydrocephalus. No pathogenic abnormalities were found in the SGP and LIS group. The chromosomal aberrations were confirmed by qPCR and parental testing. Some concerned known loci for MCD like 1p36, 6q27, 22q11; among the new loci found are 2q13, 4q22, Xp11, 21q22, 22q13. These are not annotated as polymorphic CNV in the know databases of variants and contain candidate genes. The size of the rear-

rangements ranged between 12 Kb and 10 Mb. With this technique, also single gene deletions were detected, which directly pointed to the causative mutation. Our data show that this novel approach detects up to 20% genomic abnormalities in a highly selected MCD patient population, mostly in the group of PMG and PNH.

P02.034

Detection of genomic copy number changes in Estonian patients with idiopathic mental retardation

O. Zilina¹, K. Männik¹, H. Puusepp^{1,2}, S. Parke¹, P. Palta¹, K. Õunap^{2,3}, A. Kurg¹;

¹Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia, ²Department of Pediatrics, University of Tartu, Tartu, Estonia, ³Medical Genetics Centre, United Laboratories, Tartu University Hospital, Tartu, Estonia.

Mental retardation (MR) is a highly heterogeneous condition with a prevalence of ~1-3%. It is caused by genetic, epigenetic or environmental factors solely or in combination. Despite extensive investigations the underlying reason remains unknown in about half of the cases.

We started the first comprehensive study in Estonia in order to find out causative factors in families with idiopathic MR and help to shed light on molecular mechanisms underlying MR. To date, we collected more than 230 DNA samples from MR patients with normal karyotypes and their unaffected family members.

Infinium-2 genotyping assay with Human370CNV BeadChips (Illumina Inc) was applied as initial screening tool for detection of DNA copy number changes and copy-neutral LOH events in the samples. Acquired data were analyzed using BeadStudio v3.1 (Illumina Inc) and QuantiSNP (Colella *et al* 2007) software. Relevant results were confirmed by RT-qPCR.

After validation of the study-platform using reference DNAs, first 100 individuals from 22 families were screened. About 35 genomic rearrangements per individual were detected, most of which are reported in the Database of Genomic Variants or present recurrently in our samples.

In three families, possible disease-related imbalances were found: 1.6Mb dup(X)(p22.31), 3.9Mb del(15)(q13.1q13.2), 8.3Mb del(7)(q31.1q32.1). The detected rearrangements were not present in unaffected family members. Cases with similar phenotypes and aberration(s) in the overlapping regions are also reported in the DECIPHER database.

In addition, several other potentially clinically significant aberrations were found. Involvement of these aberrations in the etiology of MR is currently under investigation.

P02.035

Application of two different copy-number detection methodologies - array-CGH and array-MAPH - with identical amplifiable target sequences.

L. K. Kousoulidou¹, K. Männik², O. Zilina², S. Parke², P. Palta², M. Remm², A. Kurg², P. C. Patsalis¹;

¹Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, ²Institute of Molecular and Cell Biology, University of Tartu/Estonian Biocentre, Tartu, Estonia.

Array-CGH has become the method of choice for the detection of subtle imbalances as cause of genomic disorders. Novel array-CGH modifications were introduced in order to detect smaller aberrations by varying the type and density of arrayed target sequences. At the same time, certain limitations have become obvious, emerging the need for alternative methodologies. Array-based Multiplex Amplifiable Probe Hybridization (array-MAPH) is a recent approach, where the analysis of copy-number data is performed by conventional MAPH, followed by rehybridization to microarrays containing DNA sequences, identical to MAPH probes. Thus, targeted amplification and reduction of the complexity in genomic material is achieved.

The aim of this study was to estimate whether a probe set, initially developed for array-MAPH, is potentially useful for array-CGH. The same human chromosome X specific probe set was applied to compare array-CGH and array-MAPH performance and to further evaluate the potential of array-MAPH methodology to be used for genome-wide identification of locus copy-number changes.

Normal male and female DNA samples were studied, as well as three patients with known chromosome X aberrations: two patients with a 12-Mb deletion and one patient with 1-Mb duplication. Our data has

proven that array-MAPH clones can be also efficiently implemented in array-CGH.

We suggest that efforts for upgrading genomic copy-number screening should not only focus on new CGH microarray probes, but also on introducing new platforms, such as array-MAPH, as a reliable, flexible and cost-effective alternative to array-CGH and high-density genotyping chips.

P02.036

Array comparative genomic hybridization and computational genome annotation in constitutional cytogenetics: suggesting candidate genes for novel submicroscopic chromosomal imbalance syndromes.

B. Coessens¹, S. Van Vooren¹, B. De Moor¹, Y. Moreau¹, J. Vermeesch²;

¹K.U.Leuven, ESAT / SCD (SISTA), Leuven, Belgium, ²K.U.Leuven, Center for Human Genetics, Leuven, Belgium.

Genome-wide array comparative genomic hybridization screening is uncovering pathogenic submicroscopic chromosomal imbalances in patients with developmental disorders. In those patients, imbalances appear now to be scattered across the whole genome, and most patients carry different chromosomal anomalies. Screening patients with developmental disorders can be considered a forward functional genome screen. The imbalances pinpoint the location of genes that are involved in human development. Because most imbalances encompass regions harboring multiple genes, the challenge is to (1) identify those genes responsible for the specific phenotype and (2) disentangle the role of the different genes located in an imbalanced region. We discuss our work on novel tools and databases that we recently developed to aid this gene discovery process. Identification of the functional relevance of genes will not only deepen our understanding of human development but will, in addition, aid in the data interpretation and improve genetic counseling.

P02.037

Cryptic chromosomal imbalances in patients with idiopathic mental retardation and multiple congenital anomalies

C. Orellana, S. Monfort, M. Rosello, I. Ferrer, S. Oltra, F. Martinez;

Fundacion Para La Investigacion, Valencia, Spain.

Background: Chromosomal abnormalities are a major cause of mental retardation and multiple congenital anomalies. Array CGH studies have shown an incidence of 10-15% of formerly undetected imbalances among these patients.

Objective: To report array CGH screening of a series of 160 patients with idiopathic mental retardation and congenital abnormalities.

Material and methods: 160 patients with normal karyotype and normal subtelomeric results by MLPA were evaluated for cryptic chromosomal rearrangements by array-CGH using a high-definition microarray consisting of 44.000 probes (Agilent technologies).

Results: A total of 46 (29%) probably pathological rearrangements were detected. Of these, 11 alterations have been proved to be pathological, while the remaining are under study. Deletions and duplications are equally represented. Duplication sizes ranged from 20 to 3,859 kb (mean 1,250 kb, SD 2,276). Deletion sizes ranged from 0.4 to 10,314 kb (mean 1,369 kb, SD 2,319).

It is worth to note the occurrence of two *de novo* alterations in one patient: a 10,3 Mb deletion at 6q16 and a 360 kb duplication at 16p11. As the phenotype is comparable to other cases with 6q16 deletion, the duplication can be considered as a *de novo* polymorphism.

Conclusions: Array CGH should be considered an essential tool for the genetic analysis of patients with mental retardation and congenital anomalies. However, caution must be taken when interpreting the results in order to distinguish pathological from polymorphic imbalances.

P02.038

Identification of disease-related copy number variation (CNV) in patients with mental retardation by high-dense SNP genotyping microarrays

N. Rivera Brugués¹, J. Wagenstaller¹, M. Hempel¹, S. Spranger², B. Kazmierczak², C. Daumer-Haas³, K. Hörtnage², T. Meitinger¹, T. M. Strom¹;

¹Institute of Human Genetics, Technical University Munich and Helmholtz Center Munich, German Research Center for Environmental Health, Neuherberg-Munich, Germany, ²Praxis für Humangenetik, Bremen, Germany, ³Pränatal-

Medizin München, Munich, Germany.

We investigated 98 children referred for unexplained mental retardation using Hap550 oligonucleotides arrays (Illumina). Conventional karyotyping did not reveal any abnormality. Data analysis was performed with median normalization and genotypes-specific dosage calculation using R-scripts. We used standard deviation (mean SD: 0.15) and mean absolute deviation (mean MAD: 0.11) of the log₂ intensity ratios to assess data quality. We also calculated a signal-to-noise ratio (mean SNR: 5.44) in male DNA samples (median log₂ intensity ratio of the X-chromosomal SNPs minus median log₂ ratio of the autosomal SNPs divided by MAD). 254 candidate regions were evaluated with 2 or 3 quantitative PCRs each. 58% were determined to be true-positive findings. Our experiments are likely to underestimate the true positive rate because we excluded all known CNV polymorphisms. Under the assumption that all detected known CNV polymorphisms are true positive, this rate would be 89.7%. 65.5% of the false positive CNVs were detected in regions defined by <8 SNPs, 32.3% in 8-20 SNPs and 1.8% in >20 SNPs. Preliminary results revealed 15 de novo CNVs, 13 deletions and 2 duplications (15%), which varied in size from 125 kb to 13 Mb. Seven CNVs were known genomic disorders. Two CNVs overlapped approximately 0.9 Mb with a DECIPHER entry. The remaining 6 CNVs were not described before.

Elucidation of Complex Structural Variations at 17q21.3, the NSF Locus

G. W. Tam, K. Porter, N. Carter, S. Grant, R. Redon;

Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Multiple studies have recently described extensive structural variation in the human genome. Among the regions with most extensive variation, the 17q21.31 locus harbours a complex architecture, with several structural variants previously associated with abnormal phenotypes. This locus is the site of a ~900kb inversion polymorphism responsible for two divergent haplotypes, named H1 and H2. In addition, the H1 haplotype is divided into subtypes which show considerable structural heterogeneity. While the H2 haplotype has been associated to one microdeletion syndrome causing learning disability and dysmorphic features, certain H1 sub-haplotypes have been linked to neurodegenerative disorders, including progressive supranuclear palsy and frontotemporal dementia. By using published copy number variation data on 270 HapMap individuals, we have defined several structural variations within the 17q21.31 locus, including a duplication polymorphism involving the 5' portion of the N-ethylmaleimide sensitive factor (NSF) gene and a second distinct CNV upstream of NSF, which is detected only in European individuals on both H1 and H2 alleles. CNV breakpoints in each sub-type were also delineated using high-resolution oligo array. We have further developed a set of quantitative PCR assays to resolve the different H1 and H2 sub-haplotypes. Given the previous association of the 17q21.31 locus with disease and the presence in this interval of several genes related to the brain function, this new genotyping assay will be a valuable resource for testing the involvement of H1/H2 subtypes in neuro-psychiatric disorders.

P02.040

A Novel familial 2q32 duplication associated with distinct behavioural phenotype

S. G. Mehta¹, C. Shaw-Smith¹, E. Kivuva^{1,2}, R. Reading³, G. Parkin¹, I. Simonon¹, L. Willatt¹;

¹Department of Medical Genetics, Addenbrookes Hospital, Cambridge, United Kingdom, ²Department of Clinical Genetics, Royal Devon and Exeter Hospital, Exeter, United Kingdom, ³Department of Paediatrics, Norfolk and Norwich

Hospital, Norwich, United Kingdom.

We have identified a patient with a novel 4 megabase duplication of 2q32.2-q32.3 chromosome region using GeneChip 250K Nsp SNP array from Affymetrix. The proband has global developmental delay, speech delay, and is aggressive with violent behaviour towards others and a tendency towards self-mutilation. She has foraging behaviour leading to obesity. She has striking blonde, dry, wiry hair, straight eyebrows and low-set ears. She has brachydactyly, and 5th finger clinodactyly. Her feet are broad, with a sandal gap, short toes and mild 2/3 toe syndactyly. The FISH studies have shown that this 4 megabase duplication has been inherited from her mother who has depression, and left school without any qualifications suggestive of a lower than average IQ. An unaffected sibling has not inherited the duplication. A recent report of a larger 2q32 deletion partially overlaps the duplication in this family. The duplicated region includes *INPP1*, previously implicated in bipolar disorder, and *COL3A1* and *COL5A2*, which are candidate genes for wrinkly skin syndrome but the proband does not share any characteristics of this syndrome except the mental retardation. Similarities with patients with the larger 2q32 deletion include a common behavioural phenotype and hair abnormalities. This suggests that copy number variation of 2q32 is a necessary, but perhaps not sufficient component for the behavioural phenotype and further analysis of the minimum region of overlap may help to identify important genes involved with this in particular. We discuss the clinical phenotype, review the literature, and discuss the difficult counselling issues involved where the link between submicroscopic DNA copy number change and phenotype is unclear.

P02.041

Confirmation of the new microdeletion syndrome of 16p11.2-p12.2

A. Battaglia^{1,2}, A. Novelli³, L. Bernardini³, T. Filippi¹;

¹Stella Maris Clinical Research Institute, Calambrone (Pisa), Italy, ²Division of Medical Genetics, Dept Pediatrics, University of Utah, Salt Lake City, UT, United States, ³Ospedale CSS-IRCCS, San Giovanni Rotondo e Istituto CSS Mendel, Roma, Italy.

We have identified a pericentromeric deletion, spanning about 8.2 Mb, in 16p11.2-p12.2, in a patient with DD and dysmorphic features, by aCGH. This deletion arose *de novo* and is flanked by segmental duplications. The probanda was the only child of healthy non-consanguineous parents, born after an uneventful pregnancy, at 40 weeks gestation, by normal delivery. She suffered from perinatal distress. Birth weight was 2,740 g, length 48 cm, and OFC 33 cm. Family history is non-contributory. Hypotonia and DD were present from early on. She started walking alone at 18/12. We first saw her at age 3 10/12 years. On examination, there were flat face; low-set, posteriorly rotated ears; high-arched palate; hypotonic face; left single palmar crease; long, thin fingers; a sacral dimple; and no speech. Height was at the 50th centile, weight at the 25th, and OFC at the 30th. DNA FraX, HRB, metabolic work-up, audiologic evaluation, brain MRI, electroencephalogram, heart/abdomen ultrasonography were normal. When last seen, aged 7 7/12 years, she had a mild-moderate MR, with a comprehension of a 4-year-old child, and was able to pronounce simple words and a few telegraphic phrases. Hypotonia was still present. Over the 3 9/12 years follow-up, we observed a slow, but constant, overall improvement. Our patient shows common clinical features to the four individuals described by Ballif et al (2007), and aCGH suggests that the deletions of all cases share the same distal breakpoint. Our observation validates the possibility that deletions in 16p11.2-p12.2 constitute a distinct syndrome.

Complex genomic structure underlying an interrupted microdeletion in 16p11.2-p12.1 with breakpoints mapping to non-homologous LCRs

B. Nowakowska¹, A. Midro², B. Panasiuk², D. Rychter³, P. Stankiewicz⁴, E. Bocian¹;

¹Institute of Mother and Child, Warsaw, Poland, ²Medical University Białystok, Białystok, Poland, ³University Hospital Leuven, Leuven, Belgium, ⁴Baylor College of Medicine, Houston, TX, United States.

The LCR-rich proximal chromosome 16p has been shown recently to be associated with the novel genomic disorders: the 7.1-8.7 Mb microdeletion 16p11.2-p12.1, and the proximally adjacent, recurrent

593 kb microdeletion and microduplication in 16p11.2 found in ~1% of patients with autism. The recurrent 16p11.2 rearrangements implicated in autism likely occur via nonallelic homologous recombination (NAHR) between directly oriented LCRs. The breakpoints of the 16p11.2-p12.1 deletions were mapped to nonhomologous sequences; however, the deletions were proposed to have arisen via NAHR. We present a 17-year-old patient with developmental delay, short stature, skeletal anomalies, and a normal G-banding karyotype and M-FISH. Using metaphase HR-CGH, we identified a deletion in 16p11.2-p12.1 and verified it by FISH with BAC clones. Whole genome array CGH with ~385,000 oligonucleotide probes (NimbleGen) defined the deletion between ~22,482,580-29,342,610 bp (6.8 Mb). Unexpectedly, we identified a second deletion ~600 kb in size, mapping ~750 kb distal to the first one. The breakpoints of both deletions map within nonhomologous sequences; breakpoint junction sequencing is in progress. We propose that the deletions arose through recently reported Fork Stalling and Template Switching (FoSTeS) replication-based mechanism (Lee et al. 2007) rather than NAHR. Phenotype-genotype correlation with the previously reported cases will be also presented.

3 Dimensional imaging in Wolf-Hirschhorn syndrome

P. Hammond¹, F. Forzano², F. Faravel³, S. Williams⁴, S. T. South⁴, J. C. Carey⁴, O. W. J. Quarrel¹;

¹Institute of Child Health, London, United Kingdom, ²Galliera Hospital, Genoa, Italy, ³Sheffield Children's Hospital, Sheffield, United Kingdom, ⁴The University of Utah, Salt Lake City, UT, United States.

Wolf-Hirschhorn syndrome (WHS) has characteristic facial features resulting from terminal 4p deletions which may be small or large; or result from unbalanced translocations. Those with small deletions are less likely to have congenital anomalies. We used 3D imaging and dense surface modelling to investigate whether facial features correlate with the aetiology of the 4p deletions.

3D images and routine karyotype results were collected from patients attending support group meetings. Excluding adults and unusable images, dense surface models from 76 Caucasian WHS cases (mean age 7.7 years, range 1.4 - 18.9 years) were compared with 150 controls (mean age 7.9 years, range 0.2 - 20.4 years). The WHS cohort consisted of 19 large deletions (breakpoint proximal to 4p16.3); 17 small deletions (breakpoint within 4p16.3); 12 (4;8) translocations; 11 other translocations and 17 unclassified mainly because the breakpoint was recorded as 4p16. Pattern recognition algorithms supported 100% discrimination between WHS and control images. Eight additional cases were tested unseen, 4 interstitial deletions and 4 from different ethnic backgrounds; all were more similar to the mean of the WHS cases than the controls.

There was a significant time lag in facial growth in WHS that does not seem to depend on deletion size. Those with larger deletions had greater facial dysmorphism and greater facial asymmetry than those with smaller deletions. There is increasing interest in those few children with the smallest 4p deletions which define the WHS critical regions. We suggest 3D imaging is used for objective assessment of these crucial cases.

P02.044

Wolf-Hirschhorn syndrome - case report

T. Marcovici¹, I. Sabau¹, I. Simedrea¹, M. Mihaescu¹, M. Puiu¹, R. Tudorache²;
¹University of Medicine and Pharmacy, Timisoara, Romania, ²"Louis Turcanu" Children's Emergency Hospital, Timisoara, Romania.

Wolf-Hirschhorn syndrome is a rare disease caused by the partial deletion of the fourth chromosome's short arm. Female to male ratio is 2:1. Because of the vast range of deleted material (1% to 50%) the effect on each child varies widely, but the facial appearance is suggestive of 4p- syndrome. No treatment exists for the underlying disorder and the management is supportive.

We present a nine months old female admitted in our clinic for systolic cardiac murmur. A comprehensive medical evaluation was made: prenatal and birth history, physical, neurologic and genetic examinations, biologic and imagistic evaluations (cardiac and abdominal ultrasonography, chest and skull films, brain MRI).

The patient is the second child of a young couple. She was delivered full term with a weight of 3400g and her development was normal.

By clinical examination we noticed craniofacial dysmorphism: right parieto-occipital plagiocephaly, downward lips, distinct „Greek warrior helmet” face with broad beaked nose, high frontal hairline, frontal bossing, hypertelorism; dysmorphic downward ears, bilateral preauricular tubercles, low occipital hair insertion. Skin dimples on elbows and left parasternal holosystolic cardiac murmur were present. Imagistic evaluations show large axial and transverse skull diameters and normal sized cerebral ventricles. Small ventricular septal defect with left-to-right shunt was detected. Serologic tests for TORCH syndrome and immunoglobulin level were normal. Karyotype analysis noticed deletion in 4p15-pter region.

Conclusion: Although the patient has no growth problems or physical disabilities, nor mental retardation, constant cardiologic and neurologic follow-up care is required.

P02.045

The 4P-syndrome. A case report and literature review

F. Mortezapour¹, F. Mahjoub²;

¹Iran blood Transfusion Organization Research Centre (IBTO), Tehran, Iran, Tehran, Islamic Republic of Iran, ²Iran blood Transfusion Organization Research Centre (IBTO), Tehran, Iran & Clinical Genetic Dept. National Institute for Genetic Engineering and Biotechnology, Tehran, Iran, Tehran, Islamic Republic of Iran.

Wolf-Hirschhorn syndrome (WHS) is a rare developmental disorder associated with a deletion of short arm of chromosome 4. Well-known features of WHS are typical facial anomalies, midline defects, skeletal anomalies, prenatal and postnatal growth retardation, hypotonia, mental retardation, and seizures.

Here we report a new case of WHS who was referred to our clinic for cytogenetic investigation.

Case Report: The patient was a 9 month old baby boy with developmental delay, hypotonia, respiratory and heart problem, prominent eyes and forehead and delayed bone age.

Materials and Methods: Lymphocyte cultures from the patients were set up in RPMI 1640 medium supplemented with 20% FBS. Cell proliferation was stimulated with phytohemagglutinin. The cells were harvested after 72 h culture time. Hypotonic treatment of the cells was performed in 0.052 M KCL for 10 min at 37c. The cells were fixed in methanol: glacial acetic (3: 1) overnight, and, after washing in fixative, were dropped onto clean slides. The slides were G-banded and analyzed.

Result :GTG banded karyotype revealed a deletion of the distal part of 4p (p15.31-pter). We describe some of the features of our case and will compare it with other reported cases.

P02.046

Pure de novo trisomy 4p: About 2 cases

M. Chaabouni¹, L. Kraoua¹, I. Ouertani¹, S. Bouzguenda², I. Chelly¹, R. Meddeb¹, L. Ben Jemaa¹, F. Maazoul¹, S. Gaig², H. Chaabouni¹;

¹Department of Hereditary and congenital disorders, Tunis, Tunisia, ²Department of Foetopathology, la Rabta, Tunis, Tunisia.

Trisomy 4p is a well-known entity as more than 80 cases have been published. Most of the reports of trisomy 4p were due to unbalanced translocations and resulting in associated trisomy or monosomy of other chromosomes. Cases with pure trisomy 4p are seldom.

We report on two cases of pure trisomy 4p arising de novo in a girl and a male foetus.

The girl aged 7 years presented with mental retardation, behaviour troubles, growth retardation, asymmetrical skull, microcephaly, triangular face, strabismus, bulbous nose, teeth malposition, abnormal shape of the ears and camptodactyly.

Standard karyotype performed on the patient and her parents showed a derivative chromosome 14 associated with a whole 4p trisomy: 46,X X,der(14)t(4;14)(p12;q11.1)mat.

The second case was a male foetus for who a karyotype was performed because of an increased nuchal translucency and revealed an add(4)(qter).The father has a balanced translocation between the homologous chromosomes 4, his karyotype was 46,XY,t(4;4)(p12;qter). Thus, the foetus' karyotype was interpreted as: 46,XY,der(4)t(4;4)(p12;qter)pat.

Fetopathological examination at 19 weeks of gestation showed slight dysmorphic features, micrognathia, pointed chin, abnormal shape of

the ears, camptodactyly, and abnormal genitalia. Genetic counselling was given.

Although 4p-syndrome is a distinct entity, it can not be recognized without cytogenetic evaluation as the features are variable sometimes very mild.

P02.047

Clinical and cytogenetic characteristics in Wolf-Hirschhorn syndrome - considerations on five cases

E. Gorduza¹, M. Covic¹, M. Volosciuc¹, E. Braha¹, M. Gramescu¹, L. Butnariu¹, O. Bartsch²;

¹University of Medicine and Pharmacy Iasi, Iasi, Romania, ²Institute of Medical Genetics, Mainz, Germany.

Wolf-Hirschhorn syndrome (WHS) is a rare chromosomal disease (1/50.000 new-borns) generated by a 4p deletion. We present five cases of WHS diagnosed in our service in last 10 years. In all cases we discovered the following features of WHS: marked growth deficiency, microcephaly, facial dysmorphism (ocular hypertelorism, down turned "fishlike" mouth, short upper lip and philtrum). We found cardiac anomalies in 4 cases, ocular abnormalities in 3 cases, cleft lip in 1 case and talipes in 1 case. Chromosomal analysis was performed in all 5 cases. At 3 patients, karyotype revealed 4p deletion specific to WHS. In last 2 cases karyotype was normal and we made FISH analysis in Clinical Genetic Institute in Dresden (Germany). In both cases was found a 4p16.3 microdeletion. In the last case, because of abnormal reproductive history of mother (2 spontaneous abortions, and 1 child death in neonate) the FISH analysis was made also in mother and indicated a t(4;20)(p16;p13) translocation. In this situation our patient presented in fact an association between a 4p partial monosomy and a small 20p partial trisomy. In the last case we estimate a recurrence risk about 10%. Our study reveals the importance of clinical examination in WHS, in all our cases clinical suspicion being confirmed. In addition, classical chromosomal analysis is not sufficient for confirmation of diagnosis. Thus, in all cases with strong evidences for WHS, but with normal karyotype are required a FISH analysis. Also, genetic counselling is difficult in some rare cases.

P02.048

Prenatal diagnosis of simultaneous Wolf-Hirschhorn and deletion 4q syndromes in a ring chromosome 4

M. J. Gómez-Rodríguez¹, A. Moreno-Izquierdo¹, F. Fernández-Martínez¹, M. Martín-Ramos¹, A. Galindo², A. Grañeras³, E. Barreiro¹;

¹Department of Genetics, Madrid, Spain, ²Department of Fetal Physiopathology, Madrid, Spain, ³Department of fetal Physiopathology, Madrid, Spain.

The phenotypes in patients with segmental aneuploidy are syndromes which often vary in their clinical manifestation depending on the size of the chromosomal region involved.

Formation of a ring chromosome 4, often involves loss of 4p and 4q telomeres and of more proximal regions on either or both chromosome arms. Deletions of the distal short arm of one chromosome 4 involving parts of 4p16 cause the Wolf-Hirschhorn (4p-) syndrome and deletions on chromosome region 4q33-4qter have also been recognised as a distinctive malformation syndrome.

To date, at least 17 cases with ring chromosome 4 have been described, but only two cases were prenatally diagnosed.

We report a case of prenatal diagnosis corresponding to the pregnancy of a 27 year old woman, which was referred for amniocentesis at 24 weeks of gestation because of intrauterine growth restriction (IUGR) showing a foetal biometry corresponding to a 18 weeks of gestation. Moreover, the fetus showed complex cardiac malformations.

Cytogenetic and molecular cytogenetic analysis of the cultured amniocytes revealed mosaic for a *de novo* ring chromosome 4: 46XY(10),45XY,-4(10),46XY,r(4)(p16,q35)(16).

The ring chromosome 4 was further characterized by fluorescence in situ hybridization (FISH) using WCP 4, CEP 4, tel 4q, tel 4p and the Wolf-Hirschhorn syndrome (WHS).

The prenatal and postnatal clinical features are well correlated with those described for simultaneous Wolf-Hirschhorn and deletion 4q syndromes.

P02.049

Evidence for epigenetic regulation of CDKN2A in normal human placenta

E. N. Tolmacheva, A. A. Kashevarova, I. N. Lebedev;

Research Institute of Medical Genetics, Tomsk, Russian Federation.

Placental development and trophoblast differentiation share many similarities with the process of tumorigenesis. These are rapid proliferation, invasiveness and gene expression profiles. It is possible, that this analogy might be provided by epigenetic mechanisms. To test this hypothesis methylation status of four tumor suppressor genes in the normal human placentas was investigated. Promoter methylation of *p14ARF*, *CDKN2A*, *CDKN2B* and *RB1* genes was analyzed by methyl-specific and methylation-sensitive PCR in the cytotrophoblast and extraembryonic mesoderm of 32 first-trimester induced abortions. Studied tissues have different dynamics of epigenetic genome reprogramming and level of methylation. No methylated alleles of *p14ARF*, *CDKN2B* and *RB1* genes were detected in normal extraembryonic tissues. However aberrant methylation of the *CDKN2A* promoter was observed in 78% of cases in both placental tissues. Heretofore aberrant methylation of *CDKN2A* gene was frequently observed in different human cancers as well as in 20% of hydatidiform moles, 40% of chorioncarcinomas (Xue et al., 2004) and even up to 14% cases of spontaneously aborted embryos with normal karyotype (Park et al., 2008). Our data for the first time have demonstrated that hypermethylation of *CDKN2A* with high frequency can occur in normal human placenta. Tendency of decreasing in mean gestational age between embryos with (8.4 weeks, n=7) or without methylation (10.2 weeks, n=25) was found. It is possible, that several cell populations with epigenetic inactivation of the cell-cycle checkpoint genes can exist in placental tissues during some periods of its development providing evidence for a new unresolved mechanism of successful placentation.

P02.050

Screening for 22q13 deletion syndrome in 40 patients with clinical features suggestive of Angelman Syndrome and normal methylation test

F. García-Santiago^{1,2}, M. Palomares^{1,2}, L. Fernández^{1,2}, P. Lapunzina^{1,2}, V. F. Montañó¹, A. Delicado^{1,2};

¹Servicio de Genética Hospital Universitario La Paz, Madrid, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER). ISCIII, Madrid, Spain.

The 22q13 deletion syndrome has been associated with neonatal hypotonia, developmental and mental delay, absent or severe expressive language delay, autistic-like behaviour and subtle facial dysmorphisms. As some of those features are suggestive of Angelman Syndrome (AS), testing for 22q13.3 deletion in patients with AS features without the characteristic molecular 15q abnormalities has been suggested.

Forty patients with mental retardation, who had been previously referred with a clinical diagnosis of AS and a normal methylation test result, were included in the study. Patients had not been screened for UBE3A mutations (about 10%). Screened for 22q13 deletions applying the SALSA P188 MLPA kit contains 37 probes detecting sequences on chromosome 22q13. This kit including four probes in the SHANK3 gene, which is thought to be responsible for at least part of the phenotype, in particular the neurological symptoms.

A 22q13 deletion was discarded in 39/40 patients (97.5%) because no deletions were detected by MLPA analysis. Only one patient showed an abnormal result consisting in a deletion of the probe located in exon 9 of SHANK3 gene, but this result needs to be confirmed.

This study confirms the findings of Vries (2002) et al. suggesting that patients with an "Angelman phenotype" are not more likely to have a 22q13.3 deletion than other individuals with mental retardation.

P02.051

Phenotypic variability in Angelman syndrome - report of two cases

M. Budisteanu^{1,2}, A. Arghir², G. Cardos², S. Chiriac², S. Magureanu¹, A. Lungeanu²;

¹Clinical Hospital of Psychiatry "Prof. Dr. Al. Obregia", Bucharest, Romania,

²"Victor Babes" National Institute, Bucharest, Romania.

Angelman syndrome is a complex neurodevelopmental disorder with a difficult clinical diagnosis and heterogeneous genetic basis.

We herewith report two cases of Angelman syndrome with different phenotypes.

First case, a 12 year-old girl, was admitted in our department for neurological evaluation because of severe progressive toraco-lumbar scoliosis, which occurred at the age of five. She also presented severe mental retardation, absence of speech, autistic features, gait difficulties with ataxia, hyperventilation episodes, and epileptic seizures. The second case, a 4 year-old boy, was referred to our department for psychomotor retardation. He had "happy-puppet" appearance, ataxic gait, and severe mental retardation. Both children were born from healthy non-consanguineous parents.

Clinical investigations included neurological evaluation, EEG, and MRI.

Chromosomal studies were performed on peripheral blood lymphocytes, by GTG banding. Locus specific BAC probes for critical region 15q11-13 and control probes were used for FISH analysis.

Normal karyotype, and 15q microdeletion was demonstrated in both cases.

In the second case, the phenotype was highly suggestive for Angelman syndrome, while in the first case, a differential diagnosis with Rett syndrome was considered, especially because of the severe vertebral scoliosis.

A diagnosis of Angelman syndrome should be considered in patients with Rett-like phenotype. Molecular investigation of specific genetic defect allowed, in our cases, the refinement of clinical diagnosis.

Financial support: CEEX (Project 150/2006).

Acknowledgements: The authors thank Prof. Jean-Michel Dupont and Mrs. Dominique Blanco for kindly providing BAC probes and Mrs. Marioara Cristea for technical assistance.

P02.052

Supravalvular aortic stenosis and Williams Syndrome

G. S. Doros, M. Gafencu, A. Popoiu, B. Zoica, J. Puiu;

Victor Babes University of Medicine and Pharmacy, Timisoara, Romania, Timisoara, Romania.

Aim: To present two cases of supravalvular aortic stenosis, selected from the group of aortic stenosis children, admitted in the IIIrd Paediatric Clinic in 2007, considered to be Williams syndrome. Williams syndrome is caused by the deletion of genetic material from the region q11.2 of chromosome 7, including more than 20 genes, several of these contributing to the characteristic features of this disorder.

Material and method: The patients were young children, one girl and one boy, extremely friendly, with moderate mental retardation, short stature, characteristic elfin face, joint laxity, systolic murmur and attraction to music. They performed clinical examination, ECG, echocardiography, cardiopulmonary X ray and angio CT, and after that they were referred to the genetician, ENT and ophthalmologic department.

Results: Supravalvular aortic stenosis was confirmed in both cases, associated with hypoplasia of aortic arch and large coarctation of the aorta in girl. She had from birth irreducible inguinal hernia, operated in newborn period, followed by cardiopulmonary arrest, resuscitated. The inghinolabial hernia reoccur. She also still have feeding problems for semisolid food. Barium examination reveal large esophageal stenosis in the 1/3 inferior part. Both of them have prominent lips with an open mouth, defective tooth enamel and spaced teeth. The girl associated hypercalcemia.

Conclusions: After examinations, both patients are able to be considered Williams syndrome. The FISH test to confirm this syndrome has to be done. They are in follow up programe and we intend, after confirmation of the genetic FISH test, to introduce them in Williams Syndrome Children Association.

P02.053

Clinical and molecular characterization of a cohort of 49 children affected by Beckwith-Wiedemann Syndrome and related congenital defects

A. Mussa¹, G. Baldassarre¹, C. Molinatto¹, L. Peruzzi², E. Pepe³, A. Riccio⁴, M. Cirillo Silengo¹, G. B. Ferrero¹;

¹Department of Paediatrics, Torino, Italy, ²Division of Nephrology, Regina Margherita Children's Hospital, Torino, Italy, ³Department of Surgery, Regina Margherita Children's Hospital, Torino, Italy, ⁴Dipartimento di Scienze Ambientali,

University of Napoli, Caserta, Italy.

The Beckwith-Wiedemann syndrome (BWS) is a paradigmatic condition of overgrowth, characterized by macrosomia, congenital malformations, neonatal metabolic anomalies, and predisposition to embryonal malignancies, and a complex pattern of inheritance. Imprinting defects in 2 gene clusters located at 11p15.5 have been identified in about 75% of the cases. We report the clinical and molecular characterization of a cohort of 49 patients (27 M, 22 F) presenting a classic BWS (34) or a BWS-like phenotype (15). A molecular lesion has been identified in 16 out of the 39 patients analyzed (41%): KvDMR hypomethylation in 7 (17.9%), paternal uniparental disomy (UPD) in 6 (15.4%), partial deletion of the IGF-2/H19 imprinting center in 3 (7.7%), 2 maternally inherited and 1 de novo. All the patients presenting a genetic/epigenetic lesion were affected by a classic BWS phenotype. Seven children of the cohort (14.3%) developed an embryonic neoplasm, 5 Wilm's tumors and 2 hepatoblastomas; all neoplasms were detected in patients presenting hemihyperplasia, and two of them were diagnosed as affected by BWS only after the onset of the embryonic tumor. We confirm the complex genotype-epigenotype/phenotype correlation in BWS, describing three cases of the rare partial deletions of the IGF/H19 imprinting center, documenting a high incidence of cancer in our cohort, occurring even in children with an extremely mild expression of the overgrowth syndrome

P02.054

Molecular defects in patients with clinical symptoms of Angelman syndrome

M. Gos^{1,2}, E. Obersztyn¹, M. Nawara¹, J. Bal¹, T. Mazurczak¹, A. Szepecht-Potocka¹;

¹Institute of Mother and Child, Warsaw, Poland, ²MSCM Cancer Center and Institute of Oncology, Warsaw, Poland.

Angelman syndrome (AS) is a rare complex neurobehavioral disorder that is due to defects in parental genetic imprinting at the 15q11-q13 region resulting in the aberrant expression of genes located within this region. It was also suggested that mutations in *UBE3A* gene might be responsible for AS.

We included 206 patients with clinical symptoms of AS in our study. First, the analysis of methylation status was performed with MS-PCR method using primers specific for *SNRPN* locus. The abnormal (paternal only) methylation pattern was found in 23 patients and in several cases it was due to the deletion in 15q11-q13 region as shown by Methylation Specific Multiplex Ligation-dependent Probe Amplification technique.

Patients with the normal methylation pattern were qualified to the analysis of *UBE3A* coding sequence. Three missense (c.1291G>A - p.Gly192Ser, c.1249G>A - p.Ala178Thr, c.1643A>G - p.Asn309Ser), two frameshift (c.3228-3231del4 and c.1683-1689del7) and one splice-site (c.2616A>G) mutations were found in our group. Moreover, a 14bp deletion (c.3298-3311del14) in 3'UTR and stop codon change (c.3275A>G) were detected in 2 and 3 patients, respectively. In 32 (15.5%) patients, a small insertion in intron 6 (c.678 -48insT) always linked to small deletion in intron 7 (c.720 -66_68delGAT) was identified. Therefore, the molecular analysis confirmed the clinical diagnosis of AS in 29 (14.1%) examined cases.

However, defects in other genes e.g. *MECP2*, *ATP10C* or *CDKL5/STK9* might be responsible for AS specific phenotype. After careful examination of clinical symptoms selected patients would be qualified to further molecular analysis.

The study was supported by grant PBZ-KBN-122/P05/01-4.

P02.055

Hypomethylation gradient at the 11p15 Different Methylated Region 2 (DMR2) in BWS patients

V. Romanelli^{1,2}, L. Magano^{1,2}, L. Fernández^{1,2}, P. Arias^{1,2}, I. Incera^{1,2}, R. Gracia Bouthellier³, P. Lapunzina^{1,2};

¹Servicio de Genética Médica y Molecular, Hospital Universitario La Paz, Madrid, Spain, ²CIBERER, Centro de Investigación Biomédica en Red de Enfermedades Raras, Madrid, Spain, ³Servicio de Endocrinología Infantil, Hospital Universitario La Paz, Madrid, Spain.

Beckwith-Wiedemann syndrome (BWS) is a genetic disease characterised by somatic overgrowth, macroglossia, abdominal wall defect and a variety of other findings including predisposition to embryonal tumours.

There are several molecular abnormalities associated with BWS. The majority of BWS patients (50-60%) have an epigenetic defect at the DMR2 of the 11p15 region. The epigenetic defect present in this region involves loss of methylation (LOM) of the maternally inherited copy of KvDMR (DMR2), a CpG island localised at the intron 10 of the maternally expressed gene KCNQ1.

In this same intron 10, this CpG island surrounds the promoter that drives a long transcript (KCNQ1OT1) with antisense transcription to KCNQ1. Normally, the maternal allele of DMR2 is methylated and KCNQ1OT1 is silenced. If there are epigenetic alterations in this region, loss of maternal methylation of DMR2 is accompanied by biallelic expression of the KCNQ1OT1 transcript, usually only paternally expressed.

We studied the methylation pattern by means of MS-MLPA technique (Methylation-Specific MLPA). With this technique is also possible to study the extension of the hypomethylation in the DMR2's CpG islands.

We studied 87 patients with BWS and among them we found that 37 presented hypomethylation at the DMR2 (42.5%). Moreover our results are consistent with similar studies which demonstrated that the hypomethylation includes the 5' end of the KCNQ1OT1 gene. Our findings suggest a clear pattern of hypomethylation at the KvDMR with a 5'-3' gradient of demethylation at this region.

Laboratory progress in molecular diagnosis of Prader-Willi syndrome and Angelman syndrome - A new strategy by methylation-specific competitive multiplex PCR

S. Y. Lin, C. H. Lin, Y. N. Su;

National Taiwan university hospital, Taipei, Taiwan.

Introduction: Most of the Prader-Willi syndrome and Angelman syndrome patients are caused by the deletion of chromosomal 15q11-13 or uniparental disomy of chromosome 15. There are many diagnostic tools available like the FISH analysis, methylation-based PCR, multiplex PCR, High Resolution Melting analysis and commercialized MS-MLPA. Each of them has some disadvantages and limitations such as high costs, time-consuming and requiring DNA bisulfite-treatment. We introduce a novel, in-house designed methylation-specific competitive multiplex PCR, which takes three hours for the reaction, avoids bisulfite-treatment of DNA and provides reliable results of PWS and AS.

Material and methods: 68 patients with clinical suspicion of PWS, two with AS, and 20 unaffected individuals from the general population were analyzed. In the MS-competitive multiplex PCR, we amplified one SNRPN control gene, the KRIT1 gene to serve as internal control, and the promoter of the SNRPN gene, which could be digested them with HhaI enzyme. By comparing the copy number of the three regions, we could differentiate the wild type, deletion type and UPD type PWS within one reaction. We also evaluated other different diagnostic technologies in clinical applications.

Results: In this article, we successfully made the molecular diagnosis of one AS patients and 46 PWS patients by several different techniques. In the MS-competitive multiplex PCR, the total copy numbers were accurately calculated in all of the cases.

Conclusions: The MS-competitive multiplex PCR strategy is a good alternative for molecular diagnosis of PWS and AS. This approach could serve as an alternative genotyping platform for epigenetics.

P02.057

From phenotype to mosaic paternal UPD11p15 in Beckwith Wiedemann Syndrome

C. Skrypnik¹, M. Bembea¹, V. Bica², C. Rusu³, C. Jurca¹, W. Kress⁴, A. Bauer⁵;

¹University of Oradea, Genetics Department, Oradea, Romania, ²Institute for Mother and Child Care, Bucharest, Romania, ³University of Medicine and Pharmacy, Genetics Unit, Iasi, Romania, ⁴Institute of Human Genetics, Wurzburg, Germany, ⁵Institute of Medical Genetics, Zurich, Switzerland.

Introduction: Beckwith-Wiedemann syndrome (BWS; MIM 130650) is a model human imprinting disorder resulting from altered activity of one or more genes in the 11p15.5 imprinted gene cluster and defined by overgrowth, macroglossia, visceromegalia and tumor predisposition. Approximately 20% of BWS cases have uniparental disomy (UPD) of chromosome 11. Material and methods: We report 4 patients, three boys and one girl, clinically diagnosed with BWS. Genomic DNA was

extracted from peripheral blood lymphocytes and PCR methylation tests for 11p15.5 loci were performed to confirm the diagnosis. Results: All patients accomplished the consensus clinical diagnosis criteria and had isoplasial hemihyperplasia. Transient neonatal hypoglycemia was recorded in two cases, three cases had cardiac involvement. The cases were confirmed by DNA methylation for loci LT1 and H19, microsatellite analysis was performed for one case and showed 11p15.5 mosaic paternal UPD. Conclusions: The consensus criteria enabled a correct and precocious clinical diagnosis in the first two months of life. The DNA tests confirmed the cases and showed that interchromatid somatic recombination was the causal mechanism for one case. Considering that all cases had a similar phenotype we assumed the same casual mechanism and established a correct tumor screening.

P02.058

Methylation Specific Multiplex Ligation-dependent Probe Amplification (MS-MLPA) in routine diagnostics of Prader-Willi and Angelman syndromes

A. Szpecht-Potocka¹, M. Gos^{1,2}, J. Bal¹, T. Mazurczak¹;

¹Institute of Mother and Child, Warsaw, Poland, ²MSCM Cancer Center and Institute of Oncology, Warsaw, Poland.

Methylation Specific Multiplex Ligation-dependent Probe Amplification (MS-MLPA) is a novel technique that allows for simultaneous detection of copy number variation and CpG methylation. The usage of probes specific for 15q11-q13 locus makes it useful as a diagnostic tool in the diagnosis of Prader-Willi and Angelman syndromes (PWS/AS). The aim of our study was the implementation of MS-MLPA technique as a standard diagnostic procedure in PWS/AS patients.

The Salsa MS-MLPA Prader Willi / Angelman Kit (ME028) was used according to MRC-HOLLAND suggested protocol. The MS-MLPA peak analysis, normalization and calculation of dosage ratio were performed with the SoftGenetics LLC GeneMarker ver 1.6 software. For the pilot study, we have chosen 20 cases with established PWS or AS molecular diagnosis based on PCR-based DNA methylation analysis of SNRPN locus (MS-PCR) and the STR analysis of deletion or UPD presence.

The results of the analysis of the copy number variation and the methylation status in 15q11-q13 locus with MS-MLPA confirmed the previous findings obtained for the pilot patients. We have also performed the copy number variation analysis in additional 16 AS and 24 PWS patients with abnormal methylation status detected by MS-PCR. The MS-MLPA technique allowed to exclude from the further molecular analysis patients with the deletion without the necessity parents testing. Therefore, it seems that the MS-MLPA is a useful method in the molecular diagnosis of PWS/AS syndromes.

The study was supported by grant PBZ-KBN-122/P05/01-4.

New hypotheses in PWS/AS research: a multidisciplinary approach of rare diseases in Romania

M. Puiu¹, M. Serban¹, N. Cucu², G. Anton³, D. Dar⁴, C. Popoiu¹, C. Rusu⁵, V. Pop⁶, C. Badiu⁷;

¹University of Medicine and Pharmacy, Timisoara, Romania, ²University of Biology, Bucharest, Romania, ³National Institute of Virusology, Bucharest, Romania, ⁴APWR, Zalau, Romania, ⁵University of Medicine and Pharmacy, Iasi, Romania, ⁶University of Medicine and Pharmacy, Cluj, Romania, ⁷Institute of Endocrinology Parhon, Bucharest, Romania.

SPW and SA are two clinical, metabolic and neurological different syndromes with 1 case for 15000 new born. The molecular mechanisms identified imply large deletions, uniparental disomy (DUP), intragenic and epigenetic modifications in the processes of imprinting and only rare balanced translocations. The actual studies have extended the area of epigenetic modifications, involving chromatin dynamic structure through covalent modifications of their components. A group of researchers from medical centers of Romania together with APWR suggests studying new etiological hypotheses of PWS/AS.

Since a small number of cases with SPW/SA do not integrate with the etiologies described by now our project have a great opportunity to discover new and interesting aspects. The project aims to follow in these patients aspects connected to environment, diet, pollution and way of life influence trying to solve the weak points of the correct imprinting process.

Knowing the epigenetic aspects from SPW/SA will allow a more pre-

cise etiological diagnosis, an adequate genetic counseling, avoiding recurrence of the disease, epigenetic therapies and an optimal management of these diseases. These objectives are doubled by the interest concerning rare diseases in generally and the opened research wants to be a beginning in the multidisciplinary approach of rare diseases in Romania.

We are proposing to contact some teams of European researchers with certain results in the study of PWS/AS to cooperate, with the purpose of deciphering the mechanisms involved in these diseases.

P02.060

Genomic and epigenetic abnormalities in Silver-Russell syndrome patients

I. Cuscó¹, L. Fernández², O. Villa¹, L. Rodríguez-Revenga³, M. Palomares², M. Rosales¹, J. del Valle¹, S. García-Miñaur⁴, F. Santos², M. Milà³, P. Lapunzina², L. A. Pérez-Jurado^{1,4};

¹Unitat de Genètica, Universitat Pompeu Fabra, U-735 CIBERER, Barcelona, Spain, ²Servicio de Genètica, Hospital Universitario La Paz, U-753 CIBERER, Madrid, Spain, ³Servei de Bioquímica i Genètica Molecular, Hospital Clínic, U-726 CIBERER, Barcelona, Spain, ⁴Programa de Medicina Molecular i Genètica, Hospital Vall d'Hebron, Barcelona, Spain.

Silver-Russell syndrome (SRS) is a heterogeneous disorder characterized by severe intrauterine and post-natal growth retardation, characteristic dysmorphic facial features and occasional asymmetry. The SRS incidence is ~1-30/100000 live-births with most cases being sporadic. Maternal uniparental disomy of chromosome 7 and maternal duplications or epimutations of the 11p15 region have been reported accounting for ~35-40% of cases. Several chromosomal abnormalities, affecting chromosomes 1, 15, 17 and X, have also been found in patients with SRS.

In order to define the molecular cause of the disease and to establish a diagnostic protocol, we have screened a collection of 46 patients with a clinical diagnosis of SRS with a "step by step" strategy. Cytogenetic abnormalities were found in three cases (r(15), sSMC(7), Xq26-q28dup). A methylation sensitive (MS) MLPA assay targeting five imprinted regions (11p15, 7q31, 15q12, 14q32, 20q13) detected epigenetic abnormalities in 4 cases, 2 with maternal UPD (verified by microsatellites) and 2 with H19 locus hypomethylation (verified by F-COBRA). Screening for copy number variants was performed by MLPA (19 candidate loci), and aCGH in the still negative cases. *De novo* putatively pathogenic rearrangements were found in 5 additional cases (15q26 deletion, 15q26del+11q24dup, 7q36dup+ 10q, 12p13dup and 1 with 4q13.3 del). Our approach was able to detect the molecular basis of 12/46 (26%) SRS patients, further confirming the syndrome heterogeneity and suggesting novel candidate loci for the disorder. Although epigenetic abnormalities at 11p15 are less frequent in our series, the use of targeted MS-MLPA and aCGH appears to be indicated in the workup of these patients.

P02.061

Mutations in SLC9A6 are present in about 4% of males with an Angelman syndrome-like phenotype

C. E. Schwartz¹, J. Barwick², R. Pate², A. Archie², B. Schuff¹, J. Garberr², R. Schroer¹, M. J. Friez¹;

¹Greenwood Genetic Center, Greenwood, SC, United States, ²Wayne State University, Detroit, MI, United States.

Recently, Gilfillan et al (ASHG, in press) reported that mutations in the *SLC9A6* gene cause X-linked mental retardation (XLMR) with epilepsy and ataxia. Additionally, for many of the patients, the phenotype resembled that associated with Angelman syndrome. With this association between gene and phenotype, we wished to determine the degree of involvement of *SLC9A6* mutations in patients with clinical findings suggestive of Angelman syndrome who had normal diagnostic testing. We tested 30 males submitted to rule out Angelman syndrome who had normal methylation studies and identified 1 mutation (3.3%). Additionally, 65 males with normal *UBE3A* sequencing were screened and 3 mutations (4.6%) were identified. Lastly, based on the phenotype, 20 families enrolled in our XLMR project were tested and 2 mutations (10%) were found. All of the mutations were truncating mutations. Taken together, our results would indicate: 1) *SLC9A6* mutations may account for about 4% of males with a phenotype resembling Angelman syndrome and 2) *SLC9A6* mutations may account for about 10% of males with XLMR associated with epilepsy and ataxia. Thus, *SLC9A6*

testing should be considered in any male with a phenotype resembling Angelman syndrome particularly if an X-linked pattern of inheritance is suspected.

P02.062

Mutations in SLC9A6 cause microcephaly, epilepsy, and severe mental retardation with abnormal postures.

F. Raymond¹, A. Whibley¹, C. Freeman¹, J. Clayton-Smith², H. Archer³, A. Clarke³, M. Bitner-Glindzicz⁴, R. Smith⁵, P. Tarpey⁶, M. Stratton⁵, A. Futrea⁶, I. GOLD¹;

¹Cambridge Institute for Medical Research, Cambridge, United Kingdom, ²Regional Genetics Service, St. Mary's Hospital, Manchester, United Kingdom, ³Medical Genetics, University of Wales, Cardiff, United Kingdom, ⁴Institute of Child Health, University of London, London, United Kingdom, ⁵Sanger Institute, Hinxton, Cambridge, United Kingdom.

We have recently reported pathogenic mutations in *SLC9A6* in 4 families with a characteristic phenotype of severe to profound mental retardation in association with microcephaly, epilepsy and abnormal postures. The differential diagnosis included Angelman syndrome in all cases but the pedigree structure suggested an X-linked mode of inheritance in 3 of the families.

There is considerable clinical overlap between Angelman syndrome, West syndrome and atypical Rett syndrome and thus we selected an additional 30 male patients from these categories and performed sequence analysis of *SLC9A6* to identify causative mutations having excluded the known causes of disease in each group i.e. *UBE3A*, *ARX* and *MECP2*. We also screened >200 males from families with X-linked mental retardation.

We report a deletion within *SLC9A6* in a pair of brothers with severe mental retardation where the mutation is likely to be pathogenic. We also report 2 sequence variants in families with X-linked mental retardation where the pathogenicity is less clear. These are a missense mutation which is likely to be a rare SNP and a splice site mutation (IVS12+4A>G) where the expression of *SLC9A6* mRNA in lymphocytes is unaltered. We did not identify further pathogenic mutations in the samples from males with Angelman, West or atypical Rett syndrome cohorts suggesting that the etiology of these conditions remains heterogenous and further genes are likely to cause these overlapping phenotypes.

P02.063

A valuation of facial dysmorphism in diagnostics of 22q11.2 microdeletion syndrome in countries with lower average income

G. M. Cuturilo¹, I. Jovanovic¹, S. Grkovic¹, M. Djukic¹, V. Parezanovic¹, G. Vukomanovic¹, M. Stevanovic², D. Drakulic²;

¹University Children's Hospital, Belgrade, Serbia, ²Institute of molecular genetics and genetic engineering, Belgrade, Serbia.

Most authors consider both specific and non-specific facial dysmorphism as an important diagnostic criterion for 22q11.2 microdeletion syndrome. As a consequence, FISH analysis should be required frequently. While in most European countries this fact does not represent a significant problem, in those with lower average income such wide coverage is still unavailable.

The aim of this study was to compare a significance of specific and non-specific facial dysmorphism in diagnostics of 22q11.2 microdeletion syndrome.

We analyzed 34 patients that underwent FISH for 22q11.2 microdeletion in our hospital in the last three years. Among nine newborn infants diagnosed as positive, eight had some kind of facial dysmorphism. Seven had non-specific dysmorphism (88%), while only one had specific dysmorphism (12%). All six children older than one month and diagnosed as positive, had facial dysmorphism. Two of them had non-specific dysmorphism (33%) and four had specific facial dysmorphism (67%).

In conclusion, it is clear that facial dysmorphism becomes more and more specific with age. In the situation of seriously limited availability of FISH testing, some narrowing of indications possibly could be achieved in group of patients older than one month (or better, older than one year) by considering only a specific facial dysmorphism as a diagnostic criterion. However, individual approach to the patient and careful clinical assessment are necessary, as it is clear that non-specific facial dysmorphism also has an important role in clinical diagnosis of 22q11.2 microdeletion syndrome.

P02.064

22q11 microduplication syndrome across four generations of a single family

S. A. McKee, S. McCullough, D. McManus;

Northern Ireland Regional Genetics Service, Belfast, United Kingdom.

Microduplication, as opposed to deletion, of the "DiGeorge region" on chromosome 22q11 is an increasingly-recognised finding, associated with a very wide phenotypic range. Patients vary in the degree of dysmorphism, intellectual disability and cardiac abnormalities, and many patients have now been reported who are classified as phenotypically normal.

We report a Northern Irish family in which the proband was diagnosed with a microduplication at the age of 20. She has mild learning problems and minimal facial dysmorphism, but has subtle abnormalities of the fingers. Her daughter developed severe seizures at birth, and has an atrial septal defect with patent ductus arteriosus. She has ocular hypertelorism, a small mandible, and significant developmental and growth delay; she tested positive for the duplication. The proband's mother and one of her brothers also carry the duplication. This makes it highly likely that one of her parents in turn also carried the duplication (these are reported as phenotypically normal; analysis is ongoing in this family).

Counselling as to the likely effects of this microduplication is very difficult, as the spectrum is so broad even within families. In particular, prenatal counselling presents significant challenges. As data continues to accumulate, more accurate risks and prevalences may be established, and potential modifying factors identified.

P02.065

Report of three cases with the 22q11.2 proximal deletionR. Queralt^{1,2}, M. Vallecillos¹, Y. Viedma¹, M. Obon³, M. Alsius³, E. Margarit^{1,2};¹Servei Bioquímica i Genètica Molecular. Hospital Clínic, Barcelona, Spain,²Ciberer, Barcelona, Spain, ³Laboratori Clínic. Hospital Dr. Josep Trueta, Girona, Spain.

Hemizyosity for the human chromosome region 22q11.2 is associated with a wide range of overlapping phenotypes including DiGeorge syndrome, velocardiofacial syndrome. The acronym CATCH 22 (Cardiac anomaly, Abnormal facies, T cell deficit due to thymic hypoplasia, Cleft palate, Hypocalcaemia due to hypoparathyroidism resulting from 22q11 deletion) has been proposed to describe the broad clinical spectrum of phenotypes with 22q11.2 deletions. The frequency of this microdeletion is approximately 1:4000-1:8000 live births. Two types of deletions have been described. The most common, affects about 85% of patients and spans a ~3 Mb proximal region. The less common, affects about 7% of patients and spans a smaller, nested ~1.5 Mb distal region. Both types of microdeletion were found to occur as a result of nonallelic homologous recombination by means of low-copy repeat sequences located in the 22q11.2 region.

We describe the cytogenetic and molecular cytogenetic analysis of three patients having the most common proximal 22q11.2 microdeletion. Karyotype analysis from lymphocyte cultures performed by conventional G banding, at the level of 500 bands, revealed normal karyotype in all cases. Fluorescence *in situ* hybridization (FISH) analysis performed with the commercial dual probe LSI TUPLE1 (22q11.2)/LSI ARSA (22q13) (Vysis) showed hemizyosity of 22q11.2 region in all three cases.

P02.066

Prenatal detection of 22q11.2 deletion: case report with wide intra-familial phenotypic variationA. Gomez Pastor¹, J. Ubeda Arades², J. L. Santome Collazo², R. Fernandez Gonzalez², P. Blanco Soto², M. Carballido Viejo², M. A. Orera^{2,3};¹Complejo Hospitalario Universitario de Albacete, Albacete, Spain, ²HospitalGregorio Marañon, Madrid, Spain, ³Laboratorio Circagen, Madrid, Spain.

INTRODUCTION: 22q11.2 deletion constitutes a contiguous gene syndrome that encompasses the clinical phenotypes formerly described as DiGeorge syndrome, velocardiofacial syndrome, conotruncal anomaly face syndrome, Opitz G/BBB syndrome and Cayler cardiofacial syndrome.

The diagnosis is routinely performed by FISH analysis.

CASE REPORT: We present a 33 years old healthy woman on is 13th gestational week that is sent to our office for genetic counseling because of a previous pregnancy that produced a newborn with Fallot te-

tralogy. Later on she had a healthy boy and a third pregnancy ended at the 9th gestational week in spontaneous miscarriage. The 450 bands karyotype of the girl was 46,XX.

The amniocentesis was performed at the 16th gestational week, and the karyotype was 46,XY. We extended the cytogenetic analysis and performed FISH of 4p16.3, 22q11.2 and 7q11.23 and we found that the fetus had a hemizygous deletion of the 22q11.2 region. The father was a carrier of the same deletion.

MATERIALS AND METHODS: FISH analysis was performed with the Vysis probe DiGeorge/UCFS (gene TUPLE1) y ARSA (control). The karyotype analysis was performed by conventional GTG banding.

DISCUSSION: This case illustrates the advantage of widening the prenatal diagnostic spectrum beyond the most common aneuploidies, tailoring the genetics tests to the family history as well as to the prenatal data. Assuming that both the Fallot tetralogy and the miscarriage were related to the familial deletion, the intrafamilial variability spans from lethal to almost normal, adding further data to the few catch 22 families studied to date.

Frequent 22q11 aberrations in patients with non-syndromic autism spectrum disorders shown by SNP array based segmental aneuploidy screeningM. Poot¹, N. Verbeek¹, R. van 't Slot¹, M. R. Nelen¹, B. van der Zwaag², E. van Daalen³, M. V. de Jonge³, W. G. Staal³, J. A. S. Vorstman³, P. F. Ippel¹, M. van den Boogaard¹, P. Terhal¹, F. A. Beemer¹, J. J. S. van der Smagt¹, E. H. Brilstra¹, G. Visser⁴, H. van Engeland³, J. P. H. Burbach², H. K. Ploos van Amstel¹, R. Hochstenbach¹;¹Department of Medical Genetics, Utrecht, The Netherlands, ²Rudolf Magnus Institute of Neuroscience, Utrecht, The Netherlands, ³Department of Child and Adolescent Psychiatry, Utrecht, The Netherlands, ⁴Department of Pediatrics, Utrecht, The Netherlands.

Autism spectrum disorders (ASD) are neurodevelopmental conditions characterized by impaired reciprocal social interaction, communicative deficits, and restricted behavioral patterns. ASD occurs in syndromic forms and as non-syndromic cases frequently involving cytogenetic abnormalities. Recently, array-based genome-wide screens have demonstrated frequent copy number variation in non-syndromic ASD. Screening 56 patients with autism and additional major or minor anomalies with the Infinium HumanHap300 SNP platform (Illumina, Inc., San Diego, CA) we found in 16 patients 9 regions with deleted and 9 with duplicated signals. Aberrant signals were distributed among 16 distinct chromosomal loci. Apart from 14 patients with unique aberrations, 2 patients carried duplications and a 3rd patient a deletion within the 22q11 region, of 0.726, 2.966, and 0.388 Mb, respectively. The duplications were confirmed by multiplex ligation-mediated probe amplification and are likely to involve LCRs A, B and D. We conclude that SNP array-based screening of ASD patients uncovers an appreciable number of CNVs, which in part overlap with loci already discovered by other approaches. Our finding that 3 out of 56 ASD patients carried aberrations within the 22q11 region is highly unexpected. The relatively small size of CNVs found in this study may allow us to pinpoint candidate genes for ASD.

P02.068

A rare recognizable 10p15 microdeletion syndrome of autism and HDRV. Herbepin-Granados¹, A. Combes¹, M. Gilet¹, A. Toutain², R. L. Touraine¹;¹CHU Saint etienne, Saint Etienne, France, ²CHU de Tours, Tours, France.

The HDR syndrome is characterized by hypoparathyroidism, sensorineural deafness, and renal dysplasia. It is caused by haplo-insufficiency of the GATA 3 gene located at 10p15 and inherited as an autosomal dominant trait.

In our study we describe a patient with HDR phenotype and associated severe autism. Molecular analysis by MLPA showed a de novo heterozygous deletion at 10p15, encompassing the GATA3 gene without involvement of the DGCR2. These results were confirmed by microsatellite analysis, showing that the deleted region is located between the D10S189 and D10S1649 markers. The size of the deletion can be estimated around 2,5 Mb. The GATA3 gene has been reported as a gene important in the embryonic development of the parathyroid, renal and auditory systems. However mental retardation or autism can not be ascribed to GATA3 mutations. Therefore we can suspect that this

deleted region contains a gene responsible for the cognitive impairment observed in our patient. 10p15 microdeletions has already been described in few patients will almost identical symptoms and similar dysmorphic features. This confirms the existence of a recognizable albeit rare microdeletion syndrome with HDR and autism.

P02.069

The developing facial phenotype of the 17q21.31 microdeletion syndrome.

N. Van der Aa¹, L. Rooms², B. Ceulemans¹, B. de Vries³, F. Kooy²;

¹Antwerp University Hospital, Edegem, Belgium, ²University of Antwerp, Wilrijk, Belgium, ³Nijmegen Centre for Molecular Life Sciences, Nijmegen, The Netherlands.

The 17q21.31 microdeletion syndrome is a new genomic disorder, characterized

by a 500-650 kb submicroscopic deletion.

Patients have a recognizable phenotype including neonatal hypotonia, mental retardation and characteristic facial features, most notably a long face, large prominent ears and a tubular pear-shaped nose.

We present a patient with a de novo 17q21.31 microdeletion, identified by multiplex ligation-dependent probe amplification with probes hybridizing to unique sequences in 2 genes located within this region, MAPT and CRHR1.

This boy was born at term with normal growth parameters. There was marked neonatal

hypotonia with feeding difficulties and necessity of nasogastric tube feeding.

Early motor milestones were significantly delayed. IQ testing at the age of 6 revealed mild mental retardation. Dysmorphic facial features noted in infancy were epicanthic folds, upslanting palpebral fissures, mild ptosis, low-set ears, a broad nose and prominent philtrum.

As the boy got older, the chin got bigger, there was marked elongation of the face and the nose became more pronounced. Subsequent pictures of our patient from age 6 months till 13,5 years illustrate this. At diagnosis age 13,5 we note a very long narrow face, large ears and a very prominent tubular pear-shaped nose with broad nasal tip. The palate is very high and there is dental crowding. We note thoracic scoliosis, wide-spaced nipples, a right pes cavus, numerous skin moles and a rather severe ichthyosis on hands and feet. He has nasal speech and a very friendly nature.

This is the first extensive description of the syndrome's developing phenotype.

P02.070

Cognitive and behavioral patterns associated with 18p-

L. O'Donnell, B. T. Soileau, C. D. Sebold, J. D. Cody;

Chromosome 18 Clinical Research Center, San Antonio, TX, United States.

Background. While deletions of 18p- are associated with short stature and minor dysmorphic features, no clear cut cognitive or behavioral patterns have emerged. Included in our longitudinal study of persons with chromosome 18 differences is a large cohort of persons with chromosome 18p-. Adaptive behavior assessment measures everyday activities while cognitive measures assess internal cognitive processes. Currently no information is available regarding the correspondence between adaptive behavior and cognitive development for this population. **Methods.** The adaptive behavior of 10 individuals with 18p- were evaluated using the Vineland Adaptive Behavior Scales (Vineland; Sparrow, Balla & Cicchetti, 1984) and estimates of intellectual functioning were gathered using either the Differential Abilities Scales (DAS, Elliott, 1990) or the Bayley Scales of Infant Development-Second Edition (Bailey-II, Bailey, 1993). All scores were converted to standard scores with a mean of 100 and standard deviation of 15. **Results.** Intellectual functioning varied from significant cognitive impairment (N=3) to low average/average intellectual functioning (N=3). Adaptive behavior skill development was commensurate with estimates of intellectual functioning in only three of the nine children's profiles. In the remaining six cases, estimates of cognitive development were lower than parental ratings of adaptive behavior. **Conclusions.** This study supports previous findings of significant cognitive variability within the 18p- population. It provides evidence of significant adaptive skill variability and also highlights within subject variability in cognitive and behavioral development. These findings suggest that for persons with 18p- deletions, it is critical to utilize both cognitive and behavioral mea-

asures to more fully understand development.

P02.071

Endocrine abnormalities in 18p-

D. E. Hale, C. D. Sebold, J. D. Cody;

Chromosome 18 Clinical Research Center, San Antonio, TX, United States.

Background. 18p- syndrome has primarily been described in case reports and small series. An endocrine abnormality is present in ~20% of reported cases. The aim of this study was to determine the incidence and types of endocrine abnormalities in our population. **Methods.** Eleven individuals with 18p- underwent an endocrine evaluation at the Chromosome 18 Clinical Research Center (the "Center"). This evaluation included anthropometrics, bone age studies and growth (growth factors and stimulation testing) and thyroid hormone testing. In addition, a review of the available medical records for 20 additional patients was completed. **Results.** Five males and 6 females were evaluated at the Center. The average age was 9⁸/₁₂ years (range 2⁸/₁₂ to 18²/₁₂). Six individuals were <5th centile for height. Three of these were diagnosed with GHD (27% of total individuals evaluated). Ten of the 11 had normal IGF1 and IGFBP3 levels and essentially normal thyroid results (one had a slightly low T4 level, but had normal TSH levels). Thyroid and IGF1/IGFBP3 results were not available on the 11th patient. Medical record review of the additional 20 patients revealed that 8 had an endocrine abnormality, including panhypopituitarism (2); precocious puberty (1); autoimmune thyroiditis (1); treatment with growth hormone (4); and hypothyroidism (1). **Conclusions.** Taken together, 11 of the 31 (35%) individuals with 18p- included in this study had some endocrine abnormality. Thus, endocrine abnormalities are relatively common in individuals with 18p- and physicians should have a low threshold for considering an endocrinology evaluation, especially GHD.

P02.072

Cytogenetic and molecular studies of the 18q deletion syndrome in two generations with phenotypic variability

T. P. Vieira¹, N. L. V. Campos¹, C. M. Monma², L. D. Kullikowsk², M. I. Melaragno², V. L. Gil-da-Silva-Lopes¹;

¹Universidade Estadual de Campinas, Campinas - SP, Brazil, ²Universidade Federal de São Paulo, São Paulo - SP, Brazil.

The 18q- syndrome is one of the most common deletion syndromes, with an estimated frequency of 1/40,000 births. This syndrome is most often caused by a terminal deletion of the long arm of chromosome 18. However, individuals with interstitial deletions have also been identified. The phenotype of the disorder varies greatly between individuals, but generally includes short stature, microcephaly, midface hypoplasia, hypertelorism, congenital aural atresia (CAA), foot deformities, mental retardation (MR), and hypotonia. Some familial cases with directed transmission of the deleted chromosome have been described. Here, we describe the cytogenetic and molecular studies of the 18q deletion syndrome in a mother and her daughter. The mother presented microcephaly, developmental delay, hypertelorism, strabismus, high palate, submucous cleft palate, bifid uvula, congenital heart disease and facial dysmorphisms. The daughter presented developmental delay, cleft palate, short neck and facial dysmorphisms. Using FISH and molecular analysis with polymorphic short tandem repeats (STR), the cytogenetic karyotype could be refined showing that: mother and daughter have the same terminal deletion, the size of the deletion was narrowed and the breakpoints were mapped between the markers D18S1313 (18q22.1) and D18S61 (18q22.2), the parental origin of the deletion in the mother is paternal. This case supports that the variability in phenotype is not only determined by the size of deletion, once mother and daughter, with similar sized deletion, present different phenotypes, suggesting that allelic variation on the haploid portion of 18q, genes on other chromosomal regions or environmental factors are modulating the phenotype.

P02.073

Clinical and molecular characterization of deletions, duplications, and mutations in the 22q11.2 region

D. Heine-Suñer¹, L. Armengol¹, L. Torres-Juan¹, M. de la Fuente³, F. Garcia-Algas³, L. Fernandez², M. Reyero², M. Juan², A. Tubau², A. Perez-Granero², M. Bernues¹, N. Govea¹, P. Lapunzina⁴, X. Estivill¹, J. Rosell¹;

¹Genetics, Hospital Universitari Son Dureta, Palma de Mallorca, Spain, ²Genes & Disease Program, Center for Genomic Regulation - CRG, Barcelona, Spain,

³Paediatrics, Hospital Universitari Son Dureta, Palma de Mallorca, Spain, ⁴Genetics, Hospital Universitario La Paz, Universidad Autónoma de Madrid, Madrid, Spain, ⁵Gynecology, Hospital Universitari Son Dureta, Palma de Mallorca, Spain, ⁶Obstetrics and Gynecology, Hospital Fundació Son Llatzer, Palma de Mallorca, Spain.

The phenotype of patients with del22q11.2 is very variable and ranges from the more severe and complex forms of the DiGeorge and Velo-cardiofacial syndromes, to isolated heart defects or isolated mental disorders. *TBX1* and *CRKL* are genes localized in 22q11.2 which have been proposed to cause the associated phenotype. We present here the results of the characterization of deletions, duplications and mutations in the *TBX1* and *CRKL* genes in prenatal samples, newborn and children with compatible malformations or phenotype. Duplications and deletions were studied by the use of a combination of a homebrew method based on microsatellites, MLPA (SALSA 23 and 250), CGH-arrays and FISH. Mutations in *TBX1* and *CRKL* were analysed by sequencing. In total, we have identified 21 patients with a 22q11.2 deletion (1.5 and 3 Mb) and one patient with a previously not described 1 Mb duplication. In patients with no deletions or duplications we found two mutations in *TBX1*. The atypical duplication was found in a boy with a ventricular septal defect (VSD) as the sole phenotypic trait. Neither his normal parents nor his sister which is also affected by a VSD are carriers of such duplication. The size of the duplication is approximately 1 Mb and is flanked by LCR22s 3a (B) and 4 (D) a region that includes the *CRKL* gene but not *TBX1*.

This work has been supported by the grant FIS 05-1585 from the Instituto de Salud Carlos III from the Spanish ministry of Health.

In recent years the increasing use of telomere screening has provided evidences of the presence of subtle abnormalities involving telomeres in around 5% of patients with idiopathic mental retardation. This fact has allowed the recognition of new distinct clinical entities such as monosomy 1p, 1q, 2q, 9q, 14q, and 22q. In surveys of subtelomeric screening, deletion of 22q13.3 is the second most common subtelomeric deletion, after deletion 1p36.3. The prevalence of 22q13.3 deletion is not yet established. Up to the present moment more than 100 cases have been reported, and a common phenotype has emerged including global developmental delay, hypotonia, absent to severely delayed speech, autistic-like behavior, normal to accelerated growth, and dysmorphic facial features. In spite of the increasing number of cases reported, this syndrome remains underdiagnosed due to the difficulty to detect the deletion of chromosome 22 in routine cytogenetic analysis even at the 550-band level of resolution, and to the lack of a distinct phenotype and the clinical variability observed.

Here we describe the clinical and molecular findings in 7 patients with monosomy 22q13. Three of them were detected by subtelomeric screening, other two were fortuitously discovered when FISH was used to rule out DGS/VCFs, and two were observed in the karyotype and subsequently confirmed by FISH.

All of them were further studied in detail by MLPA, using the specific probe mix P188 for 22q13 deletion syndrome, and arrayCGH at approximately 1 Mb resolution.

P02.075

Phenotype of a patient with pure partial trisomy 2p(p21-->pter)

M. Akbary^{1,2}, F. Mahjoub^{3,1}, N. Zolfagary¹;

¹Tehran Medical Genetic Laboratory, Taleganeh St, Tehran, Iran, Tehran, Islamic Republic of Iran, ²Medical Genetic Dept., Tarbiat Modares University, Tehran, Iran, Tehran, Islamic Republic of Iran, ³NIGEB, Tehran, Islamic Republic of Iran.

We present the case of a 7-year-old boy with additional material on 4q. The father's karyotype confirmed that the additional segment on 4q was of chromosome 2p origin, resulting in trisomy 2p21 -->2pter. The karyotype of the proband was found as 46, XY,der(4)t(2;4)(p21;q33) pat.

His father's karyotype was 46, XY, t(2;4)(p21;q33). The mother had normal karyotype. The child was found to have dysmorphic facial features, prominent ears, long fingers, short stature, thenar and hypothernar atrophy, crowded teeth, high arched palate, prognathism, low nasal bridge, large testes, developmental delay, speech delay and seizures. This case will be compared with other reported cases of partial trisomy/duplication of 2p.

P02.076

47,XXY/48,XXYY karyotype associated with multiple skeletal abnormalities and congenital heart disease

L. Mutesa¹, G. Pierquin¹, J. Vanbellighen¹, A. Hellin¹, M. Jamar¹, C. De Beaufort², J. Kieffer², V. Bours¹;

¹University of Liège, Liège, Belgium, ²Luxembourg Hospital Center, Luxembourg, Luxembourg.

We report on a 12-year-old boy with congenital scoliosis due to segmented hemivertebra between tenth and twelfth thoracic vertebrae. He had also congenital heart disease (atrial septal defect) and presented bilateral synostosis of the proximal radius and ulna associated with dislocation of both radius heads. Physical examination revealed facial dysmorphism, mild microcephaly, gynecomastia with morbid obesity, limitation of supination at the elbows, and moderate mental retardation.

Cytogenetic studies and FISH analysis showed that he had a de novo 47,XXY/48,XXYY karyotype. This case and evidence collected from the literature suggest that congenital skeletal abnormalities and heart defect may occur in the 47,XXY/48,XXYY syndrome more frequently than currently appreciated. The 47,XXY/48,XXYY phenotype may result from compounding affects of the additional X and Y chromosomes.

P02.077

Severe neurological phenotype in a boy with 48, XXYY karyotype

M. Bordignon, K. Ludwig, L. Salviati, R. Tenconi;

Servizio di Genetica Clinica, Padova, Italy.

A 18 month old boy was seen in our clinical genetics unit for further evaluation after having been diagnosed with 48, XXYY aneuploidy. He had a history of epileptic seizures, mental retardation, left cryptorchidism and a first degree atrio-ventricular block.

A thorough examination of the boy revealed many of the clinical features characteristically found in patients with gonosomal polysomies, as for example the truncular obesity, slight hypogenitalism, mental retardation and facial dysmorphisms (coarse face, mild frontal bossing, brachycephaly, bilateral epicanthic folds and maxillary hypoplasia.).

However he also presented generalized hypotonia, epileptic seizures and paroxysmal sharp-waves and polyspikes in the central occipital left hemispherical region on EEG analysis; neurological findings which have rarely described in patients with 48, XXYY karyotype.

The incidence of the 48,XXYY aneuploidy is about 1 in 50,000 newborns and initially it had been classified as a variant of Klinefelter Syndrome. Today it is defined as an independent genetic and clinical entity.

As far as we know, this is the first case report of a boy with the 48, XXYY chromosomal anomaly presenting epileptic seizures as one of the major clinical features.

P02.078**Mental Retardation, Epilepsy and Venous Thromboembolic Disease in a Patient with a 48,XXYY Karyotype**

M. Obón¹, M. Alsius¹, A. Molins², I. Recas³, A. Bustins⁴, C. Pascual Mostaza¹;

¹Department of Genetics and Molecular Biology. Laboratori Clínic ICS Girona. Hospital U. de Girona Dr. J. Trueta, Girona, Spain, ²Epilepsy Unit. Hospital U. de Girona Dr. J. Trueta, Girona, Spain, ³Department of Endocrinology. Hospital U. de Girona Dr. J. Trueta, Girona, Spain, ⁴Department of Haematology, ICO, Girona, Spain.

48,XXYY syndrome was initially considered a variant of Klinefelter syndrome. Nowadays, it is accepted as a distinct clinical and genetic entity.

We report the case of a 27-year-old man diagnosed with cryptogenic partial epilepsy and action tremor in both hands unresponsive to beta-blockers. Due to speech and language delays and mild mental retardation a karyotype analysis was performed, which indicated that all cells were 48,XXYY.

The patient was born without neonatal complications to a healthy couple with an unremarkable family history. On beginning school, language delay and learning disabilities were detected. Language therapy helped him to develop complex language skills. He was diagnosed with asthma when he was 5 years old. At 19, idiopathic deep vein thrombosis developed in his left leg which required 8 months of oral anticoagulant therapy.

Phenotypically tall with eunuchoid habitus, gynecomastia. Craniofacial dimorphism described as a "pugilistic" facial appearance. Hypergonadotropic hypogonadism, small testes and normal penis. Leg ulcers and varicosities.

Behavioural features consist of immaturity, passivity and temper outbursts but a friendly and cooperative nature. High overall scores on adaptive scales in daily living, socialization and communication. His parents have exposed their son to a variety of activities and interests and provided consistent intervention and support when needed.

The addition of more than one extra X and Y chromosome to a normal male karyotype rarely occurs and it has its own distinctive physical and behavioural profile. There are significant variations within each polysomy X and Y group and hence no generalised prognosis can be made.

P02.079**A 7-year-old boy with profound mental retardation, peculiar face, tracheo-esophageal fistula and bilateral sensorineural hearing loss caused by interstitial deletion 17q22-q23.3**

H. Puusepp^{1,2}, O. Zilina², K. Männik², S. Parke³, R. Teek^{3,4}, K. Kuuse³, A. Kurg², K. Öunap^{3,1};

¹Department of Pediatrics, University of Tartu, Tartu, Estonia, ²Department of Biotechnology, Institute of Molecular and Cell Biology, Tartu, Estonia, ³Department of Genetics, Tartu University Hospital, Tartu, Estonia, ⁴Department of Oto-Rhino-Laryngology, University of Tartu, Tartu, Estonia.

Microdeletions of the long arm of chromosome 17 are rare. By our knowledge, only few cases have been reported involving deletions of chromosome 17 in region q22-q24. Common findings are microcephaly, abnormal face, anomalies of the hands, growth retardation and severe developmental delay.

Here we present a 7-year-old boy, who was born normally at term with normal birth weight 3480g and length 50cm, and microcephaly (-2 SD). Soon after the birth tracheo-esophageal fistula was diagnosed and therefore operated. At the age 7 years clinical evaluation revealed failure to thrive (-2.5 SD), microcephaly (-5 SD), profound mental retardation, stereotypic movements, peculiar facies - high forehead, palpebral fissures slant up, blepharophimosis, ptosis, hypertelorism, epicanthal folds, strabismus, broad nasal tip, high palate, low set and dysplastic ears, and preauricular pits. Additionally he had bilateral severe sensorineural hearing loss, kyphosis, scoliosis, spina bifida occulta, contractures of joints, tall fingers, partial syndactyly of II-V fingers and II-V toes, sandal gap of toes, micropenis, cryptorchid testes, and mild hirsutism. During pediatric evaluations psoriasis vulgaris, asthma, celiac disease, iron deficient anemia and mild hypothyreosis was diagnosed. We have applied Infinium-2 genotyping assay with Human370CNV-Duo BeadChips (Illumina Inc.), which showed a 5.9 Mb deletion of chromosome region 17q22-q23.3 with a breakpoint between 48,287,327 and 54,245,662bp. The aberration was confirmed by real-time PCR analysis.

Regarding to our patients findings, we suggest that a locus for sensorineural hearing loss and a locus for tracheo-esophageal fistula may be located in the region of 17q22-q23.3. This work was supported by GARLA 6808.

P02.080**An unusual case of ring chromosome 14 with Epilepsy and developmental delay**

A. Nucaro¹, M. Falch², M. Meloni², R. Rossino³, T. Pisano², C. Cianchetti², D. Pruna⁴;

¹Istituto di Neurogenetica e Neurofarmacologia, Monserrato (Cagliari), Italy, ²Dipartimento di Neuroscienze, Neuropsichiatria Infantile, University, Cagliari, Italy, ³Dipartimento di Scienze Pediatriche e Medicina Clinica, University, Cagliari, Italy, ⁴Dipartimento di Neuroscienze, Neuropsichiatria Infantile, Cagliari, Italy.

We present a 10-year-old boy, born to young, healthy and non-consanguineous parents, with an unusual ring chromosome 14 associated to epilepsy and mental retardation. At the age of five months he had seizures confirmed by EEG as epilepsy. Seizures were resistant to common antiepileptic drugs. He also had microcephaly, hypertelorism, microretrognathia, large auricula, micropenis, hypotonia. Cytogenetic investigation and FISH studies of the proband revealed an unusual chromosomal mosaicism 46,XY,r(14)(p13q32)/46,XY,dup r(14),ish (14wcp+). Over 50 examined metaphases, 48 had a ring chromosome 14 and only 2 had a duplicated ring chromosome 14(4%).

The abnormality r(14) is a rare cytogenetic disorder with characteristic features and episode of uncontrolled seizures. To the best of our knowledge, this is the first report describing a ring chromosome 14 mosaicism associated to a duplicated ring chromosome 14. Array-CGH analysis will be performed to detect cryptic submicroscopic rearrangements in the ring formation. We carried out this study to search for the cause of the seizures in our patient. Several hypotheses could be explain these, such as mitotic instability of ring chromosome or telomere position effect in ring chromosomes. We could also hypothesize that 14p telomere silences nearby genes on the q arm and close dependent genes involved in the seizures.

P02.081**Partial trisomy 15q11-13 as a cause of acute onset intractable epilepsy**

M. Michelson^{1,2}, A. Eden^{3,2}, C. Vinkler^{1,2}, M. Yanoov-Sharav^{1,2}, T. Lerman-Sagev^{3,2}, D. Lev^{1,2};

¹Institute of Medical Genetics, Holon, Israel, ²Metabolic Neurogenetic Clinic, Holon, Israel, ³Pediatric Neurology Unit, Holon, Israel.

Various rearrangements involve the proximal long arm of chromosome 15, including deletions, duplications, translocations, inversions and supernumerary marker chromosome with the inverted duplication of proximal chromosome 15.

The large marker 15, that contains the Prader-Willi syndrome (PWS)/Angelman syndrome (AS) chromosome region, is usually associated with an abnormal phenotype of moderate to severe mental retardation, seizures, poor motor coordination, early-onset central hypotonia, autism and autistic-like behavior and mild dysmorphic features. Positive genetic linkage with 15q region has also been found in patients with schizophrenia. Most of the reported cases are of maternal origin.

We report here an eight year-old girl with normal intelligence who developed severe intractable seizures at age seven years. Family history was significant for a mother with episodes of acute psychosis.

The patient's leukocyte karyotype revealed 47XX+m. Her mother's karyotype looked identical.

Array comparative Genomic Hybridization (A-CGH) identified a gain of 13 BAC clones from 15q11.2 through 15q13.1, which was then confirmed by Fluorescent In-Situ Hybridization (FISH). This duplicated region is approximately 5.6 Mb in size and contains the SNRPN/UBE3A loci.

Although severe epilepsy has been described in association with rearrangements of the proximal long arm of chromosome 15, all reported cases had mental retardation.

This is the first report of a patient with intractable epilepsy and nearly normal intelligence, associated with partial trisomy of 15q11-13. She inherited this marker chromosome from her mother, who has psychiatric illness.

We suggest that this region should be tested by FISH in cases with intractable epilepsy, with or without developmental delay/MR.

P02.082

Phenotype and 244k array-CGH characterization of chromosome 13q deletions: An Update of the Phenotypic Map

M. Stefanova^{1,2}, **R. Stoeva**³, **A. Bisgaard**⁴, **B. Dimitrov**⁴, **G. Gillissen-Kaesbach**⁵, **J. Fryns**⁶, **H. Rose**¹, **L. Grozdanova**³, **I. Ivanov**³, **K. Keymolen**⁷, **C. Fagerberg**⁶, **L. Tranebjaerg**^{7,8}, **M. Kirchoff**¹;

¹Rigshospitalet, University of Copenhagen, Copenhagen, Denmark, ²Center for Human Genetics, Free Flemish University Hospital, Brussels, Belgium, ³Medical University, Plovdiv, Bulgaria, ⁴Center for Human Genetics, University of Leuven, Leuven, Belgium, ⁵Institute of Human Genetics, Campus Lubeck, Schleswig-Holstein University Hospital, Lubeck, Germany, ⁶Department of Clinical Genetics, Vejle Hospital, Vejle, Denmark, ⁷Department of Audiology, Bispebjerg Hospital, Copenhagen, Denmark, ⁸Wilhelm Johannsen Centre for Functional Genomics, Institute of Cellular and Molecular Medicine, The Panum Institute, Copenhagen, Denmark.

Genotype-phenotype correlation studies of partial deletions of the long arm of chromosome 13 have been reported previously, each focusing on few particular major anomalies, such as brain, eyes, inner organs, hands and feet, genitourinary or anorectal defects. Chromosome regions critical for some of the major malformations, however, vary noticeably and await precise delineation. Besides, data about the dysmorphic profile are limited. In order to update the phenotypic map for chromosome 13q deletions, we applied high resolution 60-mer oligonucleotide-based microarray containing 244.000 probes with a median spacing of 7.4 kb to 16.5 kb (Agilent Technologies, USA) to determine the exact breakpoints of such deletions in 14 patients. We linked the genotype to the patient's phenotype and were able to refine the smallest deletion region linked to microcephaly (13q33.3-q34), Dandy-Walker malformation (DWM) (13q32.2-q33.1), corpus callosum agenesis (CCA) (13q32.3-q33.1), the associated occurrence of both DWM/CCA (13q32.2-q33.1), meningocele/encephalocele (13q31.3-qter), ano-/microphthalmia (13q31.3-13q31.3qter), cleft lip/palate (13q31.3-13q33.1), lung hypoplasia (13q31.3 - 13q33.1), anal atresia/hypospadias/penoscrotal inversion (13q33.1-13q34), thumb a-/hypoplasia (13q31.3-q33.1 and 13q33.3-34). 'Typical' 13q-dysmorphic facial features were assigned along the chromosome, thereby mapping, the prominent nasal columella between 13q31.3 and 13q33.3. Our analyses support the hypothesis that haploinsufficiency of more than one locus within the 13q21.1-qter region is responsible for brain anomalies and neural tube defects. In contrast to previous reports of carriers of 13q32 band deletion as the most seriously affected patients, we present such individuals with a long-term survival.

P02.083

Clinical features of a case with trisomy 10q and monosomy 3p resulting from a maternal balance translocation: A case report and review of clinical features

F. Mahjoubi^{1,2}, **M. Akbari**³, **S. Kareme**⁴, **G. Babanohammadi**⁴;

¹NIGEB, Tehran, Islamic Republic of Iran, ²3Tehran Medical Genetic Laboratory, Taleqanee St, Tehran, Iran, ³Tehran, Islamic Republic of Iran, ⁴Medical Genetic Dept., Tarbiat Modares University, Tehran, Iran, Tehran, Iran (Islamic Republic of, Tehran, Islamic Republic of Iran, ⁴3Tehran Medical Genetic Laboratory, Taleqanee St, Tehran, Islamic Republic of Iran.

Here we describe clinical and cytogenetic data on 2 year female child with partial trisomy for the distal part of the long arm of chromosome 10 (10q22-->qter) and a concomitant monosomy 3(p25-->pter) as a result of a maternal balanced reciprocal translocation. Her karyotype was ascertained as 46,XX,der(3)t(3;10)(p25;q22). The father had normal karyotype. The mother had an apparently balanced translocation involving chromosome 3 and 10 [46,XX,t(3;10)(p25;q22)]. To our best knowledge, this is the second reported case of partial trisomy 10q and partial trisomy 3p and first reported case from Iran. Clinical features of this case and a few published cases will be reviewed briefly.

P02.084

Trisomy 13 mosaicism in a nine-year-old girl with mild global developmental delay

L. E. Kim;

McMaster University Medical Centre, Hamilton, ON, Canada.

Trisomy 13 is associated with mental retardation and a variety of congenital abnormalities. Survival past infancy is rare because of the life-threatening medical issues associated with this condition. The phenotype of mosaic trisomy 13 is extremely variable. I report on a nine-

year-old girl who was found to have trisomy 13 mosaicism at the age of eight in the course of investigations for mild global developmental delay. She was born after an unremarkable pregnancy and delivery. Her parents first became concerned when she was two-years-old because her fine motor and speech milestones were delayed. Currently, she is integrated into a regular grade three class where she receives some remedial help; a recent developmental assessment revealed that she is functioning at the level of a six-year-old. She also has some gross motor difficulties and decreased coordination. Her general health has been good. Examination revealed that her weight and height were >97th percentile and that her head circumference was at the 80th percentile. Her facial features were slightly coarse. There was no other evidence on examination of any physical features associated with trisomy 13. The patient's karyotype was done on a blood sample and revealed that 10 out of 20 cells analyzed were trisomic for chromosome 13 (ie. 50%). This case supports the previously suggested idea that the percentage of trisomic cells, which is thought to decrease with age, correlates poorly with intellectual functioning.

P02.085

Detection of Y chromosome and trisomy 8 mosaicism in a twelve year old girl with Turner syndrome

K. Koronioti¹, **P. Apostolopoulos**², **A. V. Divani**¹;

¹Department of Cytogenetics, Locus Medicus, Diagnostic Centre, Athens, Greece, ²In Vitro, Diagnostic Laboratory, Athens, Greece.

Most Turner syndrome (TS) patients show no evidence of Y chromosome sequences. According to different authors some TS patients may have Y chromosome material present in a few cells that are not detected by standard cytogenetic analysis. The rationale of identification of this low level mosaicism is of clinical importance due to the patient's increased risk of developing gonadoblastoma.

Here we report conventional and molecular cytogenetic investigations in a case of mosaic sex chromosome aneuploidy combined with mosaic trisomy 8 and the presence of low level Y mosaicism. A 12 year-old girl was presented with short stature, gonadal dysgenesis and minor craniofacial dysmorphic features.

Standard chromosome analysis on peripheral blood lymphocytes showed the presence of three cell lines, whose karyotypes were 45,X [93%], 47,XY,+8 [5%] and 46,XX [2%]. FISH analysis was performed using as probes an alpha satellite for X chromosome (CEPX, Xp11.1-q11.1), a satellite III for Y chromosome (CEPY, Yq12) and an alpha satellite for chromosome 8 (CEP 8, 8p11.1-q11.1). The results of FISH analysis were in concordance with those of conventional cytogenetic analysis showing a slight increase in the percentage of interphase nuclei revealing trisomy 8 and Y chromosome mosaicism (8% FISH versus 5% standard cytogenetics).

The importance of systematic search for hidden Y chromosome mosaicism in patients with TS is justified by the possibility of developing gonadoblastoma and it is necessary for the appropriate clinical management of the patient.

P02.086

Isolated bilateral Ulnar Agenesis due to 4q34.1 deletion in a young male patient

S. Manouvrier-Hanu^{1,2}, **M. Holder-Espinasse**^{1,3}, **B. Maisonneuve**⁴, **A. Meze**⁵, **B. Herbaux**^{6,3}, **F. Escande**⁷, **J. Kerckaer**⁸, **J. Andrieux**⁹;

¹Génétique clinique, CHRU, Lille, France, ²faculté de médecine, Université Lille 2, Lille, France, ³Faculté de médecine, Université Lille 2, Lille, France, ⁴Centre de rééducation Marc sautelet, Villeneuve d'Ascq, France, ⁵Service de chirurgie et orthopédie de l'enfant, CHRU, Lille, France, ⁶service de chirurgie et orthopédie de l'enfant, CHRU, Lille, France, ⁷Génétique moléculaire, CHRU, Lille, France, ⁸plateforme de génomique, Lille, France, ⁹Plateforme de génomique, CHRU, Lille, France.

Ulna a- or hypo-plasia is a rare condition, mostly occurring associated with other malformations as in Schinzel-Ulnar-Mammary, Weyers, or Femur-Fibula-Ulna syndromes. If isolated the disease is very uncommon and, to our knowledge, remains unexplained. We describe a 3 years old male patient with bilateral isolated ulna aplasia and 4q34.1 deletion diagnosed by Array-CGH.

This patient was the first child of young, healthy and non consanguineous parents. He had a healthy young sister. The pregnancy was uneventful. He was born at term. He had aplasia of both ulnas with bilateral but asymmetrical absence of post-axial rays. Only the thumb was

present on the right side, but the first two pre-axial rays were present on the left. Both elbows were abnormal with unusual upper extremities of the radius, and lower extremities of the humerus. No other malformation was observed even in the lower limbs. Karyotype was normal: 46,XY. At 3 years of age the patient has normal growth and psychomotor development.

Array-CGH demonstrated in the patient a 4q34.1 de novo deletion, encompassing some candidate genes. Further studies are pending and will be discussed.

P02.087

Case report: Waardenburg syndrome and chromosome 13q deletion

F. Faletta¹, V. Petix², A. Fabretto¹, V. I. Guerci¹, F. Marchetti³, F. Patarino³, V. Pecile², P. Gasparini^{1,2};

¹Genetica Medica-Dipartimento Scienze e Riproduzione dello Sviluppo, Trieste, Italy, ²Genetica Medica, IRCCS Ospedale Infantile "Burlo Garofolo", Trieste, Italy, ³Clinica Pediatrica, IRCCS Ospedale Infantile "Burlo Garofolo", Trieste, Italy.

Waardenburg-Shah syndrome (WS4; MIM 277580) is a disorder of the embryonic neural crest that combines clinical features of Waardenburg syndrome and Hirschsprung disease. The phenotype can be caused by mutation in the endothelin-B receptor gene (EDNRB), in the gene for its ligand, endothelin-3 (EDN3) or in the SOX10 gene.

We report a case of a 3 years old patient with hypotonia, mild psychomotor and speech delay, and dysmorphic features. He was born a term with a normal pregnancy. At one month he suffered of recurrent vomiting caused by hypertrophic pyloric stenosis. During the recovery were found also abnormal values of γ GT and transaminases. The ERCP and biopsy did reveal any hepatic involvement neither biliary obstruction. Moreover, a NMR was performed because of hypotonia and mental retardation and corpus callosum agenesis was evidenced. An ABR exam revealed also a monolateral sensorineural hypoacusia. The patient presents with heterochromia irides, wide nasal bridge, short nose with smooth philtrum, mild retrognathia and legs' hypopigmented skin patches. For the clinical signs a syndrome was suspected and a standard karyotype was performed. The analysis indicate an interstitial deletion of the long arm of chromosome 13. To better define the chromosomal anomaly we performed a CGH Arrays. The result showed the presence of a $12,5 \pm 1,9$ Mb deletion at 13q31.1 à q21.32 region. The deletion involves the EDNRB gene, linked to WS4. Because of the presence of the other signs that don't fit with WS4 phenotype, we are trying to correlate the clinical features with the deleted genes.

P02.088

Prenatal detection of an interstitial 10p deletion: case report

L. Lecerf¹, S. Whalen¹, J. Levailan², N. Chevalier², L. Druart³, M. Portnoi⁴, M. Goossens¹, I. Giurgea¹;

¹INSERM U841, Hôpital Henri Mondor, Créteil, France, ²Service de gynécologie-obstétrique, Centre Hospitalier Intercommunal de Créteil, Créteil, France, ³Dpt de cytogénétique, Laboratoire LCL, Paris, France, ⁴Dpt de cytogénétique, Hôpital Trousseau, Paris, France.

Background: Partial 10p monosomy is a rare chromosomal abnormality, with approximately 50 reported patients. Phenotypic spectrum of patients with chromosomal rearrangements of that region is wide. A critical haploinsufficiency region for DGS/VCFs (resembling Di George syndrome) has been described in certain patients with 10p13p14 deletion. This region encompasses two different loci, HDR1 (hypoparathyroidism, deafness, renal dysplasia) and DGCR2 (cardiac defect, T cell deficiency), but the phenotype-genotype correlation is not clear. No cases of deletions more proximal that these loci have been reported.

Case report: We report a prenatally diagnosed interstitial deletion of 10p in a male patient. Antenatal karyotype was undertaken after cerebral ventriculomegaly and ventricular septal defect (VSD) were detected. An interstitial 10p deletion was diagnosed, with normal FISH of DGCR2 locus. Few days later, the patient was born, at term, with normal growth parameters. At 13 months of age, growth was on -1.5 SD with postnatal microcephaly. He had delayed psychomotor development, axial hypotonia and peripheral hypertonia. Facial dysmorphism included bilateral ptosis and epicanthus, anteverted nares, dysplastic ears and Cupid's bow upper lip. Severe bilateral deafness, perimembranous VSD, bilateral cryptorchid, chorio-retinal coloboma and toe

camptodactyly and syndactyly were noted. Brain MRI showed ventriculomegaly, cerebellar hypoplasia and bilateral anterior optic nerve hypoplasia. Array CGH was performed after birth in order to determine the precise 10p deletion, and revealed a proximal deletion: 10p11.2-p12.1.

Conclusion: We report a patient with prenatally detected unreported proximal interstitial 10p deletion, with multiple congenital abnormalities, including conotruncal cardiac malformation, deafness, cerebral malformations and specific dysmorphism.

P02.089

Molecular cytogenetic characterization of an interstitial 14q24q32 deletion in a girl with corpus callosum hypoplasia

i. ouertani¹, m. chaabouni¹, l. kraoua¹, f. maazoul¹, i. chelly¹, l. ben jema¹, m. le lorcht², h. chaabouni¹;

¹department of congenital and hereditary disorders, tunis, Tunisia, ²department of cytogenetics, embryology and feotopathology, paris, France.

Interstitial deletions of 14q including the q31 region are uncommon. Only 15 cases were reported.

We report on a 3 year-old Tunisian girl with an interstitial deletion of the long arm of chromosome 14 diagnosed by standard karyotype.

The girl presented with dysmorphic features, developmental delay and hypoplasia of corpus callosum. Using Fluorescent In Situ Hybridization technique (FISH), we characterized the deletion boundaries corresponding to the Bacterial Artificial Chromosomes (BAC): RP11-50114 and CTD2348N10.

The karyotype was interpreted as 46,XX,del(14)(q24.3q32.2) covering nearly 24Mb.

Our patient shares with the previously reported 14q31 deletions some similar features such as microcephaly, hypotonia, ears abnormalities, strabismus, hypertrichosis and carp mouth.

She presents a corpus callosum hypoplasia on cerebral MRI which the first time reported in association to such deletion.

However, the hypoplasia of corpus callosum is described only in our patient. We propose that the deleted region in our patient could present a candidate gene for this cerebral abnormality.

P02.090

A 0.43 Mb region within the 1q44 commonly deleted in three patients with microcephaly and agenesis of the corpus callosum

A. Caliebe¹, J. I. Martin-Subero¹, J. J. S. van der Smag², H. Y. Kroes², R. van 't Slof², R. J. Nijvelstein³, K. Alfke⁴, U. Stephan⁵, R. Hochstenbach², R. Siebert¹, M. Poo⁶;

¹Institute of Human Genetics, Kiel, Germany, ²Department of Medical Genetics, Utrecht, The Netherlands, ³Department of Pediatric Radiology, Utrecht, The Netherlands, ⁴Department of Neuroradiology, Kiel, Germany, ⁵Department of Neuropediatrics, Kiel, Germany.

Complex congenital phenotypes involving mental retardation and developmental delay frequently result from structural genome aberrations such as interstitial or subtelomeric microdeletions. Although some of these aberrations may lead to recognizable phenotypes, a high degree of phenotypic variability often complicates a comprehensive clinical and genetic diagnosis. We describe three patients who share developmental delay and mental retardation, including retarded development and limited speech abilities, hypotonia, febrile seizures or epilepsy, hypertelorism, an abnormal corpus callosum and other CNS anomalies. By high resolution oligonucleotide and SNP array-based segmental aneuploidy profiling we detected in chromosomal region 1q44 three overlapping deletions of 1.250, 4.210 and 9.436 Mb in size. The three patients share a 0.43 Mb interstitial deletion, which contains the FAM36A, HNRPU and the EFCAB2 genes. This region does not contain AKT3 and ZNF238, two previously proposed candidate genes for microcephaly and agenesis of the corpus callosum. Therefore, we conclude that the HNRPU gene, which is deleted in all deletion 1q44 patients reported thus far, may represent an additional candidate for the core features of the terminal 1q deletion syndrome. Since only one of the two patients with deletions including the ZNF124 gene showed a Dandy Walker Malformation, mere hemizygoty for this gene seems not to be sufficient to cause this anomaly.

P02.091

Identification of a rare cytogenetic aberration of chromosome 5 identified by fluorescent in situ hybridization

L. Losonczy, M. Dobos, J. Szabó, J. Szabolcs, T. Bense, G. Fekete;
2nd Department of Pediatrics, Budapest, Hungary.

Introduction: We report a rare cytogenetic aberration of chromosome 5.

Case report: Our patient, after delivered from second, with polyhydramnion complicated pregnancy, had bradycardia and cyanosis. His gestational age was 39 weeks, and the birthweight was 2910 grams. After delivery he had to be ventilated for some minutes. He got antibiotics because of perinatal infection. During feeding he became cyanotic. Echocardiography revealed 10 mm wide second type atrial septal defect. Neurological investigations revealed generalized hypotonia. Other characteristic finding was the baby's strange crying. Some minor anomalies could be detected, such as low and back sitting ears, short palpebral fissure, abnormal shape of the cranium, and clubbed fingers. In the family-history was no abnormality. Because of minor abnormalities and congenital heart defect cytogenetic investigations was done. The cytogenetic investigation with G bands and FISH revealed the duplication of the cri du chat region [46,XY,dup(5)(p15.2 p15.3)]. Parents' karyogram was normal. This type of cytogenetic abnormality of chromosome 5 is rare, 9 cases have been reported until now, with similar clinical and cytogenetic findings. The feeding of the infant was difficult, suffered often from infections, had failure to thrive. Because of the wide ASD the cardiac function became worse, severe pulmonary hypertonia developed. He died at the age of 6 months, with symptoms of circulatory insufficiency. Conclusion: A rare cytogenetic aberration of chromosome 5 is described, which help to understand the genotype-phenotype correlation in patients with 5p duplication.

A submicroscopic 5q11.2 deletion in a girl with autism, mild mental retardation and mild facial dysmorphism

H. Peeters¹, A. Crepel¹, K. Devriendt¹, P. De Cock², J. Vermeesch¹, J. P. Fryns¹;
¹University of Leuven, Center for Human Genetics, B-3000 Leuven, Belgium,
²University of Leuven, Child Neurology Department, B-3000 Leuven, Belgium.

We report on a female patient with autism spectrum disorder (ASD), mild mental retardation, mild facial dysmorphism and a submicroscopic 5q11.2 deletion detected by 1-Mb array CGH. In addition, a 2Mb maternally inherited duplication on Xp22.31 (RP11-483M24->RP11-323F16) was detected. Chromosomal imbalances (deletions or duplications) appear to be present in about 25% of patients with syndromic ASD. The deletion in the present patient is approximately 8 Mb in size and is flanked by the clones CTD-2276024 and RP11-210O14. Interestingly, a similar but possibly slightly smaller deletion on has previously been described in a boy with profound speech delay, obsessional play and echolalia (K Prescott *et al.* 2005). In contrast to the patient we describe, this boy presented additional malformations like a cardiac defect (tetralogy of Fallot), a bifid uvula, velopharyngeal insufficiency and short stature. Since autistic behaviour is the only consistent finding in 2 patients with a similar deletion 5q11.2, the location of this deletion may identify a gene that is implicated in autism spectrum disorders. Furthermore our observation illustrates that array-CGH should be considered as an essential aspect in the genetic analysis of patients with syndromic ASD.

P02.093

Non acrocentric sSMC: thirteen new cases

M. Santos, A. Escalona, C. Hernando, C. Fuster;
Universitat Autònoma de Barcelona, Bellaterra, Spain.

Context Small supernumerary marker chromosomes (sSMC) are common findings in Prenatal and Postnatal Diagnosis. So far, the genetic origin of these sSMC usually remained unknown. Recently the use of several technologies based on FISH has allowed an important progress toward this goal.

Objective To characterise 50 sSMC detected in unrelated patients with constitutional genetic disorders, mental retardation or infertility.

Methodology G-banding, HR-CGH and FISH (M-FISH, BACs)

Results Acrocentric sSMC were detected in 74% (37/50) of cases. Inv dup(15) was the most commonly detected sSMC followed by inv dup(13 or 21). Non acrocentric sSMC were detected in the rest of cases (26%, 13/50). sSMC derived from chromosomes 2, 3, 4, 7, 8, 9, 11, 17,

18 (three cases), 20 and X were also identified and two of them were neocentric (those derived from chromosomes 3 and 20). In two cases, we detected at least 4 sSMC derived from the same chromosome but with different morphologies. In one they derived from chromosome 9 and in the other they derived from chromosome X. In general, we found according with the literature that the presence of euchromatin in the *de novo* sSMC is linked with an abnormal phenotype.

Conclusion The use of combined molecular cytogenetic techniques revealed that the incidence of non acrocentric sSMC is probably higher than expected.

P02.094

Familial chromosomal rearrangement with an extra micro derivative 22 compensating a 22q11.2 deletion

J. Nevado^{1,2}, M. A. Mori^{1,2}, L. Fernández^{1,2}, P. D. Lapunzina^{1,2}, B. Garcia³, M. L. De Torres^{1,2};

¹Hospital Universitario la Paz, Genética Médica, MADRID, Spain, ²CIBERER, Madrid, Spain, ³Hospital Universitario Príncipe de Asturias, Bioquímica Clínica, Unidad de Genética, Alcalá de Henares (MADRID), Spain.

We described a non-consanguineous couple (33 year-old) that underwent amniocentesis for prenatal cytogenetic studies (in the 15th gestational week) due to the man is carrying an unusual rearrangement with an extra micro-chromosome, which renders a high probability to have cases of 22q11.2 deletion syndrome in the family. His karyotype is: 46, XY [22%] /47, XY, + mar [78%]. ish del (22) (q11.2 q11.2) (D22S987E-D22S976E-) / ish del (22) (q11.2 q11.2) (D22S987E-D22S976E-), + mar. ish der (22) (D22S987E-D22S976E+).

The prenatal cytogenetic study, including FISH, in amniotic fluid (43 cells studied from three independent cell cultures) and cord blood (100 cells studied) showed a deletion in region 22q11.2: 46, XY. ish del (22) (q11.2 q11.2) (D22S987E-D22S976E-). No trace of an extra micro-chromosome was found. In the Genetic counselling clinics the couple was told about the consequences of 22q11.2 deletion syndrome and they decided termination of the pregnancy.

An important remark in this family is that, members who are carrying the extra chromosome are phenotypically normal because they are chromosomally balanced at this region. Thus, it must be important to rule out the 22q11.2 deletion, using FISH and/or MLPA, in members of the family with apparently normal number of chromosomes.

P02.095

Autistic features with speech delay in a girl with an ~1.5 Mb deletion in 6q16.1, including FUT9 and GPR63

K. W. Derwinska^{1,2}, J. Bernaciak¹, E. Obersztyń¹, E. Bocian¹, P. Stankiewicz^{1,2};

¹Institute of Mother and Child, Warsaw, Poland, ²Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX, United States.

Recent studies have shown that up to 40% of the apparently balanced reciprocal chromosome translocations in patients with abnormal phenotype can be accompanied by a chromosome imbalance. We present a 10-year-old girl with mild mental retardation, abnormal EEG, and autistic behavior, who began to speak at 5 years. She had no dysmorphic features and her brain MRI was normal. Karyotype analysis revealed a *de novo* apparently balanced translocation t(6;14)(q16;q22). Whole genome array CGH analysis with ~385,000 oligonucleotide probes (NimbleGen) identified an ~1.48 Mb deletion in 6q16.1. FISH with BAC clones mapping within and directly flanking the deleted segment showed that the deletion arose at the translocation breakpoint. Interestingly, autism has been linked previously to chromosome 6q16. The deleted segment harbors FUT9, GPR63, FHL5, KLHL32, c6orf66, and AK091365 and two predicted genes c6orf167 and KIA0776. GPR63 is expressed almost exclusively in the brain and encodes a G-protein-coupled receptor for sphingosine 1-phosphate. The fucosyltransferase 9 gene, FUT9, is highly conserved among humans, mice, rats, and hamsters and is highly expressed in brain during embryogenesis. FUT9 is considered to be involved in cell-cell interactions, differentiation, and neurodevelopmental processes. Our data confirm previous observations that copy-number variation is a significant factor responsible for autistic spectrum behavior and speech delay.

P02.096

Delineation of a Critical Region on Chromosome 18 for the del(18)(q12.2q21.1) Syndrome

K. Buysse¹, B. Menten¹, A. Oostra², S. Tavernier³, G. R. Mortier¹, F. Speleman¹;
¹Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium, ²Center for Developmental Disorders, Ghent University Hospital, Ghent, Belgium,
³M.P.I.G.O. 't Vurstjen, Evergem, Belgium.

Array CGH has been instrumental in the identification of submicroscopic chromosomal aberrations leading to mental retardation and congenital abnormalities (MR/MCA), the delineation of new microdeletion syndromes and the identification of genes implicated in MR/MCA syndromes. An important step prior to assigning particular phenotypic features to particular genes is the delineation of critical regions for these specific clinical features. To this purpose, smaller interstitial deletions can be particularly important. In some syndromes, haploinsufficiency of a single gene appears to be responsible for most of the phenotypic features, as is the case for the EHMT1 gene in the 9q34 subtelomeric deletion syndrome. In contrast to distal 18q deletions, proximal interstitial deletions encompassing chromosome band 18q12.3 and parts of neighboring bands (q12.2→q21.1) have been reported less frequently. Up to now, 24 patients carrying such deletions were described. Accurate genotype-phenotype correlations are only possible for those cases for which breakpoints have been molecularly defined.

Here we describe a boy with a submicroscopic deletion of less than 1.8 Mb of subband 18q12.3. The phenotypic features of the proband correspond well with those observed in patients with larger cytogenetically detectable deletions encompassing chromosome band 18q12.3. The deletion has been characterized at the molecular level which is important for defining small regions and eventually specific genes associated with specific phenotypic features. The deletion enabled us to define a critical region for the following features of the del(18)(q12.2q21.1) syndrome: hypotonia, expressive language delay, short stature and behavioral problems.

P02.097

A novel sex determining locus in a 46,XX-SRY negative sex reversal patient carrying a t(8;19)(q22.1;q13.1)

N. Najera, J. Berumen, S. Kofman, J. Perez, G. Queipo;
 Hospital General de Mexico/Facultad de Medicina, Mexico City, Mexico.

The sex determining genes SRY and SOX9 are required to initiate and maintain testicular development. However, genetic interactions controlling the earliest steps in gonadal development remain poorly understood. The molecular abnormalities underlying a high proportion of XX maleness remain undiscovered. Using of high density SNP array in sex reversal patients could be useful to characterize the etiology of the abnormal gonadal development and provide new molecular insights into the normal regulatory network in the testis and ovary development. We performed SNPs microarray genotyping (Affymetrix geneChip 500k) to investigate homozygosity mapping and LOH in a nuclear family (mother, father, siblings) of a 46,XX-SRY negative male carrying a t(8;19)(q22.1;q13.1). In addition we analyzed 10 sporadic SRY negative XX male. The results were also compared with the International HapMap. The analysis of the break points in the patient revealed in chromosome 19 three intervals with 59, 89, 25 and 15 homozygous SNPs and three regions containing 83, 73 and 57 LOH SNPs located in chromosome 8. Analysis of the data revealed four sex determining genes candidates, we present and discuss the genomic data and the analysis performed in order to identify a novel locus involved in the testicular development in humans.

Prenatally diagnosed recombinant offsprings resulting from adjacent-1, adjacent-2, 3:1 segregation modes of reciprocal translocations:fish and cytogenetic studies

O. Sezer, F. Ekici, B. Ozyilmaz, M. Tosun, M. Ceyhan, O. Aydin, I. Kocak, G. Ogur;

Ondokuz Mayıs University Medical Faculty, Samsun, Turkey.

Balanced translocation carriers can have recombinant offsprings due to adjacent-1, adjacent-2, 3:1 and 4:0 segregation modes. Here, we report three prenatally diagnosed recombinant fetuses resulting from balanced parental translocations.

Case1:Amniocentesis was performed because of bilateral choroid plexus cysts and hyperrechogenic bowel. Fetal karyotype showed a de-

rivative chromosome 1p[46,XY,der(1)t(1;?)(p36,1;?)] which was paternally originated:46,XY,t(1;8) (p36,1;p21,3)]. FISH confirmed translocation between chromosomes 1 and 8; fetal karyotype was interpreted as partial monosomy 1p/partial trisomy 8p. Adjacent-1 segregation mode was suggested. Parents decided to terminate the pregnancy. Fetus presented facial dysmorphism, limb abnormalities, cerebellar hypoplasia, ventriculomegaly, bilateral choroid plexus cysts, lung defects.

Case2:Amniocentesis was performed due to fetal abnormalities: cleft lip/palate, tetralogy of fallot, ASD, single artery/vein of umbilical cord. Cytogenetics revealed unbalanced chromosomal translocation:46,XY,der(15)t(10;15) (q22,2;q11,2), paternally derived [46,XY,t(10;15)(q22,2;q11,2)]. Adjacent-2 segregation mode was suggested. FISH analysis confirmed der(15)t(10;15). Pregnancy ended spontaneously after amniocentesis. The fetus couldn't be investigated.

Case3:Amniocentesis was performed because of positive maternal serum triple screening. Cytogenetics revealed a supernumerary chromosome(47,XY,+mar). Parents were karyotyped. The mother showed balanced reciprocal translocation:t(2;14)(p23;q23). Supernumerary chromosome was identified as part of chromosome 14 (FISH analysis). Fetal karyotype was interpreted as:47,XY,+der(14)t(2;14)(p23;q23)mat; partial trisomy 2p/partial trisomy 14q due to 3:1 segregation was suggested. Pregnancy was terminated. Extensive clinical evaluation showed fetal dysmorphism and open cranial sutures.

P02.099

Male pseudohermaphroditism: a case report

N. Andreescu, V. Belengeanu, D. Stoicanescu, S. Farcas, C. Popa, M. Stoian;
 University of Medicine and Pharmacy "Victor Babes", Timisoara, Romania.

Male pseudohermaphroditism is characterized by the presence of 46, XY karyotype, exclusively male gonads and ambiguous or female external and/or internal genitalia, caused by incomplete virilization during prenatal life. We report the case of an infant, in whom physical examination showed ambiguous external genitalia and some dysmorphic features. Cytogenetic investigation was performed for the correct assignment of the gender and chromosome analysis in blood lymphocytes revealed male genetic sex. The ambivalent aspect of the external genitalia, the gonads that are exclusively testes together with the result of the cytogenetic analysis showing male genetic sex, led to the diagnosis of male pseudohermaphroditism. A multidisciplinary approach involving pediatricians, specialists in the field of endocrinology, genetics, surgery and psychiatry is necessary in order to reach a prompt and correct diagnosis and treatment. In conclusion, careful examination of the external genitalia of every newborn should be systematic. Early diagnosis of a disorder of sexual development is of great importance as is the appropriate gender assignment. The most important decision will be the choice of sex assignment, which will depend on many complex factors. Birth registration should be postponed until the diagnostic evaluation enables the most appropriate choice of sex for rearing. The clinical management will help the child and the family deal effectively with this disorder.

P02.100

PCR based technique for sex selection in cattle

E. Arbabai¹, F. Mahjoubi¹, M. Eskandainasab², M. Montazeri¹;
¹NRCGEB, Tehran, Islamic Republic of Iran, ²Zanjan university, Tehran, Islamic Republic of Iran.

Embryo sexing is an important way for sex selection of offspring. This is a potential method to considerably improve animal breeding and the efficiency of dairy and meat production. A novel repeated sequence specific to male cattle has been identified and named S4. S4 is a 1/5 Kb repeating unit and which also contains various internal repeated sequence. S4 is localized on the long arm of the Y chromosome in the region of ZFY genes.

Aim: The objective of this study is to identify embryo sexing by a simple and precise PCR method.

Materials and Methods: Genomic DNA was extracted from the whole blood samples. Two sets of specific primers were designed
 Result: By this PCR based methods we could differentiate between female and male genomic DNA.

Discussion: With this technique we can distinct males from females. This method has the potential to be employed for embryonic sex selection.

P02.101**Case report: A case of a rare translocation of SRY region of the Y chromosome to the short arm of the X chromosome**

V. Radoi, L. Neagu, D. Mierla, D. Jardan;

Life Memorial Hospital, Bucharest, Romania.

The 46, XX karyotype male syndrome is a rare sex chromosome disorder occurring in less than 1 in 25 000 individuals. It mostly results from unequal crossing-over between the X and Y chromosomes during meiosis. Here we report a two weeks old boy with bilateral cryptorchidism and penile hypospadias. Chromosomal analysis revealed a 46, XX karyotype and the FISH test showed the presence of the SRY region of the Y chromosome translocated to the short arm of the X chromosome. SRY gene located in this region is the main gene responsible for gonadal differentiation in the male and it is essential for the normal development of male genitalia. This report confirms the value of karyotyping and FISH analysis in the cases of ambiguous genitalia.

P02.102**Mosaicism characterization in male with 46,XX SRY positive karyotype**

O. M. Khurs, A. D. Polityko, N. V. Rummyantseva, I. V. Naumchik; Republican Medical Center "Mother and child", Minsk, Belarus.

46,XX "male syndrome" is rare chromosomal disorder in human that occurs at about 1 in 20 000 - 25 000 males. The SRY gene, located at p11.3 chromosome Y, plays a key role in human sex determination and is responsible for the reproductive system morphogenesis. Most 46,XX male individuals with normal genitalia and karyotype 46,XX are SRY positive. This chromosomal aberration arises due to an unequal recombination between Xp and Yp terminal region during paternal meiosis.

Here we present a case of an infertile (azoospermia) 32 years old male, who has normal masculinization of the external genitalia. A standard cytogenetic study revealed the karyotype 46,XX in 25 analyzed metaphases.

FISH analysis using LSI SRY probe Spectrum Orange (Vysis) showed the presence of single SRY gene signal in 50 metaphases studied.

The subsequent FISH using chromosome X WCP probe Spectrum Orange (Vysis) has demonstrated the localization of SRY signal on p-arm of chromosome X, and constitutional karyotype abnormality was interpreted as 46,XX,ish der(X)t(X;Y)(p22.3;p11.3)(SRY+). Furthermore the analysis of 184 metaphases has allowed to ascertain the mosaic status of the karyotype in lymphocytes: 45,X,ish (wcpXx1)[4]/47,XXX,ish (wcpXx3)[3]/48,XXXX,ish (wcpXx4)[1]/46,XX,ish (wcpXx2)[176].

The results obtained demonstrate the advantage of FISH for detecting low-grade mosaicism in patients with anomalies of sex chromosomes.

[Supported in parts by DAAD 325/2003, DFG WER 17/01/04].

P02.103**Clinical, Cytogenetic and Molecular Cytogenetic Study of Three XX Male Cases**

H. A. Hussein, I. I. Mazen;

National Research Centre, Cairo, Egypt.

46,XX male is a rare disorder that occurs at about 1 in 20,000 males. It is due to accidental recombination between the short arm of the Y chromosome and the short arm of the X in paternal meiosis. This results in translocation of the SRY gene from the Y to the X chromosome.

Aim of this study is to report and highlight the value of cytogenetics and (FISH) analysis for males with 46, XX Karyotype, since the phenotype does not always correlate with the presence or absence of Y sequences in the genome.

In this report we present clinical, cytogenetic and molecular cytogenetic data of three patients referred to human cytogenetics department from Clinical genetic department. Two patients presented with infertility with normal male external genitalia and one patient was presenting with ambiguous genitalia. Ultrasonography revealed no müllerian derivatives in the three patients.

Cytogenetic results for the three cases revealed 46, XX karyotype. FISH analysis showed the presence of SRY gene on the short arm of X chromosome in cases numbers 1 & 2 and its absence in case number 3.

Analysis of these results illustrated that combined conventional cytogenetic and FISH techniques are essential for accurate diagnosis and

proper genetic counseling. Therefore we recommend performing molecular cytogenetic (FISH) in cases of male infertility or male genital ambiguity.

P02.104**A 14 bp deletion in the sry gene associated with xy sex reversal**E. Margarit^{1,2}, R. Queralt¹, M. Guitart³, E. Gabau³, R. Corripio³, A. Soler^{1,2}, A. Sánchez^{1,2};

¹Biochemistry and Molecular Genetics and IDIBAPS, Hospital Clínic, Barcelona, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Barcelona, Spain, ³Consorci Hospitalari Parc Taulí, Sabadell, Spain.

Sex-reversed XY females can arise from different mechanisms. About 15% of the XY females with pure gonadal dysgenesis are found to have mutations in the testicular determinant gene SRY (Sex Reversal on chromosome Y), specially affecting the high mobility group conserved region HMG box. The SRY gene is located at Yp11.31 and induces male sexual differentiation in human embryos from the 6th week of gestation. The failure of this process causes gonadal dysgenesis in complete or incomplete form, depending of the presence or not of testicular tissue remnants. Here we present a female 15 years old with no pubertal development, hypergonadotropism, obesity and diabetes, showing a 46,XY karyotype. The existence of the SRY gene was confirmed by PCR. Sequencing of SRY revealed a deletion of 14 nucleotides in the coding sequence of the gene (2188delAAAAGCTG-TAACTCT), located in the 5' region upstream of the HMG box. The deletion of these nucleotides originates a stop codon that will give rise to a severely truncated protein. This defective SRY protein lacks the entire DNA-binding HMG domain and will therefore most likely be non-functional. Only four different deletions have been previously identified in the SRY gene (HMGD database) associated to XY sex-reversal.

P02.105**Molecular analysis of SRY identifies familial and de novo mutations in 46,XY females with different phenotypes of gonadal dysgenesis**J. M. S. Goncalves¹, D. Gomes¹, J. Silva¹, A. Parreira¹, A. Medeira², T. Kay³, T. Oliveira⁴, L. Cortez⁵, J. Cidade Rodrigues⁶;

¹Instituto Nacional de Saúde, Centro de Genética Humana, Lisbon, Portugal, ²Serviço de Genética Médica, Hospital de S^{ta} Maria, Lisbon, Portugal, ³Serviço de Genética Médica, Hospital de D Estefânia, Lisbon, Portugal, ⁴Maternidade Júlio Dinis, Porto, Portugal, ⁵Serviço de Endocrinologia, Hospital Curry Cabral, Lisbon, Portugal, ⁶Hospital de Crianças Maria Pia, Porto, Portugal.

In human males, normal testicular determination is firstly triggered by the action of the SRY protein, which is encoded by a single exon-gene (SRY) located on Yp11.3. SRY has a high-mobility group (HMG) domain, which is able to bind and bend DNA. *De novo* point mutations in SRY that arise mainly in the HMG box domain, were identified in 46,XY female patients with complete gonadal dysgenesis (CGD). However, even very rarely, familial SRY mutations were already described.

Here, we describe eight 46,XY female patients with mutations in the SRY gene, seven with CGD and one with ambiguous external genitalia. Molecular studies were performed using four sets of primers, from nucleotides -323 to +950 of the SRY. PCR amplified DNA fragments were analysed by SSCP or DHPLC, and subsequently sequenced when appropriate.

In two patients with CGD, a microdeletion including all SRY coding region was found. In the remaining six patients the following point mutations were detected: c.53G>A(p.S18N); 89G>T(R30I); c.169C>T(E57X); 224G>T(p.P63A). While the last two, were not described before, and are *de novo* mutations, c.53G>A(p.S18N) and 89G>T(R30I) were also found in both patients' fathers. 89G>T(R30I) was also detected in a first degree cousin (phenotypically normal) of one of the female patients with CGD. None of the above mutations were found in more than 100 phenotypically normal unrelated males. We evidence, that while some SRY mutations may be the cause of complete gonadal dysgenesis, others are associated with phenotypic heterogeneity, supporting the existence of modifier genes implicated in sex determination.

P02.106**Aneuploidy of chromosome 21 in the Alzheimer's disease brain**Y. B. Yurov^{1,2}, I. Y. Iourov^{1,2}, S. G. Vorsanova^{1,2}, T. Liehr³;¹National Research Center of Mental Health, RAMS, Moscow, Russian Federation, ²Institute of Pediatrics and Children Surgery, Rosmedtechnologii, Moscow, Russian Federation, ³Institute of Human Genetics and Anthropology, Jena, Germany.

Apart from single gene mutations, Alzheimer's disease (AD) is suggested to be associated with mosaic aneuploidy of chromosome 21. This hypothesis has been repeatedly supported by studies of AD blood lymphocytes and skin fibroblasts. However, the diseased brain has not been directly studied. We have performed molecular cytogenetic studies by interphase chromosome 21-specific multicolour banding on cells of AD brain samples derived from the cerebral cortex, hippocampus and cerebellum. The analysis was performed through evaluation of about 14000 interphase nuclei. Control samples exhibited mean rate of aneuploid cells to be about 0.7% (all brain areas). The average rate of aneuploidy achieved 4% in the AD hippocampus, 3.5% _ in the AD cerebral cortex, and 0.9% _ in the AD cerebellum. Aneuploidy manifested more frequently as chromosome 21 monosomy, but the proportion of cells with additional chromosome 21 was also significant. The monosomy-to-trisomy ratio was about 2:1. AD brain exhibited significant increase of chromosome 21 aneuploidy in the hippocampus and cerebral cortex. Interestingly, these two areas are known to be more affected by neurodegenerative processes featuring AD. Together, this suggests a correlation between molecular cytogenetic and neuropathology data. We hypothesize that increased aneuploidy rates in the AD hippocampus and cerebral cortex are the results of mitotic errors during adult neurogenesis. Our data shows that specific areas of the senescent brain can be selectively affected by acquired aneuploidy. Aneuploidization of specific brain areas is, therefore, a genetic process that is likely involved in the pathogenesis of AD.

P02.107**Evaluation of micronuclei and nondisjunction frequencies in workers exposed to internal plutonium by cytokinesis-blocked binucleated cells assay**

S. A. Vasilyev, V. A. Timoshevskiy, I. N. Lebedev;

Scientific Research Institute of Medical Genetics, Tomsk, Russian Federation.

Damage or dysfunction of any component of mitotic segregation complex by mutagens can lead to mistakes in chromosome number. One of the most reliable methods of aneuploid influence detection is FISH-analysis of cytokinesis-blocked binucleated cells. Detection of micronuclei in these investigations is an indicator of clastogenic effects. We have tested abilities of this approach on a group of Siberian Chemical Plant (SCP) workers exposed to internal plutonium. We have formed groups of exposed individuals - SCP workers with incorporated plutonium (10-276 nCi) - 70 individuals, and control set - people living in Seversk and not exposed of nuclear-chemical agents - 50 individuals. In preliminary analysis we have demonstrated that missegregation frequencies for chromosomes 7 and 12 was 0.2% for each chromosome in cells of 27 SCP workers, and 0.1% and 0.075% in 8 individuals from control group, respectively. Significantly increased frequency of nondisjunction in exposed group was noted for chromosome 12 only ($p=0.03$). However, tendency to increase of missegregation of chromosome 7 ($p=0.06$) was observed. Significant differences in frequencies of micronuclei in exposed and control groups (0.77 and 0.74 %, respectively) were not found. Since we have carried out only a preliminary study of abnormal chromosome number frequency it is early to make conclusion about aneuploid influence of incorporated plutonium. However, we can suggest that this approach is sufficiently informative and sensitive for frequency detection of abnormalities which lead to genomic mutations. Subsequent analysis of segregation abnormalities provides some clues to the quantitative features of aneuploidy induction by internal plutonium.

P02.108**Cytogenetic effects of doxazosina a alpha-blocker antihypertensive drug: sister chromatid exchanges and micronuclei frequencies before and after pharmacological treatment**I. Arrieta Saez¹, O. Peñagarikano², M. Téletz¹, M. Barasoain¹, I. Huerta¹, J. Ramírez¹, B. Criado³, P. Flores⁴, A. González⁵;¹Dpto Genética, Antropología Física y Fisiología animal Facultad de Ciencia y Tecnología, Bilbao, Spain, ²Emory University School of Medicine, Atlanta, GA, United States, ³High School Da Maia, CESPU, Porto, Portugal, ⁴Dpto de enfermería, Escuela de Enfermería, Bilbao, Spain, ⁵Dpto Medicina Interna, Facultad de Medicina, Bilbao, Spain.

Arterial hypertension is a health problem representing one of the most frequent diagnoses in the population at large in terms of prevalence and incidence. Drug treatment of hypertension may last for decades. Long-term treatment require documentation of long-term safety and efficacy, including sensitive indices of genotoxic damage.

In our previous works Sister Chromatid Exchange (SCE) and Micronuclei (MN) assays were applied to assess the genotoxicity of atenolol a beta-blocker antihypertensive drug and nimodipine a calcium antagonist antihypertensive in culture peripheral lymphocytes of treated patients and control individuals. The results showed no genotoxic effect of nimodipine, however a statistical significant increase in the frequency of MN was detected in patients treated with atenolol. Application of FISH with an alphoid stellite probe revealed also a statistical significant higher percentage of centromere positive MN.

We report here our data from a study of the genotoxic potential of Doxazosina. The pharmacological application of the antihypertensive Doxazosina is due to their ability to block alpha receptors. This antihypertensive was tested for its ability to induced SCE and MN in cultured human peripheral blood lymphocytes of patients before and after pharmacological treatment, so that the patient is control himself.

The results of the study revealed that the frequency of SCE did not show significant differences. However a statistical significant increase in the frequency of centromere positive MN was detected, thus indicating more frequent involvement of aneuploidy phenomena in the origin of Doxazosina-induced MN.

P02.109**Chromosome instability in the ataxia telangiectasia cerebellum**I. Y. Iourov^{1,2}, S. G. Vorsanova^{1,2}, T. Liehr³, A. D. Kolotiř, Y. B. Yurov¹;¹National Research Center of Mental Health, RAMS, Moscow, Russian Federation, ²Institute of Pediatrics and Children Surgery, Rosmedtechnologii, Moscow, Russian Federation, ³Institute of Human Genetics and Anthropology, Jena, Germany.

Ataxia-telangiectasia (AT) is a chromosome instability (CIN) syndrome associated with progressive neuronal degeneration affecting exclusively the cerebellum. Molecular basis of cerebellar neurodegeneration in AT is unknown, but hypothesized to be closely linked to the loss of genome integrity in the cerebellar neural cells manifesting as CIN. Here, we monitored CIN in the AT brain by interphase chromosome-specific multicolour banding allowing analysis of interphase chromosomes in their integrity. We found stable 2-4-fold increase of stochastic aneuploidy involving whole chromosomes 7 and 14 in the cerebellum of the AT brain as to controls. Additionally, dramatic 5-40-fold increase of CIN involving chromosome 14 (aneuploidy (including supernumerary rearranged chromosomes) and non-random chromosome breaks) as to other brain areas has been revealed. The latter was found to progress with the age of patients. Paradoxically, the longevity of AT patients was in direct proportion to CIN levels in the cerebellum. We hypothesize that aneuploidization and acquired CIN may result from autoactivation of aberrant processes triggered in response to progressive neuronal degeneration. Newly generated neural cells, being genetically abnormal, nevertheless, partially substitute the loss of cells in the cerebellum and play an ameliorative role in stabilization of the diseased brain homeostasis. We suggest CIN in the AT cerebellum to be involved in processes that mediate either neurodegeneration or endogenous neuroprotection. The way CIN is progressed, can be, therefore, proposed as definitive for the course of neurodegeneration and for cerebellar dysfunction in AT patients.

P02.110**CSMD3, a candidate gene for autism found in two patients with autistic disorder and balanced translocations**

C. Floris¹, S. Rassu², L. Boccone³, D. Gasperini³, A. Cao¹, L. Crisponi¹;

¹Istituto di Neurogenetica e Neurofarmacologia INN-CNR, Monserrato (CA), Italy, ²Dipartimento di Scienze Biomediche e Biotecnologie, Università degli Studi di Cagliari, Cagliari, Italy, ³Ospedale Regionale per le Microcitemie, Clinica Pediatrica II, Azienda U.S.L. 8, Cagliari, Italy.

The study of chromosomal rearrangements associated with abnormal phenotypes has proven to be a powerful method for the identification of disease-related genes. Recent studies estimated a rate of 3-5% of cytogenetic abnormalities involving many different chromosomes in autistic spectrum disorders (ASDs). We report here on two unrelated males with *de-novo* translocations, autistic behaviour and psychomotor delay. They carry balanced chromosome translocations, respectively a t(5;8)(q14.3;q23.3) and t(6;8)(q13;q23.2). A detailed physical map covering the regions involved in the translocations was constructed and FISH analyses were carried out using BAC clones mapping on chromosomes 5q14.3, 6q13 and 8q23. We fine mapped the two translocation breakpoints on chromosomes 8 identifying their positions within a short 5 Mb genomic region. The results of these analyses showed that breakpoints on chromosomes 8 in both patients do not interrupt any known gene but both map in a region containing the *CSMD3* gene. No genes were interrupted on chromosomes 5q14.3 and 6q13. Taking into account that *CSMD3* is expressed in fetal and adult brain, our observations suggest that this gene is a good candidate for the pathogenesis of ASDs. To exclude an over-expression or under-expression of *CSMD3* led by the rearrangement, we verified the expression of this gene in the leukocytes of the translocated patient by RT-PCR, but any transcript was detected. Future studies, including mutational analysis of *CSMD3* in a large number of patients affected by autism and behavioural studies on a *Csmd3* knockout mouse, will be necessary to confirm or decline this hypothesis.

P02.111**Cytogenetic study of the BPES cases**

M. Kumar¹, M. Tanwar¹, P. Gupta², N. Pushkar², R. Kumar¹, R. Dada¹;

¹Laboratory for Molecular Reproduction and Genetics, Dept. of Anatomy, All India Institute of Medical Sciences, New Delhi, New Delhi, India, ²Dr. Rajendra Prasad Centre for Ophthalmic Sciences, All India Institute of Medical Sciences, New Delhi, New Delhi, India.

Blepharophimosis ptosis epicanthus inversus syndrome (BPES) is a rare genetic disorder with autosomal dominant pattern of inheritance with a frequency of 1 in 50,000. Patients with BPES have a combination of congenital anomalies as small palpebral fissures, epicanthus inversus, low nasal bridge and congenital ptosis. Other features like microphthalmos, anophthalmos, microcornea, hypermetropia, divergent strabismus, high arched palate, cup shaped ears, mental retardation and infertility in females has been reported. BPES has been categorized into two types: type I associated with primary ovarian follicle and type II involves only eye malformation in both sexes. Penetrance is 100% in type I (transmission by males only) and 96.5% in type II (transmission through both sexes). Review of reported cases concluded that a locus for eyelid development is situated at 3q. Various reports linked the deletion in 3q21, 3q22, 3q23, 3q24, 3q25 and translocations t(3;7)(q26-qter;q+), t(X;3)(p22;q21), t(3;8)(q23;p22.1) to the BPES. We analyzed 10 cases of BPES by GTG banding. Six were males with mean age of 24 years and four were females with mean age of 27 years. Different deletions and translocation of chromosome 3 has been linked with the BPES but there is no case reported with 3q26-28 and 5q31.3-33.2 deletions which we found in two cases. We also found 3qter deletion which has already been linked to the BPES. These findings represent severe manifestation of the disease. BPES is a heterogeneous entity, and evaluation and counseling of affected individuals should be undertaken with caution.

P02.112**Are evolutionary chromosome rearrangements triggered by non-random nuclear neighbourhoods?**

S. Mueller, F. Grasser, T. Cremer, M. Neusser;
Human Genetics, Munich, Germany.

We investigated whether non-random nuclear neighbourhoods may have triggered evolutionary chromosome rearrangements, focussing

on the fusion of human chromosome 2 and the reciprocal translocation t(5;17) in the gorilla.

We analysed the nuclear topology of breakpoint flanking loci in pre- and post-meiotic cells from cryo-sections of Rhesus macaque testis tissue, where the fixation of chromosomal rearrangements is expected to occur. Chromosome 5 and 17 breakpoint flanking BAC clones did not co-localise, but were positioned toward the nuclear centre and at the chromosome territory surface. Both findings can be correlated with their rather gene-dense local genomic environment. The resulting short distances between the two loci may have acted as probabilistic trigger for evolutionary rearrangements of gene-dense genomic regions, even more if these reside exposed at the territory surface. Indeed, in silico analysis indicates that the majority of breakpoints in great apes characterized so far reside in genomic environments with elevated local gene density compared to the average of the respective chromosome.

In the light of these results it was surprising to find chromosome 2 fusion point flanking BAC clones localized in the nuclear periphery. Despite this, the two loci were frequently positioned in close physical proximity in Rhesus macaque spermatocytes, and even to a higher degree in spermatogonia.

In conclusion, non-random nuclear positioning of genomic loci during meiosis may have triggered these two evolutionary rearrangements. These triggers may be probabilistic, as shown for the t(5;17), or specific side-by-side arrangements in the case of the fusion of human chromosome 2.

P02.113**Chromosomal mosaicism of the skin: A preliminary study**

M. Pérez-Iribarne^{1,2}, C. Fons^{3,2}, M. González-Enseñat^{4,2}, A. Vicente^{4,2}, I. Plensa^{1,2}, P. Poo^{3,2}, M. Pineda^{3,2}, C. López^{1,2}, T. Zabala^{1,2}, E. Geán^{1,2};

¹Secció Genètica, Esplugues (Barcelona), Spain, ²Hospital Sant Joan de Déu, Esplugues, Spain, ³Servei Neurologia, Esplugues (Barcelona), Spain, ⁴Servei Dermatologia, Esplugues (Barcelona), Spain.

Introduction : The concept of cutaneous mosaicism has now been proved by numerous studies. It seems likely that the two skin types represent two different genotypes, even though this has been remarkably difficult to prove. Our aim is to describe the neurocutaneous symptoms and skin chromosomal mosaicism spectrum in a series of 14 pediatric patients.

Patients and Methods: We have reviewed the karyotype of cultured fibroblasts from 75 pediatric patients, who presented skin lesions suggestive of pigmentary mosaicism, studied in our institution from August 1998 to October 2007. Biopsies were obtained from both hypopigmented and hyperpigmented skin. Conventional chromosome banding studies were performed and karyotyped (ISCN, 1995).

Results: We reported 14 patients with skin mosaicism: three boys and eleven girls. Six of them presented numerical abnormalities: three cases with diploid/triploid mosaicism, two patients with a marker chromosome (one of them with persistence of the marker in peripheral blood karyotype); and one patient with a chromosome 20 trisomy and West syndrome. The rest of patients (n=8) had structural chromosomal abnormalities, with different chromosomes involved. All of them had typical linear cutaneous lesions except a two-year-old girl with Pallister-Killian syndrome.

Conclusion: There is an association between chromosomal mosaicism and hypopigmentation and hyperpigmentation especially following Blaschko lines. We did not find in all patients direct correlation between a specific chromosomal abnormality and neurological affection. Patients with atypical cutaneous lesions or with neurological symptoms could be candidates to perform a skin karyotype even though blood karyotype is normal.

P02.114**Cytogenetic effects in somatic cells of irradiated individuals with developed thyroid gland cancer**

E. Dyomina;

R.E. Kavetsky Institute of Experimental Pathology, Oncology and Radiobiology of NAS of Ukraine, Kyiv, Ukraine.

Essential growth of thyroid gland cancer (TGC) among population of extensive territories of Ukraine, Russia and Byelorussia suffered after "iodine stroke" testifies that thyroid gland pathologies - one of the most expressed health consequences of the Chernobyl accident. Data of

biologic (cytogenetic) indication of radiation injury may specify radiogenic character of TGC. Results of radiation epidemiological and cytogenetic examinations at liquidators of the Chernobyl accident consequences have confirmed the radiogenic character of TGC developed at the group of radiated persons.

Increase in frequency of malformations among endocrine pathologies from 1,4 % in 1993 up to 8,9 % in 2001 (more than in 6,3 times) was registered.

It was revealed the correlation of frequency of chromosomal aberrations - radiation markers (dicentric and rings) in peripheral blood lymphocytes with radiation dose (correlation coefficient - 6,0) in the remote terms after accident in this group of patients.

Mean value of chromosomal aberrations frequency at group of TGC patients living in territories with high density of radioactive pollution exceeds more than 2 times spontaneous level value.

Assignment to TGC patients thymine preparations is recommended in connection with the radioprotective action registered on level of chromosomal aberrations in somatic cells, and also with the purpose of improvement of quality of patient life based on effective hormonal homeostasis rehabilitation after erasion of thyroid gland.

P02.115

Individual chromosomal radiosensitivity of human lymphocytes as a parameter of cancer risk

N. Ryabchenko, E. Dyomina;

R.E. Kavetsky Institute of Experimental Pathology, Oncology and Radiobiology of NAS of Ukraine, Kyiv, Ukraine.

Cytogenetic methods based on chromosome aberrations analysis (G2-assay) make it possible quantitative estimation of radiation effects on human organism taking into account its individual peculiarities and thus to estimate its IR. The main basis for application of cytogenetic methods in radiobiology are high radiosensitivity of human PBL and formation of stage specific radiation-induced chromosomal aberrations. From the other hand elevated levels of chromosomal aberrations are considered to be the proven markers of cancer development in the calculations of cancer risk after exposure to ionizing radiation. The aim of the presented work was evaluation of chromosomal radiosensitivity of healthy individuals and determination those with the increased susceptibility to radiogenic pathologies.

On the basis of the obtained "stage-effect" and "dose-effect" dependencies for chromosomal aberrations modifications of G2-assay were developed. Analysis (in the first mitosis) of chromosomal aberrations levels induced by G2 irradiation (1,5 Gy) of PBL cultures of 110 healthy individuals revealed their high interindividual variability. The highest differences were registered for chromatid breaks which predominated in the spectrum (CV= 37,5%). Statistical analysis of the distributions of the obtained individual cytogenetic parameters indicated bimodality and make it possible to reveal 12% individuals with increased chromosomal radiosensitivity. Cytogenetic evaluation of individual chromosomal radiosensitivity based on G2-assay has its perspectives in the formation of groups with increased risk of radiogenic cancer development and its primary prophylactics among healthy population.

P02.116

Clinical Cytogenetics Study in Pediatric Pathology: A Comparison with Unselected Studies

J. M. Pina-Neto, D. Orlolan, L. F. Mazzucatto, V. Bitar, L. C. Peres;
School of Medicine of Ribeirão Preto, Ribeirão Preto, Brazil.

We studied 1558 pediatric autopsies. 33.1% had congenital anomalies. Cytogenetic evaluation was successfully performed in 298. Based on clinical criteria, karyotyping was performed in cases of isolated malformations and in cases of two malformations when presenting minor anomalies and in cases of multiple congenital anomalies except in those cases due known monogenic disorder.

The distribution by age was: 142(47.6%) perinatal deaths, 37(12.4%) late neonatal, 87(29.9%) postneonatal, 26(8.7%) preschool age, 3(1%) school age, and 1(0.3%) an adolescent.

We collected blood from superior sagittal sinus, skin and fascia from the rectus abdominis muscle.

We studied 206 cases of isolated malformations and 34 with two malformations and none presented any chromosomal anomaly. In the 256 cases of multiple anomalies were detected 70 with chromosomal anomalies. Among the cases of perinatal death there were 24 chromosomal anomalies, of those 17(70.8%) were autosomal trisomies, 4 (16.6%) were structural anomalies, 2 cases (8.8%) were triploidies and 1 case was a mosaic 46,XY/47,XY +mar. There were 46 chromosomal anomalies among the cases of postneonatal death, of those 39(84.8%) were autosomal trisomies, 5 cases of structural anomalies and 2 cases of mosaics with chromosomal markers.

The best combination for metaphases obtention was fascia and skin. The frequency of chromosomal anomalies was 4.5% (70/1558) very similar to unselected studies, but if we consider only the perinatal deaths was 2.9%(24/835) which is lower when compared with unselected studies (5.9%). Will be discussed the results comparing with unselected studies.

mosomal anomalies, of those 17(70.8%) were autosomal trisomies, 4 (16.6%) were structural anomalies, 2 cases (8.8%) were triploidies and 1 case was a mosaic 46,XY/47,XY +mar. There were 46 chromosomal anomalies among the cases of postneonatal death, of those 39(84.8%) were autosomal trisomies, 5 cases of structural anomalies and 2 cases of mosaics with chromosomal markers.

P02.117

Chromosomal mosaicism in spontaneous abortions: a case-control study of 500 consecutive chorionic villus samples by interphase FISH (I-FISH)

S. G. Vorsanova^{1,2}, I. Y. Iourov^{1,2}, A. D. Kolotij¹, E. A. Kirillova³, V. V. Monakhov², I. A. Demidova^{1,2}, A. K. Beresheva^{1,2}, V. S. Kravets¹, O. S. Kurinnaya¹, I. V. Soloviev², Y. B. Yurov^{1,2};

¹Institute of Pediatrics and Children Surgery, Rosmedtehnologii, Moscow, Russian Federation, ²National Research Center of Mental Health, RAMS, Moscow, Russian Federation, ³Woman's Medical Center, Moscow, Moscow, Russian Federation.

Spontaneous abortions (SA) commonly arise from chromosomal abnormalities, which are usually assessed by standard cytogenetic techniques. This suggests significant underestimation of chromosomal mosaicism and application of interphase molecular cytogenetic techniques (i.e. FISH) for uncovering the true occurrence of mosaics among SA. We have analyzed 500 consecutive chorionic villus samples derived from SA by interphase FISH (I-FISH) with DNA probes for chromosomes 9, 13/21, 14/22, 15, 16, 18, X and Y. Chromosome abnormalities were found in 50% of cases. We detected aneuploidy in 39.6% of samples (aneuploidy of chromosome 16 - 10%; monosomy of chromosome X - 8.2%; polysomy of chromosome X - 5.2%; aneuploidy of chromosome 13 or 21 - 5%; aneuploidy of chromosome 14 or 22 - 4.6%; aneuploidy of chromosome 15 - 3.2%; aneuploidy of chromosome 18 - 2.2%; aneuploidy of chromosome 9 - 1.2%). Polyploidy was found in 10.2% of cases. One case was a chimera with multiple aneuploidies (case reported in Vorsanova et al., 2006). Multiple chromosome abnormalities manifested as aneuploidy involving both autosomes and sex chromosomes was detected in 3.7% of cases. Chromosomal mosaicism (aneuploidy/polyploidy affecting at least 5% of cells) was detected in 23.6% of all cases and 47.6% of cases with chromosome abnormalities. To the best of our knowledge, the present set of SA samples is the largest one analyzed by I-FISH. Our data demonstrate that chromosomal mosaicism is highly frequent and provide evidence that chromosomal mosaicism is better to study by I-FISH, rather than alternative approaches. Supported by Philip Morris USA.

P02.118

Chromosomal translocations in couples with recurrent miscarriage - a retrospective study

C. Gug¹, I. Cioata¹, A. Cretu¹, G. Budau¹, M. Cartis¹, L. Stelea¹, F. Dorneanu¹, M. Munteanu¹, D. Hutanu¹, N. Milos¹, L. Sabau²;

¹University of Medicine and Pharmacy "Victor Babes", Timisoara, Romania, ²University of Oradea, Faculty of Medicine and Pharmacy, Oradea, Romania.

Studies have shown that couples with reproductive loss have a high frequency regarding chromosomal translocations (of 3% for females and 2% for males). This study presents the results of conventional cytogenetic analysis in 700 couples referred to our genetic center. Chromosomal analyses were performed using Giemsa-banding according to standard procedure on peripheral lymphocytes. Each couple has received genetic counseling. Translocations have been identified in 23 cases, 11 in male patients and 12 in female patients. Two Robertsonian translocations *rob(13;14)* have been found in male patients, in different families and 5 types of balanced translocations, on a number of 9 male patients: *t(2;21)(q34;p11.2)* one case, *t(4;16)(q34;q24)* one case, *t(2;17)(p22;q21)* one case, *t(7;15)(q14;q27)* one case, *t(7;14)* one case, *t(7;18)(p13;q11)* one case, *t(1;5)(q23;p12)* three cases in one family. In women patients, we have identified one case of Robertsonian translocation, *rob(13;22)*, and 9 different types of balanced transloca-

tions in 11 persons: t(1,5)(q42.2;q35.2) one case, t(8;16)(q22.2;q13) one case, t(8;X)(q24.2;q26) one case, t(7;10)(p22;p12.1) two cases, t(8;11)(q22.3;q13.5) two cases, t(5;8)(31.2-ter) one case, t(17;20)(q12;q11) one case, t(6,11,12) one case, t(3;6)(q21;q23.2) one case. The frequency of translocations in our study is similar with those present in other studies, and was almost equal in males and females. Knowing the fact that one person is a translocation carrier confirms the etiology of recurrent miscarriage, and allows us to determine the risk of recurrence. These couples received the recommendation to perform amniocentesis in future pregnancies. Both genetic counseling and cytogenetic analysis should be performed before the application of an assisted reproductive technology.

P02.119

Identification of chromosomal aberrations in Maruthamalai hills, Coimbatore city, India

L. Balasubramaniam, V. Balachandar, R. Sangeetha, K. Suresh, K. Sasikala; Human Genetics Laboratory, School of Life Sciences, Bharathiar University, Coimbatore, India.

The aim of the study was to identify dwellers risk of irradiation exposure in the Maruthamalai hills, Coimbatore. The present study analyzed levels of chromosomal aberrations, a well-known biomarker of early biological effects and a predictor of cancer risk. Cytogenetic analyze has remained the most suitable assay for the evaluation of the genetic damage induced in somatic cells by clastogens present both in occupational and environmental settings. Present study seems to be novel to use for the evaluation of genetic damage in dwellers of Maruthamalai hills, simultaneously the conventional cytogenetic analysis as well as identify the radiation level by assessing the thermo luminescence dosimetry (TLD). TLD were sent by mail to residents who requested the radiation survey. In the present study 54 experimental subjects were selected and equal number of controls also selected. After signing a consent form, both cases (experimentals and controls) provided a blood sample (5 ml) to establish cell cultures. Using the conventional cytogenetic analysis, chromosomal- type and chromatid - type aberrations were observed in some experimental cases. Dicentrics and acentric fragments are unstable types of aberrations but in the present study have not observed any of this aberration in experimentals. Finally, present study may conclude that low-doses of ionizing radiation are exposed do not represent by themselves any significant risk of genetic damage as measured by the conventional cytogenetic analysis.

P02.120

Clinical manifestation of chromosome 2 long arm deletion: report of five cases presentation of four cases

L. Míguez Alvarez¹, A. Escalona², M. Santos², C. Hernando², A. González-Meneses³, A. Plaja⁴, C. Fuster²;

¹Fundación Pública Galega de Medicina Xenómica. Unidade de Diagnóstico Prenatal. Hospital Clínico Universitario, Santiago de Compostela, Spain, ²Unitat de Biologia Cel·lular i Genètica Mèdica. Facultat de Medicina. Universitat Autònoma de Barcelona, Barcelona, Spain, ³Unidad de Dismorfología. Hospital Virgen del Rocío de Sevilla, Sevilla, Spain, ⁴Unitat de Genètica. Hospital Materno-Infantil de la Vall d'Hebron, Barcelona, Spain.

Terminal and interstitial deletion of the long arm of chromosome 2 belongs to the most common structural chromosomal aberrations. Clinical manifestations of this syndrome comprise: global psychomotor delay, moderate to severe mental retardation with specific facial dimorphism. We report the characteristics of clinical features in five cases of terminal or interstitial deletions in 2q32.2q35, 2q33q34, 2q36, 2q37 and 2q37.3 identified in conventional G banding, fluorescent in situ hybridization (FISH) and High Resolution Comparative Genome Hybridization (HR-CGH) techniques. In one case the deletion of subtelomeric region of chromosome 2 (2q37.3) was added to 2q34q37.2 duplication. A comparison was made of clinical symptoms present in our patients with relevant data concerning other cases of 2q monosomy reported in literature in order to establish an accurate phenotype-genotype correlation and proper genetic counselling of these families.

P02.121

Chromosome 9: Deletion Duplication of chromosome 9 Phenotype karyotype correlations Case Reports brief review

D. S. Krishna Murthy;

Microtest Innovations Pvt Ltd, Bangalore, India.

Chromosome 9 exhibits marked heteromorphism and pericentric inversion. Deletion of chromosome 9p presents with characteristic phenotype occasionally with overlapping features of Down syndrome. Terminal deletion of 9- was first reported by Alfi et al., Deletion 9p is a rare syndrome. We report here clinical and cytogenetic findings in two cases of deletion 9p and two case of partial trisomy 9. resulting familial translocation (t8p9q)mar and a balanced de novo translocation t(Yq;9p).

The clinical finding is correlated with karyotypes and compared with other reported cases in the literature.

A brief review of literature of deletion duplication of chromosome 9 will be presented.

P02.122

Combined interstitial duplication 11q22q23 and deletion of 11q24.3: report of a case.

A. Plaja¹, A. Escalona², T. Vendrell¹, B. Fernández¹, A. Fernández¹, M. Carboneras¹, C. Fuster²;

¹Programa de Medicina Molecular i Genètica. Hospital Vall d'Hebron, Barcelona, Spain, ²Unitat de Biologia Cel·lular i Genètica Mèdica. Facultat de Medicina. Universitat Autònoma de Barcelona, Barcelona, Spain.

Background: Detection of abnormal karyotypes with associated clinical manifestations is an important tool for the identification of chromosome regions with genes that confer susceptibility to genetic disorders.

Objective: Identified the extra material present in a *de novo* 46,XY,add(11)(q24.1) karyotype from a child with mental retardation, ocular malformations, mild dimorphic faces, thrombocytopenia and hypogammaglobulinemia.

Methodology: Conventional cytogenetics, High Resolution Comparative Genome Hybridization (HR-CGH), FISH with BAC probes.

Results: The HR-CGH profiles showed the gain of 11q22q23 and deletion of 11q24.3 chromosome bands. Reevaluation of G-banded chromosome spreads and FISH with BAC probes across the region confirmed CGH results.

Conclusion: Partial 11q trisomy is unusually in Prenatal and Postnatal Diagnosis. In most cases is associated with 11q/22q translocation and a 3:1 meiotic disjunction with 47 chromosomes. The presence of the pure dup (11)(q22q23) in our patient provide an opportunity to delineate the phenotypic features due this partial trisomy, since deletion of 11q24.3 associated phenotypic features are well known.

P02.123

Hidden chromosome instability in peripheral blood lymphocytes of unexposed and irradiated persons revealed by means of "G2 bleomycin sensitivity assay"

M. A. Pilinskaya, S. S. Dibskiy, Y. B. Dibskaya, L. R. Pedan;

Research Centre of Radiation Medicine, Kijiv, Ukraine.

With help of modifying "G₂-bleomycin sensitivity assay" (treatment of human peripheral blood lymphocytes culture in late post-synthetic phase of mitotic cycle by bleomycin in concentrations 0,05 and 5,00 mcg/ml) the investigation of hidden chromosome instability in 9 unexposed donors and in 32 persons with different intensity of radiation exposure (Chernobyl liquidators including patients with acute radiation syndrome - ARS) had been fulfilled. Main criterion of chromosomes' sensitivity to bleomycin exposure total frequency of chromosome aberrations had been considered. In all examined groups individual levels of chromosome injuries under identical mutagenic exposure varied in wide range and didn't depend on their initial values in intact cultures. In control donors and in 10 liquidators with low radiation exposure the mean-group frequencies of induced chromosome aberrations were quite the same under both testing concentrations of bleomycin. Among control donors and liquidators three by three hypersensitive persons had been identified with aberrations' rates 35.0, 34.0, 16.0 and 34.5, 20.0 19.3 per 100 cells, accordingly that can be considered as genetically caused phenomenon. In 19 ARS patients increased mean-group frequencies of aberrations induced by bleomycin in both concentrations had been revealed - 16.80±0.50 (8.7 - 38.2) and 28,04±0,63 (6.0

- 60.0) per 100 cells accordingly. In this group 13 persons with hidden chromosome instability (from 22.2 till 60.0 aberrations per 100 cells) had been found. The data received permit to assume that high radiation doses even in delayed terms following irradiation can modify inherited human chromosomes susceptibility to mutagen exposure.

P02.124

Chaotic banding pattern of a chromosome 3 in a patient with mental retardation

M. Martínez-Fernández^{1,2}, L. Rodríguez^{1,2}, T. Liehr³, K. Mrasek³, M. Martínez-Frías^{1,2,4},

¹Joint Centre for Biomedical Research on Rare Diseases (CIBERER), Madrid, Spain, ²Estudio Colaborativo Español de Malformaciones Congénitas (ECEMC) del Centro de Investigación sobre Anomalías Congénitas (CIAC), Instituto de Salud Carlos III, Ministerio de Sanidad y Consumo, Madrid, Spain, ³Institut für Humangenetik und Anthropologie, Friedrich Schiller Universität Jena, Jena, Germany, ⁴Departamento de Farmacología, Facultad de Medicina, Universidad Complutense, Madrid, Spain.

Constitutional complex chromosomal rearrangements (CCRs) are very unusual, and most of them involve more than one chromosome. As far as we know there are only eight published cases having a CCR involving four or more breakpoints within a single chromosome.

Here we present an intrachromosomal CCR in a chromosome 3 having five breakpoints, which was found in a patient without major congenital defects but presenting mental retardation.

The patient was a 30-year-old male, product of the second pregnancy of healthy and non-consanguineous parents. He was born at 42 weeks of gestation by normal vaginal delivery. Few hours after birth, he suffered a hypoxia episode without an apparently cause, that required oxygen therapy. His evolution showed psychomotor delay.

The patient was referred to us for diagnostic evaluation at the age of 30 years, referring mental retardation and a previous karyotype with an inversion in chromosome 3 with breakpoints in p12-q32. We performed a high resolution G-band karyotype and found a chromosome 3 with a chaotic banding pattern. This alteration was "de novo".

Fluorescence *in situ* hybridisation (FISH) with subtelomeric probes 3p/3q showed that they were located at normal position. FISH with WCP3, showed the derivative chromosome 3 homogeneously stained, demonstrating the intrachromosomal nature of the rearrangement. Multicolour-banding FISH was performed and revealed the presence of five breakpoints.

We postulate the different steps that happened to generate the chaotic banding pattern of this CCR.

ACKNOWLEDGEMENTS. This work was supported by a Grant PI020028 (FIS), Spain and the Evangelische Studienwerk e.V. Villigst.

P02.125

Comprehensive Copy Number Variant (CNV) analysis of neuronal pathways genes in mental retardation

A. Brunet¹, E. Saus¹, M. Gratacós^{1,2}, L. Armengol¹, E. Gabau³, M. Guitart³, X. Estivill^{1,2,4},

¹Center for Genomic Regulation (CRG), Barcelona, Spain, ²CIBERESP, Barcelona, Spain, ³Corporació Sanitària Parc Taulí, Sabadell, Spain, ⁴Pompeu Fabra University, Barcelona, Spain.

Cryptic copy number variants (CNVs), including deletion and duplication, translocation and inversions, in chromosomes have been identified in about 10% of patients with mental retardation (MR) of unknown origin. The aim of this work is to perform a comprehensive screening of CNVs that contain genes related to neurodevelopment. We selected 364 genes involved in neuronal pathways and used the Database of Genomic Variants to identify genes predicted to be in CNVs (n=75). We designed four Multiple Ligation Probe Amplification (MLPA) assays to detect variations in copy number between patients and controls. We studied 93 children with unexplained MR and normal karyotype and 332 control samples. We discovered 13 CNVs in MR patients, 5 of which were not present in controls. When available, parental samples were also analysed by MLPA to assess the inheritance of the CNV. We found 6 genes located in de novo genomic alterations corresponding to four different genomic loci: 1q42.1 (DISC1 and TSNAX), 3p26.1 (GRM7 and CNTN6), 7q31.33 (GRM8) and 17q21.31 (MAPT). The locus on chromosome 17q21.31 has been validated by CGH-array and coincides with the recently described 17q21.31 microdeletion syn-

drome. Some of the regions described here were previously described in other patients with MR. Our results indicate that a considerable proportion of genes involved in neuronal pathways show variability in copy number and that de novo events might be related to the aetiology of MR. Further investigation in larger cohorts of patients should allow a definition of the potential role of genomic variability in MR.

P02.126

Cryptic deletion Xp21 with the loss of the genes DMD, GK and NR0B1 in a female child with mild psychomotor retardation and stereotypies

D. Orteschi¹, G. Marangi¹, V. Leuzzi², E. Tabolacci¹, G. Neri¹, M. Zollino¹;

¹Institute of Medical Genetics, Università Cattolica del Sacro Cuore, Roma, Italy, ²Department of Child Neuropsychiatry, Università "La Sapienza", Roma, Italy.

We present the case of a female child at age of 21 months who presented the following clinical features: delayed motor milestones, hypotonia, lethargy during the first months of life, attention deficit, motor limitations (i.e. running difficulties), stereotypies and some autistic features, sleep disturbance, hyperCKaemia. Her psychomotor development improved significantly after the age of 1 year.

By the mean of Array-CGH analysis (BAC-array at an average resolution of 1 Mb) we revealed a de novo deletion of about 4,5 Mb on chromosome Xp21, with the complete loss of the genes DMD (dystrophin), GK (glycerol kinase), NR0B1 (nuclear receptor subfamily 0, group B, member 1) and, probably, of part of the gene IL1RAPL1. The deletion arose on paternal X-chromosome. A random X-inactivation pattern was found.

Clinical-pathogenetics features are discussed, mainly with regard to the early onset of signs of dystrophinopathy in a female patient with an heterozygous deletion of the gene DMD and to the possible phenotypic causal role of the gene IL1RAPL1, whose mutations in hemizygous males has been reported in literature as responsible of some cases of X-linked mental retardation.

P02.127

Proximal interstitial deletion in the short arm of chromosome 3: a report of a child whose mother carries a balanced reciprocal translocation t(7;14)(p32;q32)

C. Vinkler¹, M. Michelson¹, T. Lerman-Sagie², D. Lev¹;

¹Institute of Clinical Genetics Wolfson Medical Center, Holon, Israel, ²Pediatric Neurology Wolfson Medical Center, Holon, Israel.

Proximal 3p deletion is a rare condition. To date, 14 patients have been described. This recognizable phenotype consists of growth retardation, developmental delay, hypotonia and dysmorphic features (plagiocephaly, broad forehead. Broad nasal bridge, low set ears, long philtrum).

We describe a boy with a de novo interstitial deletion at band 3p13p12.3, who presented with a phenotype similar to the previously described cases. However, his mother carries a balanced translocation involving different chromosomes, t(17;14)(p32;q32).

The patient was born at 36 weeks gestation and was diagnosed with hypotonia, feeding difficulties, dysmorphic features and ASD. Brain CT showed partial agenesis of the corpus callosum. G-banded metaphase chromosomes revealed a normal karyotype 46,XY.

At the age of five years, he came for genetic reevaluation. He has psychomotor retardation, severe speech delay and he suffers of seizures. He has dysmorphic features similar to those described in other patients with proximal 3p deletion. CGH microarray analysis was performed using 4685 BAC clones (Signature Genomics Laboratories, Spokane, WA). An interstitial deletion at the short arm of chromosome 3p13p12.3 was identified. FISH analysis, confirmed the microdeletion on the patient's karyotype, but not on the parents' karyotype.

Although the mechanism underlying this cytogenetic event is not understood, we suggest that offsprings of balanced reciprocal translocation carriers, may be more prone to other cytogenetic abnormalities warranting further investigation.

P02.128

Accuracy of analysis in Cytogenetics

R. J. Hastings¹, O. Bartsch², G. Florida³, K. Held⁴, B. Quellhorst-Pawley¹, C. Ramos⁵, M. Rodríguez de Alba⁵, K. Simola^{6,7}, D. Taruscio³, R. Howell¹;

Germany, ³Instituto Superiore di Sanita, Rome, Italy, ⁴Fertility Centre, Hamburg, Germany, ⁵Fundacion Jimenez Diaz, Madrid, Spain, ⁶Tampere University Hospital, Tampere, Finland, ⁷Labquality Ltd, Helsinki, Finland.

Cytogenetic tests are undertaken to ascertain a specific syndrome/disorder, exclude a chromosomal cause for multiple miscarriages, define gender, or whether a pregnancy is chromosomally abnormal. For most patients a genetic test is only performed once in a lifetime and it is essential, therefore, that patients receive an accurate result.

A measure of the accuracy of a diagnostic service can be provided through External Quality Assessment (EQA), including the new European EQA scheme, CEQA (Cytogenetic European Quality Assessment) and the National EQA schemes. CEQA has been piloted for the last two years supported by the Eurogentest Network of Excellence.

The majority of laboratories participating in these EQA schemes demonstrated satisfactory EQA performance. However, some laboratories did not detect the chromosome abnormality and in rare cases even invented a chromosome abnormality.

An important aspect of cytogenetic analysis is to ascertain the breakpoints involved in a structural rearrangement. However, marked differences in breakpoints were allocated by participating laboratories for the same chromosome abnormality. Information on chromosome breakpoints may be used to initiate additional genetic tests, to ascertain whether a child will be affected with a specific syndrome, to identify a critical region or for gene mapping. This imprecision may have consequences for the validity of any subsequent investigations. The EQA process has also identified significant variation in the extent of interpretation given. Some of the common problems identified through EQA submissions will be presented.

P02.129

Mosaic partial trisomy of chromosome 8 in a dysmorphic newborn child with multiple anomalies

T. Zoerjanova¹, K. Kuuse², T. Illus², R. Zordania¹;

¹Tallinn Children's Hospital, Tallinn, Estonia, ²Department of Genetics, Tartu University Clinics, United Laboratories, Tartu, Estonia.

We present a case of a dysmorphic newborn girl having congenital anomalies - polycystic kidneys and agenesis of corpus callosum. Anamnestically: the patient was born 4G/3P prematurely at 33. gestation week. Pregnancy duration and results of antenatal investigations were abnormal - polyhydramnion and dysplastic kidneys were diagnosed by ultrasound at 32 gestational week and bone dysplasia was suspected. Birth anthropometry of the patient (2092g/47 cm; OFC 32 cm) was according to gestational age, due to respiratory failure she needed artificial ventilation. The patient died at the age of one month. Phenotype of the patient was dysmorphic: low forehead, enophthalm, bulbous nose, deformed earlobes, bilateral contractures in III fingers and congenital anomalies of brain and kidneys were diagnosed.

Cytogenetical investigations: Rapid chromosomal analysis from peripheral blood showed mosaic result: 46,XX/47,XX,+mar. Additional cytogenetical analysis by G-banding and FISH method (Chr.8 Whole Chromosome Painting Probe, Cytocell) revealed the marker chromosome to be a derivative chromosome 8:

47,XX,+der(8)(pter→q21).ish der(8)(pter→q21)(wcp8+)[14]/46,XX[6]. The karyotypes of parents were normal.

In conclusion we identified a mosaic partial trisomy of chromosome 8 in a dysmorphic newborn. Discussion of possible etiology and clinical effect of this cytogenetical result will be presented.

P02.130

De novo cryptic deletion of 2q37 in a child with hypotonia and congenital heart defect

S. K. Murthy, S. Naveed, E. E. M. Al-Rowaished, S. Mani, S. M. Padariyakam, P. S. Jacob, M. T. A. Ali;

Molecular Cytogenetic Unit, Genetics Center, DOHMS, P.O.Box 9115, Dubai, United Arab Emirates.

Unbalanced cryptic chromosomal rearrangement involving the telomeric region is one of the major causes of complex genetic diseases resulting in mild to severe clinical conditions. We present here genetic studies on a one month old female child with hypotonia, poor feeding and congenital heart defect who was referred for chromosomal studies. Cytogenetic and FISH studies showed a *de novo* and unbalanced cryptic chromosomal rearrangement resulting from a translocati-

on between chromosomes 2q37.1 and 20p13. The final karyotypic and FISH results were interpreted as 46,XX,der(2)t(2;20)(q37.1;p13).ish der(2)(2ptel+,2qtel-,20ptel+)dn, leading to trisomy of 20pter and monosomy of 2qter. Due to the severity of her condition she underwent cardiac surgery, but failed to survive. More than 60 cases of 2q37 terminal deletion have been reported so far with features ranging from developmental delay, mental retardation, dysmorphism, autism, cardiac or renal abnormalities etc. A subset of patients with this distal deletion, are reported to mimic Albright hereditary Osteodystrophy (AHO). Recent array CGH studies by Lukusa et al (2004) correlated 2q37.3 deletion with autism. Molecular cytogenetic studies using FISH and array CGH should be considered for patients presenting with hypotonia, feeding difficulties and failure to thrive. Literature review and genotype-phenotype correlation involving 2q37 microdeletion will be discussed.

P02.131

The facial dysmorphism in the newly recognised microdeletion 2p15-p16.1 refined to a 570 kb region in 2p15

E. Chabchoub¹, J. R. Vermeesch¹, T. de Ravel¹, P. de Cock², J. P. Fryns¹;

¹Centre for Human Genetics - University Hospital Gasthuisberg, Leuven, Belgium, ²Department of Neuropaediatrics - University Hospital Gasthuisberg, Leuven, Belgium.

The implementation of new technologies such as array-based comparative genomic hybridisation (aCGH) in the genetic diagnosis screening of patients with mental retardation and multiple congenital anomalies (MR/MCA) enabled the detection of novel subtle chromosomal imbalances, as well as the refinement of already known chromosomal imbalances and, in some cases, the identification of the respective genes. Recently a novel 6.2 Mb microdeletion involving 2p15-p16.1 was reported in two patients with autistic disorder (AD) and MR/MCA with recognisable dysmorphic features.

While screening for genomic copy number variations with a 1 Mb resolution bacterial artificial chromosome (BAC) aCGH in patients referred for the aetiological diagnosis of MR/MCA, a *de novo* 2p microdeletion was detected and refined by fluorescence in-situ hybridisation (FISH) to a 570 kb region in 2p15 in a 16 year-old boy presenting with mild mental retardation and multiple congenital anomalies with facial dysmorphism, ecomorphic habitus, kyphoscoliosis and congenital heart defect. In a first step, Marfan and Williams-Beuren syndromes were excluded by, respectively, *FBN1* gene mutation screening and *ELN* gene locus specific FISH probe.

We compare our findings with those already reported and we discuss the phenotype-genotype correlations.

This report supports the evidence of a newly recognised microdeletion syndrome involving 2p15-16.1. We show that this smallest 570 kb deletion of 2p15 is most likely responsible for the characteristic facial dysmorphism in this syndrome.

P02.132

A case of interstitial (4)(31.23q34.2) *de novo* deletion, detected by GTG, FISH and m-CGH analyses in a boy referred by a programme of 22q deletion searching

S. Zajączek¹, M. Constantinou², E. Grygieńczo - Raźniewska³, E. Studniak³, E. Kamińska⁴, E. Gawrych⁵, B. Kałużewski²;

¹Cytogenetics Unit, Szczecin, Poland, ²Dept. of Medical Genetics, Medical University, Lodz, Poland, ³Cytogenetics Unit, Dept of Genetics and Pathology, Pomeranian Medical University, Szczecin, Poland, ⁴Dept of Paediatrics, Children Hematology and Oncology, Pomeranian Medical University, Szczecin, Poland, ⁵Dept of Child Surgery, Pomeranian Medical University, Szczecin, Poland.

Terminal deletions of 4q are rarely described (less than 100 cases) and frequently misdiagnosed at first as "22q deletion suspicion". We present a 9 year old boy with global retardation, epilepsy, bilateral lips and cleft palate, unusual facial appearance, ASD II and some other anomalies. He was recruited to diagnosis by the 22q deletion searching programme, but karyotype analyses (lymphocytes, GTG 450-800 bb., RBG, FISH) did not show any anomaly of 22nd chromosome, but surprisingly revealed deletion, described at first as 46,XY,del(4)(q34qter). Karyotypes of both parents were normal. More precise m-CGH analyses (2,44 OLIGO m-CGH Agilent) showed interstitial 25.6 Mbp deletion, mapped between loci 178055037 and 152423109 (39 Mbp higher to telomere). Final karyotype description was then corrected as follows: 46,XY,del(4)(q31.23q34.2). Possible correlations between ge-

netic map of deleted region and clinical features are now discussed. In all cases of del(22)(q11), suspected with negative results of typical cytogenetic analyses, possibility of subtle aberrations of 4q terminal region must be carefully considered.

P02.133

Interstitial deletion of the long arm of the chromosome 10: about a Tunisian case with del(10)(q23q25)

I. ben jemaâ, I. kraoua, r. meddeb, m. chaabouni, f. maazoul, r. mrad, h. chaabouni;

service des maladies congénitales et héréditaires, tunis, Tunisia.

We describe a Tunisian patient, a one month-old boy which is the second child of healthy unrelated parents. During pregnancy there was intra-uterine delay of growth.

The infant was premature and was born at 35 weeks of pregnancy. Birth weight was 1850 g, length was 49 cm, and head circumference was 33 cm.

There was a facial dysmorphism consisting of down slanting palpebral fissures, prominent forehead, broad nasal bridge, anteverted nares, thin lips, high palate, low-set ears, long philtrum and retrognathia. He had short neck, clinodactyly of the fifth fingers, a unique left kidney, shawl scrotum and club foot varus.

The cytogenetic analysis revealed deletion of the long arm of chromosome 10: 46,XY,del(10)(q23q25) in all mitosis. His parents showed normal karyotypes.

Interstitial deletions of 10q are rare, this report describes a boy with a de novo interstitial deletion of the long arm of chromosome 10. Typical presentation includes craniofacial dysmorphisms, postnatal growth retardation, digital anomalies, developmental delay, congenital heart defects and urogenital anomalies. The clinical findings are mainly the same as those reported in patients with interstitial deletion of this region especially facial dysmorphism, our patient has no congenital heart defect, why he has unique left kidney and most of the patients described have a deletion more distal than our deletion.

The breakpoint will be confirmed by FISH analysis and will permit to compare exactly the phenotype in this case with those described in literature where there is only few cases of this deletion.

P02.134

Deletion (1)(p32.2-p32.3) detected by Array-CGH in a Patient with Developmental Delay/Mental Retardation, Dysmorphic Features and Low Cholesterol: A New Microdeletion Syndrome?

F. Quintero-Rivera¹, T. P. Leren², J. Llerena^{3,4}, N. Rao¹, M. Mulatino^{3,1};

¹David Geffen School of Medicine at UCLA, Department of Pathology and Laboratory Medicine, Los Angeles, CA, United States, ²Medical Genetics Laboratory, Department of Medical Genetics, Rikshospitalet-Radiumhospitalet Medical Center, Oslo, Norway, ³Universidade Federal do Rio de Janeiro, UFRJ, Rio de Janeiro, Brazil, ⁴Instituto Fernandes Figueira, IFF/FIOCRUZ, Rio de Janeiro, Brazil.

We report a 25-year-old male with developmental delay/mental retardation, low levels of total and LDL cholesterol and dysmorphism, which includes macrocephaly, hypertelorism, downslanting palpebral fissures, low set ears, bilateral cataracts, cleft palate, bilateral cleft lip and wide spaced nipples. While his karyotype and subtelomeric FISH studies were normal, a 5.4 Mb interstitial deletion at 1p32 [del(1)(p32.2-p32.3)] was identified by array-CGH. This region encompasses a cluster of genes involved in fatty acid oxidation and cholesterol metabolism. One of these genes is PCSK9 (proprotein convertase subtilisin/kexin type 9), which is a key regulator of the number of cell-surface LDL receptors. Another gene deleted is DAB1 (Disabled 1 homolog of Drosophila), which is involved in brain development. Based on the findings in our patient and in the two previously reported individuals with del(1)(p32.2-p32.3), they may have a new microdeletion syndrome that previously has been difficult to detect by G-banding because it is located in a G-negative band, but it can easily be identified by array-CGH

P02.135

Identification of a 2.7 Mb deletion of 3q25.1-3q25.2 in a patient with complex rearrangements of chromosome 3 by oligo-array CGH

E. Seo, J. Lee, H. Yoo, I. Park;

University of Ulsan College of Medicine and Asan Medical Center, Seoul, Republic of Korea.

Interstitial deletion of chromosome 3q23 is known in blepharophimosis-ptosis-epicanthus inversus syndrome (BPES). Recently, a 1.9 Mb deletion of 3q24 harboring ZIC1 and ZIC4 has been identified in Dandy-Walker malformation. We present a Korean boy with mild dysmorphism and congenital heart disease such as pulmonary atresia, VSD and major aortopulmonary collateral artery (MAPCA) at birth. He had a apparently balanced translocation, 46,XY,der(3)inv(3)(p25q25)t(3;8)(q29;q24.1),der(8)t(3;8) de novo, with complex rearrangements of chromosome 3. A high density array CGH with 244k oligonucleotide probes detected a 2.7 Mb deletion at 3q25.1-3q25.2. Further investigation by FISH analysis with BAC clones confirmed the heterozygous deletion at the same region. The genes COMM2, RNF13, PFN2, SERP1, EIF2A, SELT, SIAH2, CLRN1, and several open reading frames are included in the deletion interval. Among them, some genes may be good candidates for the congenital heart disease or other phenotypes.

P02.136

A patient with a 6p interstitial deletion and a complex translocation involving chromosomes 2, 6, and 14

D. Misceo^{1,2}, K. Bjørge¹, E. Ormerod¹, Ø. Ringer³, C. van der Hagen¹, M. Rocher², E. Frengen¹;

¹Department of Medical Genetics, Ullevål University Hospital and Faculty of Medicine, University of Oslo, Oslo, Norway, ²Department of Genetics and Microbiology, University of Bari, Bari, Italy, ³Eye Department, Ullevål University Hospital, Oslo, Norway.

We describe a 5 years old patient with global developmental delay. He lags about one year behind his peers. The language development is most delayed, especially the pronunciation. As a baby he was quiet and slept excessively. The patient has hypermetropia of 2.5 diopters bilaterally and minor exophoria. Eye examination revealed a chorioretinal coloboma inferonasally in the left eye. He shows dysmorphic features: hypertelorism, deep set eyes, prominent philtrum, slightly prominent forehead, low set and backward rotated ears.

A combined approach of G banding, aCGH and FISH revealed complex chromosome rearrangements, involving chromosomes 2, 6 and 14. These rearrangements are de novo, since both parents have a normal karyotype. He also has two healthy sibs.

Beside the reciprocal translocation between chromosome 2q and 6p, we also detected an insertion of a large segment from chromosome 14 into chromosome 6p, and an extensively reshuffled 6p: chromosome der(6)(p) also carries a 4 Mb interstitial deletion and a small paracentric inversion.

Because of the high number of chromosome breakpoints in this patient we cannot connect the involvement of each breakpoint to the clinical phenotype. However, the most significant aberration is the 6p interstitial deletion. Interstitial deletions of 6p are rare events that to our knowledge previously have been reported in a total of eight patients. We compare the clinical traits of our patient to the few cases of 6p interstitial deletions previously described and we discuss the potential role of TFAF2A and FOXC1 in relation to the choroidal coloboma.

P02.137

Dicentric Inv Dup of the Whole 4p Without Deletion. Description of the First Case

L. Rodríguez¹, M. Martínez-Fernández^{1,2}, M. Aceña¹, S. López Mendoza³, L. Martín Fumero³, M. Rodríguez de Alba^{4,5}, M. Fernández^{4,5}, M. Martínez-Frías^{1,4,6};

¹Est. Colaborativo Español de Malformaciones Congénitas del Centro de Investigación sobre Anomalías, Madrid, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Madrid, Spain, ³Servicio de Pediatría. Hospital Nuestra Señora de la Candelaria, Santa Cruz de Tenerife. Islas Canarias, Spain, ⁴Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Madrid, Spain, ⁵Servicio de Genética. Fundación Jiménez Díaz, Madrid, Spain, ⁶Departamento de Farmacología,

Facultad de Medicina, Universidad Complutense., Madrid, Spain.

Terminal inversion duplications (inv dup) are relatively uncommon. The most frequent and well characterized inv dup, involved the 8p, where a maternal heterozygous inversion between the two OR gene-clusters, are causally related to the inv dup, and has always associated a terminal deletion and an intact segment 8p.

Here we describe a female patient with a dicentric inversion duplication 4p without any apparent euchromatin deletion.

The patient was a female newborn, first daughter of a young, healthy and non-consanguineous couple. Pregnancy was uneventful, until the 37th gestational week when a maternal hypertension was diagnosed. The delivery was induced at 38 weeks. At birth she showed microcephaly, a right cephalohematoma, craniofacial anomalies and skeletal anomalies of hands and feet.

High resolution G-band karyotype from peripheral blood lymphocytes, revealed a "de novo" 4p+ chromosome. FISH analyses with 4p probes, showed that the extra material on 4p was a dicentric inverted duplication (cen-p16.3::p16.3-qter).

We postulate that a chromatic breakage could have happened at the very terminal end of the chromosome 4, losing the common telomeric region (-TTAAGGG-) but saving the subtelomeric specific region. This was followed by U-type reunion producing a dicentric chromosome, which after a break at a centromeric region, gave rise to the abnormal dic inv dup 4p chromosome. The abnormal 4p was afterwards stabilized by the addition of a new -TTAAGGG- repeat sequence mediated by the telomerase, but surprisingly this sequence was internal to the centromere sequence.

P02.138

DNA methylation patterns of extra chromosomes in chorionic villi cells of missed abortions

O. A. Efimova¹, M. A. Andrushuk¹, A. A. Pendina², O. G. Chiryayeva², L. I. Petrova², N. A. Sadik², V. S. Dudkina², T. V. Kuznetsova², V. S. Baranov²;

¹Saint-Petersburg State University, Saint-Petersburg, Russian Federation, ²Ott's Institute of Obstetrics and Gynecology, Saint-Petersburg, Russian Federation.

Distribution of 5-methylcytosine (5-MeC) in human chromosomes reveals specific MeC-banding pattern. It remains unknown whether methylation pattern of extra chromosomes is the same as in normal euploid cells or it bears changes of functional significance. We compared DNA methylation patterns of extra chromosomes in cytotrophoblastic cells of missed abortuses with abnormal and euploid karyotypes. Methylation patterns of extra chromosomes in trisomies 9,7,13,16,17 (one chorion sample for each case), in triploidy (three samples) and tetraploidy (one sample) as well as structurally rearranged chromosomes were studied on direct metaphase preparations from cytotrophoblast of human missed abortuses at 5-8 weeks of gestation.

Indirect immunofluorescence with monoclonal antibodies (Eurogentec, Belgium) was applied to detect chromosome regions, enriched in 5-MeC. No difference of 5-MeC signal distribution along chromosomes and its intensity between normal and aneuploid/polyploid cells was detected. In either case, 5-MeC-rich sites corresponded to T-, R-bands, short arms of acrocentrics and heterochromatin of chromosomes 1,9,16. Methylation intensity in homologues differed only in 9q12 and 16q11 (heterochromatin) in triads and tetrads.

DNA methylation pattern in structurally rearranged chromosome 7 (47,XX,i(7)(q10),+i(7)(p10)) was studied. The pattern 5-MeC signal distribution in both der(7) was band-specific and did not differ from that of the structurally normal one, as well as from homologues in normal karyotype.

Thus, methylation pattern in extra copies of normal and rearranged chromosomes is identical to that in normal karyotypes. Different methylation of 9q12 and 16q11 in homologues is more probably due to special role of heterochromatin in cytotrophoblast cells rather than change of methylation in aberrant karyotypes.

P02.139

Unusual Clinical Manifestations Associated with Down Syndrome

H. Mutlu, M. Ture, S. Sarisoy, S. Sarisoy, K. Baysal, F. Ekici, B. Ozyilmaz, C. Celenk, G. Ogur;

Ondokuz Mayıs University Medical Faculty, Samsun, Turkey.

Down syndrome (DS) is by far the most common and best known chromosomal disorder. The cause is full trisomy 21 in the majority patients (94%). Mosaicism (2.4%) and translocations (3.3%) account for the rest. Most unbalanced translocations are de novo (75%), and the rest result from familial translocation. Here we report 3 cases of Down Syndrome presented with unusual clinical findings.

CASE 1: 3-month-old infant with DS was cytogenetically diagnosed as translocation type "der(13;21)" resulting from a Robertsonian translocation of the mother. Radiological evaluation confirmed an asymptomatic Morgagni Hernia.

CASE 2: 18-month-old DS patient presented with cleft lip-palate. Karyotype revealed regular Trisomy 21.

CASE 3: Cytogenetical analysis of a 2-month-old infant presenting DS showed 47,XY,+21 karyotype. Physical examination revealed a female external genitalia and inguinally located bilateral gonads. Ultrasound confirmed absence of uterus.

Association of DS with cleft lip/palate, Morgagni hernia and androgen insensitivity is been rarely discussed. To our knowledge 32 cases have been reported so far; and for androgen insensitivity association only 3 cases have been referred. As up to date no androgen receptor gene mutation has been identified in similar cases, it is yet not clear whether this association is directly correlated. Cleft lip-palate is as well rarely reported in DS. Coincidental occurrence could thus be discussed.

P02.140

Cytogenetic and parental age study of 545 cases of Down syndrome in Iran. A forty years study

M. Shariaty¹, I. Nabipour², F. Farzanfar³, S. Beig², M. Shariaty¹, Z. M. Honarmand¹, E. Daei¹;

¹Medical Genetics Center, Rafsanjan, Islamic Republic of Iran, ²Persian Gulf Health Institute, Bushehr, Islamic Republic of Iran, ³Medical Genetics Department, Cancer Res. Institute, Tehran, Islamic Republic of Iran.

Objective: To determine the karyotypic and maternal age profile of Down syndrome in Iran this study started in 1965 and ended in 2004. Methods: 931 clinically diagnosed Down patients referred to the first author were studied. Peripheral bloods were cultured using Leukocyte culture method of Moorhead (1) or micro culture technique of Shariaty (2). Giemsa stained mitoses were analysed. Since 1975 G-banded mitoses at the 300-450 band resolution were karyotyped

Results: Karyotypes consistent with Down syndrome were observed in 545 patients out of 763 cases. 305 patients were male (56 per cent) and 240 cases were female (44 per cent). 66 per cent were born in Tehran while the rest were born across the country. Frequency of free trisomy 21, translocation 21 and mosaics were 89.5, 5.3 and 5.2 per cent respectively. The mean age of parents was 34.67 (SD 9.14) years for Fathers and 28.49 (SD 7.71) for Mothers. 52 per cent of our cases were the result of first or second pregnancies. Only 11.3 per cent had consanguineous parents.

Conclusion: Our study of 545 cytogenetically proven Down syndrome patients show a rather different picture regarding age of parents and parity in mothers as compared to the western reports. In our study the mean maternal age is 28.4 with peak at 22 while in western countries it is 34. Also 52 per cent of our cases are the results of first or second pregnancies while 48 per cent are the results of 3rd to 18th pregnancies.

P02.141

Pure 20q11.2 duplication: a specific behavioural phenotype?

J. Puechberty¹, G. Lefort¹, A. Schneider¹, A. Chaze¹, A. Weise², T. Liehr², H. Starke², F. Pellestor¹, P. Sarda¹;

¹Service de Génétique, Hôpital Arnaud de Villeneuve, Montpellier, France,

²Institute of Human Genetics and Anthropology, Jena, Germany.

Pure 20q11.2 duplication has only been reported once to the best of our knowledge. We report a second case of pure 20q11.2 duplication in a 9 year-old-girl presenting mainly peculiar behaviour, a few dysmorphic features and no malformations. The proposita was born to non-consanguineous parents with uneventful histories. She was eutro-

phic at delivery. Minor neonatal problems included polycythaemia and neonatal jaundice. During the first months the baby was hypotonic. Physiotherapy achieved walking at 16 months. Course was marked by delayed speech with phonatory difficulties. Academic delay was due mainly to hyperactivity and impaired concentration. At 9 years intelligence was borderline (IQ:74). Dysmorphic traits included small dysplastic ears and a large mouth. There was strikingly happy and jovial behaviour. Karyotype analysis of RHG and GTG-banded blood metaphases showed 46 chromosomes, with an abnormally elongated long arm of one chromosome 20. Initial FISH studies (wcp 20, subtelomeric 20p and 20q probes and CEP 20 probe) suggested interstitial chromosome 20 duplication. Thorough FISH characterization of the anomaly concluded to partial trisomy 20q11.2 resulting from an inverted duplicated chromosome 20. A similar but apparently slightly larger duplication was reported by Wanderley et al. in 2005 in a 16-month-old boy with slightly dysmorphic features and the same happy disposition. This behavioural characteristic could be related to 20q11.2 duplication.

P02.142

De novo duplication of 7(q21.2---q32) in a patient: cytogenetic diagnosis and clinical finding

F. Nasiri¹, F. Mahjoub²;

¹Blood Transfusion Organization Research Center, Tehran, Iran, Tehran, Islamic Republic of Iran, ²Blood Transfusion Organization Research Center, Tehran, Iran & National Institute for Genetic Engineering and Biotechnology, Tehran, Iran, Tehran, Islamic Republic of Iran.

Trisomy/duplication of 7q is associated with a characteristic syndrome and has been described in published cases. The main clinical features are: frontal bossing, retrognathia, small jaw, low-set ears, dysplastic ears, deep-set eyes, prominent eyes, strabismus, downcurved upper lip, small mouth, short hands, stiffness fingers, joint laxity, joint stiffness, scoliosis, reduced muscle tone, hydrocephalus, growth retardation, strabismus, coloboma of iris, drooping upper eyelid, widely spaced eyes, long eyelashes, short space between eyelids (1-8). Here we describe clinical and cytogenetic findings on a 1 year old male child whom referred to our clinic due to developmental delay and hypotonia.

To our best knowledge this report is the first case of a *de novo* case with pure partial duplication of 7 (q21.2---q32).

P02.143

Rare unbalanced aberration of chromosome 18 in patient with severe dysmorphic features and poor prognosis

A. Matulevičienė^{1,2}, B. Aleksūnienė^{1,2}, N. Krasovskaja¹, E. Preikšaitienė², V. Kučinskas^{1,2};

¹Centre for Medical Genetics at Vilnius University Hospital Santariškių Klinikos, Vilnius, Lithuania, ²Department of Human and Medical Genetics Faculty of Medicine, Vilnius University, Vilnius, Lithuania.

The unbalanced aberration of chromosome 18 is very rare chromosomal rearrangements. We present a patient with rare unbalanced aberration of chromosome 18. He was a first child of the first pregnancy from non-consanguineous parents. His mother was consulted during pregnancy at the Center for Medical Genetics. Risk of congenital malformations for foetus was calculated due to maternal age, gestation and obstetric history. The risk of trisomy 21 was 1:1099 according to the mother's age. Ultrasound scan was performed at 16th week of gestation. Neither foetal structural malformations nor minor defects or markers of chromosomal diseases were detected. Triple test was performed at 16th week of gestation. Biochemical risk of trisomy 21 was 1:55, for Trisomy 18 - 1:1708, for neural tube defects - 1:356. According to biochemical test results of trisomy 21 invasive procedure was performed for aneuploidy testing by QF-PCR. Test results were negative. At birth the weight was 2470g and dysmorphic features were characterized - microcephaly, low hairline, hypertelorism, prominent nasal bridge, long philtrum, short neck, overlapping position of the fingers, micropenis and corpus callosum agenesis. Expressed respiratory insufficiency was also observed. The death at sixth months was final outcome of this patient. Chromosomal analysis of peripheral blood lymphocytes revealed 46,XY,der(18)t(4;18)(p14;q12.2) karyotype. Cytogenetic analysis was performed from GTG banded metaphases. The resolution level was 400-500 bands. Cytogenetic investigation of the parents showed a chromosome aberration in mother: she presented a t(4;18)(p14;q12.2). These results identified the exact nature of the unbalanced aberration of our patient.

P02.144

A syndrome of ectodermal dysplasia and MR due to del(2)(q31.2q33.2): further clinical and CGH-array characterization

A. Verloes¹, M. Port-Lis², S. Drunat³, A. Tabet⁴, B. Benzacken³, L. Rifai⁴, A. Aboura³;

¹Robert debré, Paris, France, ²Genetic Unit, University Hospital, Pointe-à-Pitre, Guadeloupe, ³Robert debré, Bd Sérurier, France, ⁴National Institute of Health, Rabat, Morocco.

We report a patient with a 23 Mb deletion at 2q23, presenting with severe growth and mental delay, and partial ectodermal dysplasia (hair and teeth involvement). This recurrent deletion appears to show a consistent phenotype, previously reported in 4 cases. Further patients will be necessary to determine which gene in the interval explain skin and developmental anomalies. Comparing clinical features from our patient and others who show an overlapping deletion, a common "del 2q32 phenotype" emerge: *microcephaly, long face, high forehead, abnormal teeth, low-set ears, midface hypoplasia, high palate, micrognathia, transparent and thin skin, sparse hair, high frequency of inguinal hernia, severe development impairment, and behavioral problems*. Anomalies of hands and feet are also common: this might be caused by the deletion of the HOXD cluster which is involved in distal limb morphogenesis. Cleft palate is due to the deletion of the SATB2 gene most likely by haploinsufficiency. Both ZNF533 and MYO1B genes are located in the deleted region. They are involved in neuronal function. These genes may be good candidates for the neurological phenotype which is however not present to date in our patient. Is there a new locus for ectodermal dysplasia on chromosome 2q31q33? This hypothesis is supported by the observations of Stenvik et al. (1972) who described patients with congenitally missing teeth and sparse hair and taurodontia. Nails and ability to perspire were not specifically mentioned. Levin (1985) saw brother and sister with hypodontia and sparse, slow-growing hair. The sister had taurodontia of deciduous and permanent teeth. In addition, fingernails and toenails were slow-growing, thin, and spoon-shaped. No abnormalities in perspiration were noted. (taurodontia, absent teeth, and sparse hair. MIM 272980)

P02.145

A 6qter deletion results in a phenotype of mental retardation and classical cutaneo-articular Ehlers-Danlos syndrome

A. Mosca¹, P. Callier¹, A. Masurel-Paule², C. Thauvin-Robine², N. Marle¹, M. Nouchy³, D. Dipanda⁴, F. Mugneret¹, L. Favier²;

¹Laboratoire de cytogénétique, CHU le Bocage, Dijon, France, ²Service de Génétique Médicale, Hôpital d'Enfants, Dijon, France, ³Laboratoire Pasteur Cerba, Val-d'Oise, France, ⁴Service de Rééducation et de Réadaptation, CHU le Bocage, Dijon, France.

Ehlers-Danlos syndromes (EDS), belonging to a heterogeneous group of inheritable connective tissue disorders, are attributed to mutations within a subunit of the Vth chain of the collagen gene. Here, we report on a 6-year-old patient with history of congenital hip dislocation, major joint hypermobility, fragile and hyperextensible skin, persistent atrophic scars, and asthenia. Her father and one of her sisters had mild joint laxity. She was referred to the genetics department for investigations of speech delay, mild mental and growth retardation and minor dysmorphic features. A standard karyotype revealed a 6qter deletion. Cytogenetic studies of the parents were normal in favour of a *de novo* deletion. A CGH-array (Integrage) is in progress to better characterize the breakpoints of this deletion. Cerebral magnetic resonance imaging, cardiac and abdominal ultrasounds were normal. It is interesting to note that two patients with EDS type VII and EDS type II respectively have been reported with a 6q deletion. None of the genes of this subtelomeric 6qter region seems to be a strong candidate gene by its function for EDS. The review of other cases with chromosome 6q deletions including the q26-q27 bands did not show any other cases with EDS phenotype but revealed patients with congenital hip dysplasia.

P02.146

Encountered chromosomal abnormalities in children with epilept

E. R. Raouf, N. A. Mohamed;

National Research Center, Cairo - Giza, Egypt.

Objective: Increased evidences of chromosomal aberrations in association with epilepsy suggest a genetic predisposition to the disease. We

aimed at identifying the frequency of chromosomal aberrations among children with epilepsy. Methods: Twenty Egyptian children with epilepsy were recruited for this study. Full history, clinical & neurological examination together with some investigations (EEG, MRI & CAT) was done. Chromosomal analysis using GTG banding and high resolution techniques were evaluated, FISH technique was done to one case only. Results: Chromosomal aberrations were observed in 3/20 (15%) of which one case had mosaic interstitial deletion 15(q11q13), the second case had mosaic inversion 22(q11q13), While the third case had a ring of chromosome 18. Conclusions: The possibility of chromosomal abnormality in cases of epilepsy without apparent etiology and / or associated congenital malformation or without frank dysmorphic features should be seriously acknowledged. Genetic evaluation including high resolution chromosomal study, FISH technique and molecular study should be used for proper management and counseling.

P02.147

Induced chromosomal breakage rate in children referred for aplastic anemia

N. Selenti, A. KoliAlexi, E. Kouvidi, H. Fryssira, S. Kitsiou, V. Toulaitou, E. Kanavakis, A. Mavrou;

Medical Genetics Athens University School of Medicine, Athens, Greece.

Background: Fanconi Anemia (FA) is a rare autosomal instability syndrome characterized by bone marrow failure, developmental anomalies, acute nonlymphocytic leukaemia and cellular hypersensitivity to cross linking agents such as diepoxybutane (DEB) and mitomycin C (MMC). However, a number of patients display only minor phenotypic variations or lack congenital anomalies.

Material & Methods: Chromosomal breakage analysis using MMC and DEB was performed to differentiate FA from aplastic anemia in 166 children aged from 2 months to 14 years with myelodysplasia with or without congenital malformations. Matched for age and sex donors were used as controls. Peripheral blood samples were analysed with conventional cytogenetic techniques. For clastogen-induced chromosome damage both MMC and DEB were added. A minimum of 150 metaphases per case were analyzed. FA positive was considered the case in which the percentage of breaks was 7-10 times higher as compared to controls.

Results: Incused breaks were detected in 8/166 patients tested with both clustogens. Six were diagnosed as FA while the remaining two, despite the high percentage of clastogenic damage, were characterized as Silver Russell syndrome and Blackfan Diamond anemia respectively. 3/6 FA patients presented with congenital anomalies and 3 only with aplastic anemia. 2/6 FA patients were dizygote twins. No relationship was found between the clinical severity of the disease, age of onset, and the anemic status.

Conclusions: The present study illustrates that clustogens induced stress tests provide the means of differentiation between FA and «aplastic anemia» and allow for accurate and timely diagnosis to implement appropriate therapy.

P02.148

Molecular cytogenetic characterization of the same translocation in two siblings

T. V. Zolotukhina¹, N. V. Shilova¹, N. B. Rubtsov², T. Karamysheva¹, Z. G. Markova¹, V. A. Galkina¹, T. G. Tsvetkova¹;

¹Research Centre for Medical Genetics of RAMS, Moscow, Russian Federation,

²Institute of Cytology and Genetics SB RAS, Novosibirsk, Russian Federation.

We are reporting the clinical, molecular cytogenetic studies of two female siblings of 14 and 6 years, who was referred for karyotyping because of multiple congenital anomalies and mental retardation. The karyotypes of parents were normal. Phenotypes of proband were similar and included: spine deformity, mild microcephaly, large nose with high nasal bridge, micrognathia and crowded teeth. Conventional cytogenetic analysis of both siblings using GTG-banding revealed 46, XX,der(15) karyotype. FISH analysis with mFISH probe kit (MetaSystems), wcp15, wcp 8, telomere specific for chromosome 8 DNA-probes (Abbott) was performed to identify derivative chromosome. mFISH showed the origin of the material from the chromosomes 8 and 15. FISH with wcp15, wcp 8 confirmed this date and 8q telomere was seen on the derivative chromosome. Thus the derivative chromosome was composed from the part of long arm of chromosome 8 and whole chromosome 15. For detailed karyotype description DNA probes were generated

from abnormal chromosomes followed with DOP-PCR and labeling of PCR products in additional cycles of PCR. In patients FISH of these microdissected DNA probes painted abnormal chromosome 15(p11.2-qter) and 8(q22.1-qter). In healthy donors they painted 15(p11.2-qter) and 8(q22.1-qter). Technique of M-bands with DNA probes derived from two different mar(15) revealed no additional reorganization in pericentromeric region of abnormal chromosomes. Obtained data allowed us to described abnormal karyotypes as 46, XX, der(15)t(8;15)(q22.1;p11.2). The normal karyotypes of both parents led us to hypothesis that this der(15) is probably a result of parental gonadal mosaicism. Different biological father cannot be excluded

P02.149

MCA/MR Syndrome with (4; 10) (q25; q26) Translocation

A. A. Dardir, H. A. Hussein, N. A. Meguid;

National Research Center, Cairo, Egypt.

We describe a 52 days boy with low birth weight, sparse scalp hair, absent eye brows and eye lashes and bilateral corneal opacities, umbilical hernia and anal stenosis. Limb anomalies in the form of bilateral syndactyly between first, second and third fingers, bilateral lower limb preaxial polysyndactyly and bilateral soft tissue syndactyly between second and third toes are described. The karyotype of the infant revealed a unique de novo translocation involving chromosomes 4 and 10, which was confirmed by Fluorescence In Situ Hybridization (FISH) technique, resulting in t(4;10)(q25;q26). No other patients, to our knowledge, with an identical phenotype and chromosomal finding have been reported. Our report suggests that regions 4q25 and 10q26 may be involved in the development of the limb anomalies, eye anomalies and other characteristic clinical findings presented in our patient.

P02.150

Detecting of gonadal mosaicism for trisomy of chromosomes without severe imprinting effects

M. Tahmasebi-Hesari, N. V. Kovaleva;

St. Petersburg Medical Academy of Postgraduate Studies, St. Petersburg, Russian Federation.

Gonadal mosaicism (GM) may account for both recurrent cases of chromosomal anomalies and appreciable proportion of "sporadic" cases. However even in the case of a recurrent anomaly, it is not always easy to discover a suspected GM in the absence of the abnormal line in a somatic tissue of a carrier. To optimize the testing procedure, we have conceived the following algorithm. (i) Study on parental origin of the extra chromosome in the trisomic offspring. (ii) Finding apparent non-disjunction (NDJ) is followed by testing the grandparents on the parent-of-origin's side. Presence of two homologs from the same grandparent in the parent-of-origin (uniparental disomy, UPD) and in the trisomic proband, would indicate GM in the parent-of-origin. (iii) Finding a "new" extra chromosome in the proband is followed by testing the grandparents on both sides. Presence of a grandparental homolog not seen in both parents in the proband, would uncover a carrier of GM. Presence of crossovers ("new" allele) may add to uncovering both GM and its carrier. Finding UPD or a "new" chromosome/allele in a healthy offspring may also help to reveal the presence of GM in a parent. (iv) Parents-of-origin with undetectable GM should receive a rigorous multi-tissue cytogenetic investigation for the presence of abnormal line. We believe that expenses of labour- and time-consuming testing of families for suspected GM can be rewarded by the opportunity of choosing a desirable reproduction strategy. Results of a pilot study of 30 families with trisomy 21 offspring will be presented.

P02.151

Karyotyping of early passaged human mesenchymal stem cells

J. Shalygina¹, A. Pendina², O. Efimova¹, T. Kuznetsova², P. Kruglyakov³, E.

Shvedova³, D. Polyntsev³, V. Baranov²;

¹Saint-Petersburg State University, Saint-Petersburg, Russian Federation, ²D.O.

Ott's Institute of Obstetrics & Gynecology RAMS, Saint-Petersburg, Russian

Federation, ³Transtechnologies Ltd., Saint-Petersburg, Russian Federation.

Human mesenchymal stem cells (hMSC) have a great potential for a wide range of therapeutic purposes. Their medical application necessarily requires preliminary passaging. The question of unfavorable effects of passaging of hMSC on their genome (chromosome) stability remains controversial.

We have studied genome stability of hMSC, obtained from 6 healthy

(according to questionnaire) volunteer donors by bone marrow aspiration. To test genome stability, we performed karyotyping by QFH-banding technique with AcD-counterstaining.

First, we made a comparative analysis of hMSC karyotype with that of relevant dcPHA-stimulated lymphocytes, cultured under standard conditions. Lymphocytes demonstrated normal male or female karyotypes in either donor. Comparative analysis of metaphase chromosomes showed perfect karyotype concordance in both hMSC and lymphocytes.

Second, we analyzed hMSC karyotype at early passages - from 4 to 7. Metaphase chromosomes were obtained by colchicines treatment 5 hours before fixation; 8-15 metaphases were selected for karyotyping in each case. No differences in hMSC karyotype among cells of the same culture as well as among cells from cultures after different passages could be detected. No aneuploid or polyploid cells as well as no cells with structural chromosome rearrangements were registered.

Thus, no adverse effect of cell passaging on chromosome number or their morphology could be detected, advocating for genome stability of hMSC at early passages.

Supported by RFBR.

P02.152

Familial chromosome 9 balanced intrachromosomal insertion leading to offspring with A 9Q34

F. Girard¹, N. Carelle-Calmels¹, C. Jourard¹, A. Bazin², P. Kleinfinger², H. Freysz², E. Flori¹;

¹Hopital de Haute-pierre, Strasbourg, France, ²Laboratoire Pasteur-Cerba, Cergy-Pontoise, France, ³Centre Hospitalier de Sélestat, Sélestat, France.

Shifts or intrachromosomal insertions represent very rare complex three-break rearrangements. They are classified in peri- or paracentric insertions depending on their occurrence within one or two arms. They can be direct or inverted depending on the orientation of the inserted segment with regard to the centromere. The normal carriers have a high reproductive risk.

We report on a family with a chromosome 9q paracentric insertion discovered through a newborn male referred for cytogenetic analysis because of the association of facial dysmorphism, radio-ulnar synostosis, undescended testes and hydronephrosis. A recombinant chromosome 9 was found. Parental karyotypes showed a paternal intrachromosomal insertion of a part of 9q34 band. By using molecular cytogenetic techniques (CGH-array and FISH), we characterized the break points of the insertion. After chromosomal study of the family, four other carriers of the insertion were found. A prenatal diagnosis could be proposed to a pregnant woman whose husband was a normal carrier and a 56 year old woman with an unexplained abnormal phenotype was identified as a carrier of the recombinant chromosome 9. We discuss the mechanism which have led to this duplication.

P02.153

Paternal origin of a large inv dup(15) supernumerary marker: no abnormal phenotype at 2 years old

a. guichet¹, p. boisseau², o. ingster¹, s. beziau², d. bonneau¹;

¹service de genetique, angers, France, ²service de genetique, nantes, France.

Inv dup(15) can be classified into 2 major groups according to size, determined by presence or absence of Prader-Willi/Angelman syndrome critical region (PWACR). Small inv dup (15), not containing PWACR seems to have no phenotypic effect where as large ones, containing 2 or more extra copies of the 15q11q13 region, are associated with abnormal phenotype. In those cases, inv dup(15) are maternal in origin. We report on a prenatal observation with a mosaic marker confirmed after birth. The proband is the second child of a young, healthy and unrelated parents. Prenatal diagnosis performed due to increased fetal nuchal translucency at 22 weeks of gestation indicated cytogenetic mosaicism for a supernumerary marker. The low level of mosaicism did not permit to identify it: 47,XX,+mar[3]/46,XX[52]. Normal karyotypes were found in both parents.

After birth, the karyotype was analysed on different tissues and all confirmed mosaicism for the marker: 45% for blood sample and 25% for fibroblasts. FISH studies with commercial probes and BACs probes from 15q11q13 region allowed us to characterize the marker as an inv dup (15)(q11q12) including the Prader-will/angelman critical region. Moreover, molecular studies for parental origin demonstrated a paternally derived inv dup (15).

At 2 years old the young girl has a normal phenotype with no dysmorphic features and no psychomotor retardation.

Conclusion: we report on a young child with a large mosaic inv dup(15) whose paternal origin was rarely reported and supposed to be the explanation for the good psychomotor development of this child.

P02.154

The recurrence of pericentric inversions of chromosome 12 in the Tunisian population

R. Louati¹, F. Kallebi¹, R. Frikha¹, M. Meddeb², T. Rebai¹, N. B. Abdelmoula¹;

¹Medical University, Sfax, Tunisia, ²Laboratory of Genetics, Tunis, Tunisia.

We report a recurrent pericentric inversion of chromosome 12 in five Tunisian families. It was ascertained through cytogenetic analysis of 3 men investigated before ICSI treatment for idiopathic infertility and two sisters explored because of IVF attempts failure and recurrent early pregnancy losses. The fifth family was ascertained through a prenatal diagnosis because of a familial history of a chromosome 12 inversion in an infertile female member. In these families, there was no familial occurrence of patients with mental retardation or multiple congenital anomaly syndromes, suggesting that unbalanced recombinations seem to be lethal. The same inv(12) was reported by other Tunisian cytogenetic laboratories, in association with infertility or recurrent abortions.

These pericentric chromosome 12 inversions have two different breakpoints: inv(12)(p11q12) shown in three families originated from Sfax town and inv(12)(p12q11) revealed in two families originated from suburbs of Sfax town.

This inversion may have an independent occurrence from different ancestors or has been transmitted from a common founder. Further more, observation of 2 different breakpoints can be explained by genomic structure of chromosome 12 which contains numerous duplicated and repetitive sequence elements that could mediate the formation of this recurrent inversion. We propose that pericentric inversion of chromosome 12 is a recurrent observation in Tunisian population and need characterization of breakpoints at the molecular level, to ascertain whether the formation of the inversion is mediated by repetitive sequence elements and haplotype analysis, to determine the proportion of inv(12)s that arose independently and the proportion that share an ancestral founder.

P02.155

Unexpected prenatal detection of recombinant chromosomes derived from pericentric inversions: report of two cases

C. Morales¹, A. Soler^{1,2}, J. Bruguera³, I. Mademont⁴, E. Margarit^{1,2}, A. Sánchez^{1,2};

¹Servei de Bioquímica i Genètica Molecular, Hospital Clínic, Barcelona, Spain,

²IDIBAPS, Barcelona, Spain, ³Fundació Clínic per a la Recerca Biomèdica,

Barcelona, Spain, ⁴CIBERER, Barcelona, Spain.

Pericentric inversions, excluding variant forms, are rare chromosomal abnormalities and have an estimated frequency ranging from 0.12% to 0.7%. During meiosis, recombination could lead to the formation of unbalanced recombinant (rec) chromosomes. Two alternative recs are possible: duplication of q-arm and deletion of p-arm or duplication of p-arm and deletion of q-arm. The probability of recombination increases with the size of the inverted segment. However, the viability of the recombinants depends on the length of the non-inverted segments. We report two prenatal diagnoses of fetuses with recombinant chromosomes resulting from parental inversions recently detected in our laboratory. Case 1: CVS was performed on a 30-year-old pregnant due to edema, increased nuchal translucency and suspicious of cardiopathy. The karyotype showed a derivative chromosome 14 with partial deletion of q-arm. Subtelomeric MLPA showed 14qter deletion. Cytogenetic analysis of the mother showed that she was carrier of an inv(14)(p11.1q24). The pregnancy was terminated and the pathological examination confirmed tetralogy of Fallot. The karyotype of the fetus was described as 46,XY,rec(14)dup(14p)inv(14)(p11.1q24)mat. Case 2: CVS was performed on a 32-year-old pregnant due to increased nuchal translucency and positive screening for Edwards's syndrome (1/10). Cytogenetic analysis showed extra material on chromosome 4p. Subtelomeric MLPA showed 4pter deletion and 4qter duplication. After karyotyping the parents, the father proved to be carrier of an inv(4)(p15.3-p16q33), so the karyotype of the fetus was described as 46,XX,rec(4)dup(4q)inv(4)(p15.3-p16q33)pat. First trimester cyto-

netic study allows the correct diagnosis of such cases and provides an early genetic counselling in patients with high recurrence risk.

P02.156

Inversions detected in a study of 79920 prenatal and postnatal karyotypes

C. Hernando, R. Pujol, L. Cusidó, D. Carbonell, M. Rigola, R. Fernández, S. Escorihuela, N. Pujol, J. Barderi, C. Muñoz, L. Maynes, C. Preciado, J. Martos, S. Leal, O. Casablanca, E. Rodríguez, B. García, M. Cuartero, M. Pleguezuelos, J. Hernández, P. Grao;

CERBA Internacional, Sabadell, Spain.

Inversions are intrachromosomal rearrangements apparently balanced, generally without consequences for the carrier; however, an abnormal phenotype may be expressed if a breakpoint disrupts a critical gene. The observed phenotype depends on the length of the inverted segment, number of chiasmata produced and the genes of the involved region.

The incidence of pericentric and paracentric inversions in general population ranges from 0,12 to 0,7/1000 and 0,1 to 0,5/1000 in newborns respectively. The frequency in the general population is estimated at 1-2%. It is 13 times higher among infertile men than in general population. Indeed, these chromosomal abnormalities can perturb spermatogenesis and lead to the production of unbalanced gametes.

Out of 79920 cases that came in for genetic counseling during the last 6 years, we have detected 146 chromosome inversions, excluding polymorphic inversions of chromosome 9. Among these cases, 63 have been prenatally detected and 83 postnatally, 108 are pericentric inversions and 33 cases are inherited.

We have identified inversions for chromosomes 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14, 18, 20, X and Y.

Abnormal phenotype has been observed in 5 postnatal cases (3,4%). In 8 cases, the reason for referral was infertility or miscarriages, nonetheless ascertainment was primarily incidental.

In conclusion, our study has revealed an incidence of inversions in agreement with what it was expected. According to the literature, we have found that the presence of an inversion is rarely linked with an abnormal phenotype or abnormal progeny, nevertheless caution is recommended when counseling.

P02.157

De novo isodicentric X chromosome: report of two new cases

M. Pilechian Langeroudi, C. Azimi, M. Khaleghian, F. Farzanfar;

Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran.

Isodicentric X chromosomes with an Xq deletion are uncommon. Phenotypes are variable and correlate with the existence of mosaic or non-mosaic isodicentric X chromosomes and also depend on the amount of deleted genetic material in the patients.

We report two new cases which were referred to our Department due to primary amenorrhea. First case was 20-year-old, 158 cm height, 54 kg weight and with intermediate IQ. She presented with the typical features of Turner syndrome: broad and shield-shaped thorax, small breasts, wide-spaced nipples, cubitus valgus, short and thickened neck, low hairline, scant axillary and pubic hair, infantile external genitalia. Sonography report showed lack of ovaries and hypoplasia of uterus. Her thyroid hormones were normal but her FSH and LH were high. Karyotyping was performed on peripheral blood lymphocytes using different banding techniques according to standard methods. Her karyotype was: 46, X, idic (X)(q24). Chromosome studies of her parents and her three sibs revealed normal.

Second case was 18-year-old, 155 cm height, 62 kg weight and sub-normal intelligence. Her clinical features were: shield-like chest, no breast development, widely spaced nipples, pigmented nevi, normal neck, absence of axillary hair, limited pubic hair, infantile external genitalia. Her sonography revealed horseshoe kidney, hypoplastic uterus and absence of gonads. She had elevated FSH and LH. Her karyotype was: 45, X [80%] / 46, X, idic (X)(q22) [20%]. Cytogenetic investigations of her parents and her four sibs revealed normal.

P02.158

Jumping translocation in a phenotypically normal male - a study of mosaicism in spermatozoa, lymphocytes and fibroblasts

E. Iwarsson, S. Sahlén, A. Nordgren;

Dept of Molecular Medicine, Stockholm, Sweden.

Jumping translocation refers to a rare type of mosaicism, in which the same chromosome segment is translocated to different chromosome sites in different cell lines. We report a case of mosaicism for two cell lines, each cell line containing a different de novo Robertsonian translocation with the common breakpoint in the centromeric region on chromosome 13, in a phenotypically normal male. The karyotype was defined as: 45,XY,der(13;13)(q10;q10)/45,XY,der(13;15)(q10;q10) de novo. The relative occurrence of the two clones in lymphocytes, fibroblasts and spermatozoa was determined using karyotype analysis and fluorescence in situ hybridisation (FISH). Karyotype analysis of lymphocytes revealed 57 % der(13;13) cells and 43 % der(13;15) cells and for skin fibroblasts the figures were almost identical (56 % and 44 % respectively). FISH analysis showed 55 % balanced nuclei for unselected spermatozoa and after swim-up selection the number of balanced spermatozoa decreased to 41 %. In addition, 16 % of the unselected spermatozoa and 27 % of the spermatozoa after swim-up selection carried an additional chromosome 13, indicating a high risk for trisomy 13 offspring (Table 1). To the best of our knowledge this is the first study on meiotic chromosome segregation in spermatozoa from a jumping translocation carrier as well as a Robertsonian der(13;13) carrier. The reproductive significance of the abnormality and its implications will be discussed.

Table 1 Results from FISH-analysis of one thousand spermatozoa

Chromosome	13/15	13/15*	13/15*	13/15	13/15	13/15	13/15	13/15
No of signals from chromosome 13/15	1/1	0/1	2/1	1/0	1/2	2/2	2/0	3/1
% of spermatozoa	Before swim-up selection	54,80	26,10	15,70	1,80	0,80	0,20	0,30
	After swim-up selection	40,60	30,50	26,60	1,50	-	-	0,30
Segregation mode	Alternate	Adjacent				3:0†	Other††	

*These columns also contain segregation products of the homologous Robertsonian translocation der(13;13), which are not true adjacent segregation. †Using this two-colour FISH approach, it is not possible to differentiate between diploid spermatozoa and 3:0 segregation as both show two hybridisation signals for the probes used. ††Nuclei with an unexpected combination of signals according to the possible segregation modes are classified as other.

P02.159

Low level mosaicism homologous Robertsonian translocation (21;21) in a mother of boy with unbalanced der(21;21)

S. Teofilova^{1,2}, M. Bulatović^{1,2}, O. Miljanović^{1,2};

¹Center for Medical Genetics and Immunology-Clinical Center of Montenegro, Podgorica, Montenegro, ²Institute for Children s Disease- Clinical Center of Montenegro, Podgorica, Montenegro.

Parents of fetuses and children with unbalanced homologous acrocentric rearrangements are rarely found to be carriers or mosaic for the same rearrangements. Carriers of homologous acrocentric rearrangements (Robertsonian translocation) phenotypically normal they are at very high risk of having multiple spontaneous abortions and chromosomally abnormal offspring. Very frequently fetuses with homologous Robertsonian translocation arise postzygotic and are of maternal and parental origine.

We report about a phenotypically healthy woman with low level mosaicism for Robertsonian translocation (21;21). She delivered her first child in 21 year and he had Down's syndrome. Chromosomal preparations were made and banded using standard techniques. The karyotype of the boy was 46,XY,t(21;21),+21. After genetic counseling were made analysis parents. Father had normal karyotype 46,XY. Mother's chromosomes analysis showed very low level mosaicism, karyotype 46,XX [95]/45,XX,t(21;21) [5], which was detected because analysis made in a large number of cells.

After prenatal chromosomal diagnostic this woman delivered two healthy boys. Fourth pregnancy was aborted because prenatal cytogenetic analysis fetus showed unbalanced Robertsonian translocation. Identification of mosaicism allows for accurate genetic counseling and discussion of reproductive options.

P02.160

Characterization of nine small supernumerary marker chromosomes detected in 7,000 fetal karyotypes

N. Ploumis¹, E. Manolakos², M. B. Petersen¹, H. Kontos¹, P. Malligiannis³, A. Bolland⁴, T. Liehr⁵, R. Neroutsou²;

¹Genomedica, Athens, Greece, ²Bioiatriki S.A., Athens, Greece, ³Embryo Research Center, Athens, Greece, ⁴Research Center for Prenatal Diagnosis, Larissa, Greece, ⁵Institute Of Human Genetics and Anthropology, Jena, Germany. Small supernumerary marker chromosomes (sSMCs) are structurally abnormal chromosomes that cannot be characterized unambiguously by conventional cytogenetic banding techniques. Until recently, the great variety of marker chromosomes and difficulties with their identification presented a problem for the cytogenetic interpretation of the karyotype. The risk for an abnormal phenotype is about 7% when de novo sSMCs derived from chromosomes 13, 14, 21, and 22 are ascertained prenatally.

In a Greek survey of 7,000 amniotic fluid samples, nine fetuses with marker chromosomes were detected in our laboratory. Using combined approaches of conventional cytogenetics including special staining techniques and fluorescence in situ hybridization (FISH), we successfully characterized all of them, which assisted subsequent genetic counseling and decision making. Eight of the SMCs were proven to be of autosomal origin. Of the autosomal SMCs, two originated from chromosome 15, one from chromosome 9, one from chromosome 18, one from chromosome 20, and three from chromosome 22. One marker chromosome was of sex chromosome origin. Euchromatin material was detected in 7 cases. Five of seven de novo marker chromosomes were associated with abnormal findings and were terminated. Our study demonstrates that molecular cytogenetic characterization of marker chromosomes detected at prenatal diagnosis, is of crucial significance to risk evaluation and decision making of the couple.

P02.161

A complex chromosome 7q rearrangement identified in a patient with mental retardation, anxiety disorder and autistic features

J. G. Dauwerse, C. A. L. Ruivenkamp, K. B. M. Hansson, D. J. M. Peters, M. H. Breuning, Y. Hilhorst-Hofstee;
LUMC, Leiden, The Netherlands.

We present a 15 year old girl, the second child of healthy parents. The girl is mentally retarded, suffers from a severe anxiety disorder and has autistic features. Her mean IQ was 48. She has a coordination disorder and hypotonia. She has small palpebral fissures, simply formed low set ears, abnormal palmar creases, scoliosis, long halluxes and her thumbs are proximally implanted. Length and skull circumference were -1 and -2.5 SD respectively. G-banding indicated a *de novo* paracentric inversion 46,XX,inv(7)(q31.3q34). SNP-array analysis, however, revealed a ~10Mb, 7q21.11-7q21.3 deletion in the paternal chromosome. Subsequent FISH analysis with \pm 90 BAC/PAC clones in the 7q21-q35 region confirmed this deletion, but the expected paracentric inversion turned out to be an intra-chromosomal insertion of the fragment 7q31.31-q35 into band 7q21.3. PAC clone RP4-545C24 spans the breakpoint in band 7q35, positioning the breakpoint between the genes *NOBOX* and *TPK1*. The 7q31.31 breakpoint disrupts clone RP5-1047E14 and the predicted gene *NP079189*.

Six other patients with a deletion of 7q21.1-q21.3 have been reported previously. They share with our patient the following clinical features: mental retardation/developmental delay, microcephaly, mild facial dysmorphism, hypotonia, ear anomalies and small palpebral fissures. Our patient did not show any hearing loss, genital anomalies or growth deficiency, found in all of the previously reported patients. However none of the previous cases were reported to have anxiety disorder and/or autistic features. Therefore it is possible that disruption of the *NP079189* gene contributes to the anxiety disorder and the autistic features in our patient.

Cytogenetics Results in 301 Consanguineous Iranian Patients with Mental Retardation

F. Behjati¹, S. Ghasemi Firouzabadi¹, K. Kahrizi¹, R. KarimiNejad², J. Oveis³, P. Jamali⁴, F. Mojahed⁵, I. Bagherizadeh¹, J. Ansari¹, M. Fallah¹, F. Mojtahedi¹, S. Abedini¹, R. Vazifehmand¹, G. Bahrami Monajemi¹, H. Darvish¹, F. Rakhshani², A. Zadeh-Vakil³, A. Naghavi³, G. Mollashahi Sanatgar³, H. Najmabadi¹;

¹Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran, ²Kariminejad and Najmabadi Pathology and Genetics Center, Tehran, Islamic Republic of Iran, ³Zahedan University of Medical Sciences, Zahedan, Islamic Republic of Iran, ⁴Shahroud Behzisty Organization, Shahroud, Islamic Republic of Iran, ⁵Mashhad Genetics Counselling Center, Mashhad, Islamic Republic of Iran.

Mental Retardation (MR) has heterogeneous etiology mostly with genetic causes. Chromosomal aberrations are one of the most common causes of MR and are responsible for 4-28% of all the mental retardation. In order to identify genes involved in mental retardation, 301 Iranian families with consanguineous marriage and positive family history for MR have been investigated in Genetics Research Center in collaboration with Max Planck Institute in Berlin. In these families at least two sibs were affected. As a first step, both chromosome investigation and fragile-X screening were carried out to exclude any abnormality. Molecular investigations were done on all the normal karyotype and fragile X negative patients. Standard Cytogenetics techniques using high resolution and GTG banding were carried out on all the patients. The overall chromosome abnormality rate was 3% (8 patients). The abnormalities included der(18)t(4;18)(q31.1;q23)mat, der(22)t(21;22)(q11;q13), 46,XY karyotype with female phenotype, and premature chromosome condensation in three different MR patients with microcephaly. However, our abnormality rate is lower than the reported cases. This is due to biased referral reasons, as all our cases are due to consanguineous marriage and therefore suggestive of autosomal recessive inheritance.

P02.163

Premature chromosome condensation, Microcephaly and Mental Retardation: A report of three large consanguineous Iranian families

S. Ghasemi Firouzabadi¹, F. Behjati¹, K. Kahrizi¹, M. Garshasb², M. Motazacker², S. Esmaeili Nieh², S. Abedini¹, M. Mohseni¹, H. Darvish¹, G. Bahrami Monajemi¹, R. Vazifehmand¹, F. Rakhshani², A. Zadeh-Vakil³, J. Oveis³, A. Naghavi³, G. Mollashahi Sanatgar³, H. Ropers², H. Najmabadi¹;

¹Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran, ²Max Planck Institute for Molecular Genetics, Berlin, Germany, ³Zahedan University of Medical Sciences, Zahedan, Islamic Republic of Iran.

We report three out of a total of 50 Iranian consanguineous families affected with microcephaly, growth retardation, and mental retardation. These three families were unrelated and from northern and southern parts of Iran. Six members of one family and two of the other two were affected. Parents in all families were first cousins. Chromosome analysis using GTG banding technique on the probands showed a high frequency of prophase-like cells (80%) compared to normal controls (13%). The morphology of chromosomes was very poor and appeared fragile, twisted, curly and with raised breakage and overall very unusual looking. This phenomenon is due to premature chromosome condensation. Molecular investigation in the first family, using array-based homozygosity mapping and array CGH revealed deletion in the MCPH1 gene, one of four genes that have previously been implicated in autosomal recessive mental retardation with microcephaly. In the other two families, using homozygosity mapping, linkage to MCPH1 locus was suggested. MCPH1 gene is the only microcephaly gene associated with premature chromosome condensation.

The Cytogenetics findings demonstrating premature entry of cells into mitosis suggested mutation of genes involved in cell cycle regulation, which was then confirmed by molecular investigation. Our findings emphasize the importance of chromosome studies on patients with mental retardation and microcephaly. Findings of chromosomes with premature condensation in such patients implicate mutation in MCPH1 gene, which would therefore warrant further molecular investigations.

P02.164

Pseudo-Angelman phenotype in two patients with a 2q23.1 microdeletion identified by array-CGH

S. Jaillard^{1,2}, C. Dubourg^{3,2}, M. Gérard⁴, A. Delahaye⁵, L. Pasquier^{6,2}, C. Dupont^{4,5}, C. Henry¹, A. Tabet⁴, J. Lucas¹, A. Aboura⁴, V. David^{6,2}, B. Benzacken^{4,5}, S. Oden^{6,2}, E. Pipiras⁵;

¹Laboratoire de Cytogénétique, Rennes, France, ²UMR 6061, IFR 140 GFAS, Faculté de Médecine, Rennes, France, ³Laboratoire de Génétique Moléculaire,

Rennes, France, ⁴Département de Génétique, INSERM U676, Hôpital Robert Debré, AP-HP, Paris, France, ⁵Département d'Histologie Embryologie Cytogénétique, Hôpital Jean Verdier, Bondy, AP-HP, UFR-USMBH, Paris XIII, Paris, France, ⁶Service de Génétique Médicale, Rennes, France.

Background: Genome-wide screening of patients with mental retardation using Array Comparative Genomic Hybridization (array-CGH) has identified several novel imbalances. With this genotype-first approach, the 2q22.3q23.3 deletion was recently described as a novel microdeletion syndrome. We report two unrelated patients with a *de novo* interstitial deletion mapping in this genomic region and presenting similar "pseudo-Angelman" phenotypes, including severe psychomotor retardation, speech impairment, epilepsy, microcephaly, ataxia and behavioural disabilities.

Methods: The microdeletions were identified by array-CGH using oligonucleotide and BAC-arrays, and further confirmed by Fluorescence *In Situ* Hybridization (FISH) and semi-quantitative PCR.

Results: The boundaries and sizes of the deletions in the two patients were different but an overlapping region of about 250 kb was defined, which mapped to 2q23.1 and included two genes: *MBD5* and *EPC2*. The *SIP1* gene associated with the Mowat Wilson syndrome was not included in the deleted genomic region.

Discussion: Haploinsufficiency of one of the deleted genes (*MBD5* or *EPC2*) could be responsible for the common clinical features observed in the 2q23.1 microdeletion syndrome and this hypothesis needs further investigation.

P02.165

Etiological Investigation of the Midline Facial Defects with Hipertelorism by Molecular and Cytogenetic Techniques

E. L. Freitas¹, S. M. Gribble², M. Simioni¹, E. Prigmore², N. P. Carter², V. L. Gil-da-Silva-Lopes¹;

¹Universidade Estadual de Campinas, Campinas, Brazil, ²The Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

The Midline Facial Defects with Hipertelorism (MFDH) are a heterogeneous and rare group of craniofacial disorders mainly characterized by ocular hypertelorism and bifid nose. The pathogenesis of these conditions is still unknown. All 14 individuals in this study were previously investigated by clinical, dysmorphic and neurological evaluation, skull and facial X-rays, computerized tomography and MRI of the brain, and ophthalmologic and otorhinolaryngologic evaluation and GTG banding. The evaluations demonstrate facial alterations, structural and functional anomalies of the central nervous system, indicating, mainly, cortical migrations errors, perfusion variances and cerebella involvement. Based upon these observations, we determined an initial molecular investigation strategy. The phenotypes and a review of the literature suggested genes related to face and CNS development such as *SHH*, *PAX3* and *FGF8* may be involved in these disorders. These genes have been reported to participate in embryological development and are associated with some syndromes with craniofacial anomalies. The *SHH*, *PAX3* and *FGF8* genes were screened by direct sequencing and however mutations were found. To complement these studies, the whole genome tiling path *array-CGH* technique was performed and one deletion was found that affected *PAX3* in a familial case. Other copy number changes were detected and these findings are currently being confirmed by *FISH* and PCR. These preliminary results suggest our initial hypothesis that developmental genes, such as *PAX3*, play a role in the MFDH etiology.

P02.166

Diagnosis of Miller-Dieker syndrome (MDS) by fluorescence in situ hybridization (FISH)

M. Bassecourt, M. Alcaine, S. Izquierdo, E. Garcia, M. Calvo; Hospital Universitario Miguel Servet, Zaragoza, Spain.

Introduction: Mieller Dieker Syndrome (MDS) involves a deletion of the chromosomal band 17p13.3 which contains the gene called LIS 1 (lissencephaly-1). It is a syndrome with a very low frequency, estimated in 11,7 cases for each million of births, although the incidence and the prevalence are probably higher.

Objective: The aim of this study is to report a case from "breast-fed baby" with a extensive record: premature baby, dismorphic phenotype, lissencephaly, agenesis of the corpus callosum and septum pellucidum. Molecular techniques are used to confirm the submicroscopic

deletion on 17p13.3.

Methods: It was realized a double culture of lymphocytes with conventional banding GTG high resolution, followed by a FISH with the probe LSI 1 (maps to the 17p13.3 region on chromosome 17 containing the gene localization of the MDS).

Results: The fetu's karyotype is: Male: 46, XY, del (17) (p13.3). After hybridization with the probe, the SpectrumOrange LSI 1 signal was present in only one chromosome 17 and the SpectrumGreen LSI RARA 17q21.1 signal (control) was present in both chromosomes 17. Male: 46, XY, ish del (17)(p13.3 p13.3)(LIS1-).

The parents' karyotypes are in progress.

Conclusions: Our results postulate that approximately 90 percent of the patients with MDS phenotype show deletion of the band 17p13.3 but only in a 50 percent of these cases the deletion is visible by high resolution cytogenetic techniques. The own specificity of FISH achieves cytogenetic diagnosis that rarely it is obtained with banding techniques, unless prometaphasic chromosomes with high number of bands would be used.

P02.167

The results of missed abortus testing from Istanbul Memorial Hospital

O. Oner, G. Ozgon, C. Aslan, B. Onal, F. Fiorentino; Genoma Turkey, Istanbul, Turkey.

INTRODUCTION: The aim of this study is the retrospective data collection for patients underwent IVF treatment and spontaneous pregnancy lost between 2000-2007 for missed abortus with indications such as; advanced maternal age (ama), recurrent implantation failure (rif), recurrent pregnancy lost (rpl) and male factor.

MAT- METHOD: Tissue cultures were performed for missed abortus materials. Culture developments were observed and underwent harvesting steps in the optimum timing. Slides were stained with giemsa staining techniques (GTG) and 30 cells were counted.

Between years 2000-2007, tissue cultures were performed to 308 patients in our center. 149 of them were IVF patients, and 159 were spontaneous missed abort.

38/149 IVF and 48/159 spontaneous missed abort cases had abnormal karyotypes. We also analysed Trisomy 9, Trisomy 8, Trisomy 4 and Mosaic X in 4 PGD cases. The indications and chromosome analysis results of 38/149 IVF cases are represented in the table.1 below.

Table 1

Indications	Results
RPL (n=3)	Trisomy 8 (n=1) Triploidy (n=1) Trisomy X/ Trisomy 20 (n=1)
AMA (n=4)	Trisomy 13 (n=1) Trisomy 16 (n=1) Trisomy 18 (n=1) Trisomy 13/16 (n=1)
RIF (n=22)	Trisomy 3 (n=1) Trisomy 13/16 (n=1) Trisomy 12 (n=2) Trisomy 16/20 (n=1) Trisomy 13 (n=1) 45,X (n=1) Trisomy 15 (n=1) 47,XXY (n=1) Trisomy 16 (n=4) Tetraploidy (n=3) Trisomy 18 (n=1) del(1)(q32.1q42.1) (n=1) Trisomy 19 (n=1) der(14;14),+14 (n=1) Trisomy 20 (n=1) Trisomy 22 (n=1)
Male Factor(n=9)	45,X (n=4) Trisomy 16 (n=1) Trisomy 4 (n=1) inv(10q) (n=1) Trisomy 7 (n=1) Trisomy 9 (n=1)

Spontaneous missed abortus results (n=48)

Trisomy 3 (n=1) Trisomy 21 (n=3)
Trisomy 6 (n=2) Trisomy 22 (n=6)
Trisomy 7 (n=1) Triploidy (n=5)
Trisomy 8 (n=3) Tetraploidy (n=1)
Trisomy 16 (n=5) 45,X (n=11)
Trisomy 15 (n=5) Mosaic X (n=1)
Trisomy 17 (n=1)
Trisomy 18 (n=1)
Trisomy 20 (n=2)

DISCUSSION: In this study, we present that performing tissue cultures and karyotype analysis approve that PGD is a reliable option for the patients with several indications to have a non-affected offspring.

P02.168
Chromosomal Abnormalities in a Referred Population for Karyotype, Role of FISH to Refine the Diagnosis

A. K. Kamel, A. M. Mohamed, N. A. Helmy, H. A. Hussein, S. A. Hammad, H. F. Kayed, M. I. Shehab, A. Gerzawy, M. Eid, H. Afify;
National Research Centre, Cairo, Egypt.

The aim of this study was to evaluate the cytogenetic findings in Egyptian cases referred for suspected chromosomal anomalies and to clarify the role of FISH to refine the clinical diagnosis. Cytogenetic study was performed on 4890 cases referred to Human Cytogenetic Department, National Research Centre. Referrals were grouped into 20 different categories of which genetic counseling represented the highest group 19.2% followed by short stature 12.4%, repeated abortions 10.2%, MCA/MR 10% Down syndrome 9.2%. Chromosomal aberrations were identified in 17.8% of cases, sex chromosome abnormalities represented 22% of the abnormal chromosomes. The most common autosomal abnormality was Down Syndrome 52%. In structural chromosome aberrations of autosome, deletion was the most common 6.8%, inversion 6% and translocation 5.2%. Different FISH probes were used when indicated, it was applied in 10% of referred cases as in cases of microdeletion syndromes, marker chromosomes, cryptic translocation, sex chromosomes identification and subtelomeric deletion. Accurate and refined cytogenetics and molecular cytogenetics diagnosis in our cases was the corner stone in proper genetic counseling.

P02.169
Characterization of rare karyotype anomaly 45,XX,-21/46,XX,r(21) by comprehensive FISH: mosaic status and constitution of ring chromosome 21

A. D. Polityko¹, I. Naumchik¹, N. Rumyantseva¹, O. Khurs¹, E. Jaroshevich¹, K. Mrasek², T. Liehr²;

¹Republican Medical Center "Mother and Child", Minsk, Belarus, ²Institute of Human Genetics and Anthropology, Jena, Germany.

Mosaic combination of monosomy 21 and partial monosomy due to ring chromosome 21 is a very rare finding in human karyotype. Here we describe a 2,5 years old female who has been referred to genetic department because of multiple congenital malformations (microphthalmia, cataract, corneal opacity, cerebellum abnormality, heart defect (ASD), craniofacial dysmorphias) and mental/growth retardation. Parents were young healthy non-consanguineous couple. Conventional cytogenetic study of affected child revealed diagnosis 45,XX,-21[160]/46,XX,r(21)(p11q22)[160] de novo (parental karyotypes were normal). Somatic aberrations of ring chromosome in clone with r(21) were not found.

Molecular cytogenetic analysis was performed to characterize the constitution of r(21). Following probe sets were used for that: subtel 21q (Abbott/Vysis), BAC 105E1 (21q21.1), BAC 143N1 (21q21.3). Subtelomeric segment has been deleted by ring chromosome formation, and finally r(21) was described as ish r(21)(p12q22)(BAC 105E1+, BAC 143N1+, subtel 21q-).

Possible mechanisms of the mosaic karyotype abnormalities formation, clinical and cytogenetic aspects of examination of the patient, and data of the literature are discussed.

[Supported in parts by DAAD 325/2007, DFG WER 17/01/06].

P02.170
Multiple chromosome abnormalities in a case of neuroblastoma

R. Sonar, B. B. Ganguly;

MGM Center for Genetic Research and Diagnosis, New Bombay, India.

Chromosomal abnormalities play pivotal role in the process of malignant transformation of neural cells which is named as neuroblastoma. This malignancy has been studied extensively by various techniques like cytogenetics, flow cytometry, molecular methods, histopathology etc. to identify the genetic markers for their classification and gather information on significant prognostication for selection of appropriate choice of treatment. The most common genetic events associated with neuroblastoma are loss of heterozygosity (LOH) for the short arm of the chromosome 1 (1p), over expression of *N-myc* proto-oncogene, triploidy or tetraploidy, and defects in expression or function of nerve

growth factor receptor (NGFR). In our study, chromosomal analysis was carried out in the bone marrow sample of 4 years old boy following unstimulated cell culture technique. Conventional G-banding analysis of 40 cells revealed multiple complex chromosomal rearrangements, 48,XY,t(1;15)(p22;q24),add(6q25),add(7q32)x2,t(11p;?),t(11q23),add(12q24),t(19q13;?),del(20q13),+mar in 98% cells. In addition one tetraploid cell was observed. In this case 1(p22) was not deleted but translocated to chromosome 15(q24). Presence of t(11q23) suggests the loss of critical heterozygous region. The above abnormality suggests advanced stage of the disease and will experience poor prognosis. However, most of the participating chromosomes and their break points could not be identified due to limited resolution of the technique. Hence, it has been understood that cytogenetic study could form the primary step for understanding the disease and could further guide for employment of molecular techniques for analysis of amplification and/or deletion of other genes.

P02.171
Cytogenetic findings in one case of Nijmegen Syndrome developing Burkitt lymphoma

V. Belengeanu¹, M. Stoian¹, N. Andreescu¹, A. Belengeanu¹, M. Banateanu², E. Ormerod³;

¹University of Medicine and Pharmacy, Timișoara, Romania, ²II Pediatric Clinic, Emergency Clinical Hospital, Timișoara, Romania, ³Department of Medical Genetics, Ullevål University Hospital, Oslo, Norway.

Here we report an 8 years old girl who had post natal growth deficiency, microcephaly, facial dysmorphism, partial syndactyly of the second and third toes, susceptibility to infections, leucocytosis, immunodeficiency, adenopathy, but no sign of telangiectasia, ataxia and in evolution developed malignancy (Burkitt lymphoma). The first lymphocytes culture from this patient was unsuccessful, which is concordant with other reports from literature. It is known that it is difficult to perform cytogenetic analysis due to the poor proliferation capacity of lymphocytes. From the first culture, 9 mitoses could be analysed, 6 metaphases had a normal karyotype while 3 were incomplete. The second culture revealed 16 mitoses, including four incomplete metaphases. Cells rearrangements of chromosomes were found in 4 metaphases. Chromosome anomalies that we found are: isochromosome 11q, int del(7)(q21), acentric chromosomes and marker chromosome. The images of the metaphases were sent for reevaluation at Ullevål University Hospital Oslo, Department of Medical Genetics. By combining clinical manifestations and laboratory findings including cytogenetic findings and taking in account the evolution of the patient we sustain the diagnosis of Nijmegen Breakage Syndrome. At the moment of reporting this case, the diagnosis of Nijmegen breakage syndrome was confirmed by molecular analyses. Our patient had developed malignancy in a relative short period of time after she was first investigated and the prognosis is estimated to be poor. This is the first case of Nijmegen Breakage Syndrome reported in Romania.

P02.172
A child with proportional pre- and postnatal growth retardation, oculocutaneous albinism and normal intelligence with a 15(q26.2-qter) deletion

M. Poot¹, M. J. Eleveld¹, R. van 't Slot¹, A. A. Verrijn Stuur², M. M. van Genderen³, R. Hochstenbach¹, F. A. Beemer¹;

¹Department of Medical Genetics, Utrecht, The Netherlands, ²Department of Pediatric Endocrinology, Utrecht, The Netherlands, ³Institute for visually handicapped children Bartimeus, Zeist, The Netherlands.

We report on an 8 ½ years old girl with severe pre- and postnatal growth retardation, congenital heart malformation, facial asymmetry, oculocutaneous albinism, and subluxation of the radial heads. Postnatal growth was severely retarded and proportionate (height -4.5 SD, OFC -3SD at 8 years of age). Her intelligence was in the low normal range. Extensive endocrinological studies showed a normal growth hormone response to glucagon, without high growth hormone levels possibly indicating growth hormone resistance. At 7 years of age oculocutaneous albinism was diagnosed. The albinotic phenotype was unusual because, despite clear ocular and systemic features of albinism, the girl did not have foveal hypoplasia, misrouting, or nystagmus. By GTG-banding a deletion of band 15q26 was found. Array-CGH, using a 3783 BAC array, revealed a segmental monosomy of the 15(q26.2->qter) region, which was narrowed down to a 6.87 Mb deletion by us-

ing the Illumina Infinium 317 K SNP array system, and subsequently confirmed by fluorescence in situ hybridisation (FISH) analysis. The deletion appeared to have arisen de novo. The *IGF1R* (insulin-like growth factor 1 receptor) and the *NR2F2* genes were situated within, but the *OCA2* (oculocutaneous albinism II) gene (formerly called the P gene) was located outside the deleted region. Clinical findings in our patient were compared with previously reported cases carrying terminal deletions of 15q26.2. This allowed us to expand the clinical phenotype of terminal 15q26.2 deletions and to indicate candidate genes for several phenotypic features.

P02.173

Array CGH with genomic DNA extracted from peripheral blood detects overrepresentation of 12p material in a boy with Pallister-Killian syndrome features

S. Uhrig¹, A. Obenauf¹, U. Gruber-Sedlmayr², S. Langer³, M. R. Speicher¹;
¹Institut für Humangenetik, Graz, Austria, ²Abteilung für Allgemeine Pädiatrie, Universitätsklinik für Kinder- und Jugendheilkunde, Graz, Austria, ³Institut für Humangenetik, Technische Universität München, München, Germany.

Pallister-Killian syndrome (PKS) is a rare disorder characterized by multiple congenital anomalies. The cytogenetic hallmark change in PKS is the presence of a supernumerary isochromosome 12p (i(12p)), which is usually limited to skin fibroblasts. Here we report on a 11-year-old boy with clinical features suggestive for PKS. Amniocentesis performed elsewhere did not show any abnormality. At the age of 9 years he developed seizures requiring anticonvulsant treatment. When we saw the boy at age 11, he had a coarse face with hypertelorism, a broad nasal bridge, a highly arched palate, long philtrum and prominent lower lip. On the right forehead and chest were streaks of hypo- and hyperpigmentation. G-banding analysis of peripheral lymphocytes revealed a mosaic karyotype with a small metacentric supernumerary marker chromosome (SMC) in about 30% of metaphases. Array CGH using genomic DNA extracted from peripheral blood identified overrepresentation of 12p, however, several 12p-clones showed a balanced ratio profile, which was not compatible with an isochromosome 12p. Therefore, we further characterized the marker by forward painting with subtelomeric BAC-clones for 12p (GS-496A11) and 12q (12q-21K18). While both clones showed regular signals on both chromosomes 12, the marker had a signal on only on one end. Hybridising the centromere specific probe for chromosome 12 both normal chromosomes 12 and the marker showed unique hybridization signals. At present, we are using additional clones to characterize this der(12) further. Our results suggest that array CGH is suitable for the detection of low level mosaics and may thus complement conventional banding analyses.

P02.174

Molecular cytogenetic study of the partial monosomy 21q

L. Nazaryan¹, S. Midyan¹, R. S. Møller^{2,3}, R. Ullmann⁴, N. Tommerup²;
¹Center of Medical Genetics and Primary Health Care, Yerevan, Armenia, ²Wilhelm Johannsen Centre for Functional Genome Research, Institute of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark, ³Danish Epilepsy Centre, Dianalund, Denmark, ⁴Max Planck Institute for Molecular Genetics, Berlin, Germany.

INTRODUCTION: Partial monosomy 21 is rare and only a few cases have been reported so far. Furthermore, the extent of the deletions has not been determined in the majority of these cases, which makes phenotype-genotype correlation difficult. In this study we present a 1 year old girl with severe neonatal hypotrophy, microcephaly, mental retardation, large low-set and deformed ears, wide forehead, strabismus, massive nose, long philtrum, wide mouth with thin lips, micrognathia, pectus excavatum, spinal curvature and clubfoot.

METHODS: The patient was analysed using conventional cytogenetics, array CGH and FISH. Array CGH was carried out using a sub-megabase whole genome tiling path BAC array and the results were verified by FISH analysis.

RESULTS: Cytogenetic analysis of the patient and her parents revealed a de novo deletion of chromosome 21q22.11-qter. The deletion was further characterized by array-CGH which justified the borders of the deletion to 21q22.12-qter (chr21:35,860,000-46,940,000, hg17). In addition we detected a 0,9 Mb duplication on chromosome 17q12. Array CGH was also performed on the cytogenetically normal parents and the results showed that the duplication was inherited from the phenotypically normal father.

CONCLUSION: In the present study we analysed a patient with a terminal deletion of 21q22. The clinical manifestations of our patient are mostly consistent with previously reported cases. However, since the extent of the majority of these deletions has not been determined, though phenotype-genotype correlation is difficult. We therefore recommend that patients with chromosomal abnormalities diagnosed by conventional karyotyping should be reinvestigated by array CGH.

P02.175

Partial trisomy of chromosome 10q due to the paternal balanced t(10;22)(q24;p11)

T. Cora¹, H. Acar¹, M. Acar¹, B. Alımcı¹, R. Örs²;

¹Dept. of Medical Genetics, Medical Faculty, Selçuk Univ, KONYA, Turkey,

²Dept. of Pediatri, Medical Faculty, Selçuk Univ, KONYA, Turkey.

The distal part of the long arm of chromosome 10 trisomy is a well defined, but rare syndrome. This chromosomal abnormality is almost the result of an balanced translocation from the parents. In the present report, we present a family having a girl with balanced translocation, a healthy girl and a malformed female infant with the pure partial trisomy of the long arm of chromosome 10q (q24 leads to qter), resulting from an unbalanced segregation of a paternal balanced translocation t(10;22)(q24;p11). In this patient, physical examination showed to have abnormal phenoty such as microcephaly, small nose, depressed nasal bridge, blepharophimosis, micrognathia, hypotonicity and growth retardation. These clinical findings are compared with the other previously described cases with the trisomy 10q in the literature.

P02.176

Report of a dysmorphic case from IRAN with a new finding, and structural abnormality in the long arm of chromosome 1.

F. Hadipour¹, Z. Hadipour², F. Behjat^{3,4}, Y. Shafeghat^{3,1};

¹Sarem Women's Hospital, Tehran, Islamic Republic of Iran, ²Sarem Women's hospital, Tehran, Islamic Republic of Iran, ³Genetics Research Center, Tehran, Islamic Republic of Iran, ⁴Sarem Women's Hospital, Tehran, Islamic Republic of Iran.

Background: Partial trisomy of 1q42 is one of the structural Chromosome abnormalities with a distinctive phenotype.

Material and Method: Here in we report a 1-year-old Iranian girl referred to our genetics center because of neuro-developmental delay and dysmorphic findings.

Cardinal features were: trigonocephaly, microcephaly, spastisity, sunken eyes, prominent forehead, low set and malformed ears (with posterior rotation and abnormal helix), micrognathia, long philtrum, carplike mouth, frontal bossing, high palate, high nasal bridge, high arched eyebrows, short neck, strabismus, and asymmetric face and locked jaw, abnormal and small hands and feet, brachydactily of fingers and toes, flat feet, congenital hearth disease, dysplastic nails, simian crease in right hand and abnormal sole in the left hand.

Chromosome study: according to the MR, and MCA we carried out chromosome analysis by high resolution GTG banding technique. The result was a structural abnormality, a duplication in1q42 region. Parents were investigated and they were normal.

Conclusion: our study showed that this chromosome Abnormality was de novo in this case. So, we should consider structural and numerical chromosome abnormalities in the patients, with MCA+MR. Microcephaly is a new finding for this locus, and was not reported before.

Keywords: Partial trisomy of 1q42, trigonocephaly, microcephaly,

P02.177

X chromosome centromere instability: an epiphenomenon of ageing or of Alzheimer disease?

L. Zivkovic¹, B. Spremo-Potparevic¹, Z. Milicevic², N. Djelic³, V. Bajic⁴;

¹Faculty of Pharmacy, Institute of Physiology, Department of Biology and Human genetics, Belgrade, Serbia, ²"VINCA" Institute of Nuclear Sciences, Laboratory for Molecular Biology and Endocrinology, Belgrade, Serbia, ³Faculty of Veterinary Medicine, Department of Biology, Belgrade, Serbia, ⁴Institute of Biomedical Research Galenika, Belgrade, Serbia.

Premature centromere division (PCD) as a cause of improper chromosome separation is found in ageing cells, Alzheimer disease patients, various chromosome instability syndroms and cancers. Gender plays an important role in the pathogenesis of AD and can influence the risk of developing AD. Is PCD a cytogenetic marker of this disease, or only epiphenomen of ageing? PCD phenomenon of metaphase chromosome

from peripheral blood lymphocytes were evaluated in 25 sporadic AD subjects (14 females and 11 males) and 25 healthy elderly subjects (14 females and 11 males). Multifactorial analyses of variance was used to assess the frequency of PCD in our samples in correlation to age (up to 65, including 65 years vs. over 65 years) and illness (AD patients vs. elderly controls).

A statistically significant difference was found in the number of metaphase with PCD, X chromosome comparing AD female and female controls ($P = 0.02$) and in the number of total PCD, X chromosome in female sample ($P = 0.04$). Our results showed no positive correlation with age concerning the X chromosome. These results point to a fact that the X chromosome is preferentially affected in AD cases of women and that the amplification of instability of the X chromosome in women are not precisely connected to age.

P02.178 Congenital Lower Lid Entropion with pericentric inversion 9(p13-q12) and deletion in Chromosome 10(q23-qter)

M. Tanwar¹, M. Kumar¹, P. Gupta², N. Pushkar², R. Kumar¹, R. Dada¹;

¹Laboratory for Molecular Reproduction and Genetics, Dept. of Anatomy, AIIMS, New Delhi, India, ²Dr. Rajendra Prasad Centre for Ophthalmic Sciences, AIIMS, New Delhi, India.

Entropion is an inversion of the eyelid toward the globe. The lower eyelid is more frequently affected and depending on the underlying disorder. Entropion may be either unilateral or bilateral. Congenital entropion is an extremely rare disorder, usually involves the lower eyelids. It is often familial and seen more frequently in Asians. The possible causes for this condition include structural tarsal plate defects (horizontal tarsal kink syndrome) and shortened posterior lamella (tarsus, conjunctiva, eyelid retractors). It has been reported that congenital entropion is a part of a syndrome involving multiple systemic anomalies. A case of primary congenital upper eyelid entropion with cardiovascular, musculoskeletal, and central nervous system abnormalities and another with congenital heart defect has been reported. But, to the best of our knowledge there is no report describing the genetic background of the disease. We report a patient of congenital lower lid entropion and corneal opacity who was referred to us for cytogenetic analysis. GTG-banding of 50 well spreaded metaphases revealed an interstitial deletion in chromosome 10 and pericentric inversion of chromosome 9. Chromosomal analysis showed 46, XX (57%)/46,XX,del(10q23-qter)(10%)/46,XX,inv(9p13-q12)(33%) karyotype. Most publications suggest that pericentric inversion of chromosome 9 is a polymorphic variation and its clinical significance is uncertain. Thus our finding raises the possibility that the congenital lower lid entropion locus may be located on chromosome 10. This represents a severe manifestation of the disease. Finally, a workup of this finding is suggested and more cases of congenital lower lid entropion needs to be screened using cytogenetics

P02.179 Chromosome segregation in blastomeres from translocation carriers.

M. Trčková, N. Jenčíková, H. Peková, V. Nedomová, J. Horáček, D. Stejskal;
The Centre of Medical Genetics and Reproduction Medicine GENNET Ltd., Prague, Czech Republic.

Balanced carriers of reciprocal and Robertsonian translocations suffer from reduced fertility and are at increased risk of recurrent spontaneous abortions or chromosomally unbalanced offspring. During meiosis I, segregation of the translocated chromosomes and their normal homologues produces a variety of unbalanced gametes. Preimplantation genetic diagnosis (PGD) offers to the translocation carriers an alternative to prenatal diagnosis and a possible pregnancy termination. PGD allows not only selection of normal embryos but also provides unique information about the chromosome segregation.

Interphase FISH combining subtelomeric and centromeric probes was used to examine the blastomeres of 126 embryos from 6 Robertsonian (2 female/4 male carriers) and 12 reciprocal translocation carriers (6 female/6 male carriers). In Robertsonian translocation carriers, 39.3% normal and 53.6% aneuploid (25% trisomic and 28.6% monosomic) embryos were found. Each reciprocal translocation had a different segregation mode, but at least one balanced blastomere was found in each translocation. The lengths of translocated segments varied from 7.8Mb to 140.4Mb (4% to 73% of the chromosome involved). Alternate

segregation (chromosome balanced) was found in 31% blastomeres. In unbalanced blastomeres, 39.4% resulted from adjacent segregation, 15.5% from segregation 3:1 and 14.1% of blastomeres were haploid, polyploid or chaotic. No statistical difference between male and female rates of chromosome abnormalities in both Robertsonian and reciprocal translocation carriers was observed. Comparison of the length of translocated chromosome segment and the type of segregation revealed a trend for higher proportion of normal blastomeres when shorter chromosome segments were involved.

P02.180 Array CGH analysis (two novel deletions) in pigment dispersion syndrome

R. Mikelsaar¹, H. Molde², O. Bartsch³, M. Punab⁴;

¹Institute of General and Molecular Pathology, Tartu, Estonia, ²Joint-Stock Company of Ophthalmic Surgery, Tallinn, Estonia, ³Institute for Human Genetics, Mainz University School of Medicine, Mainz, Germany, ⁴Andrology Unit, Tartu University Clinics, Tartu, Estonia.

Pigment dispersion syndrome (PDS) is an ocular disorder in which melanin granules from the iris pigment epithelium are distributed throughout the anterior segment on various ocular structures. The prevalence of PDS is 2.5% in whites, and 1.6% in black population. In half of cases, PDS progresses to pigmentary glaucoma. The etiology of PDS is not known. Only one locus for PDS has been identified at 7q35-q36. We report the first, a 34-year old, male with PDS and a balanced 10;15 translocation, revealed using GTG banding. Molecular cytogenetic breakpoints were located using fluorescence in situ hybridisation (FISH) analysis at chromosome 10cen and on 15q between D15Z alphoid DNA (CP5033) and SNRPN (DNA probes from Abbott-Vysis and Oncor). The proband's karyotype was interpreted as 46,XY,t(10;15)(p11.1;q11.1). Array CGH analysis using the DNA sample of the patient was genotyped in duplicate with the HumanHap300-Duo Beadchip (Illumina). Array CGH analysis did not show altered DNA sequences in the breakpoints of the translocation, but revealed two novel deletions in 2q22.1 and 18q22.1. These two CNV regions are not previously described in the Database of Genomic Variants. We suppose that the coexistence of t(10;15) and PDS in our patient is a coincidence. However, the deletion in 2q22.1, where the gene LRP1B has been located, may play a major role in the dysembryogenesis of the eye and cause the disorder. As array CGH shows a number of the chromosomal alterations, it is important to use this molecular karyotyping in diagnostic laboratories.

P02.181 Polymorphic variants and phenotype correlation. Findings in a Brazilian reference center

C. L. Campanhol¹, R. Paleari¹, A. Bedone², K. C. Andrade³, R. Barini⁴, J. K. R. Heinrich¹;

¹Laboratorios Clínicos Especializados CAISM/UNICAMP, Campinas, Brazil,

²Tocogynecology Department/ Faculdade de Ciências Médicas / UNICAMP,

Campinas, Brazil, ³Ultrasound Unit CAISM/UNICAMP, Campinas, Brazil, ⁴Fetal

Medicine Unit and Tocogynecology Department/ Faculdade de Ciências Médicas / UNICAMP, Campinas, Brazil, Campinas, Brazil.

Objective: To describe the frequency of polymorphic variants such as inv(9), 9qh+, 16qh+ and satellite increase and associated phenotype in a clinical cytogenetics core in a Women's University Hospital.

Methods: A retrospective review of the laboratory databases identified all cases of polymorphic variants from January 2003 to December 2007. Clinical records were also evaluated.

Results:The total number of cases analyzed in 5 years was 797. Cytogenetic evaluation of prenatal diagnosis cases with abnormal ultrasound findings were the most frequent (n=602[75.5%]) and showed rates of 73.5% (n=443) of normal karyotypes, 21.8% (n=131) of abnormal karyotypes and 4.7% (n=28) of polymorphic variants. Out of 162 karyotypes in women who were evaluated for sex-related disorders, 67.3% (n=109) presented a normal karyotype, 23.5% (n=38) presented an abnormal karyotype and 9.2% (n=15) presented polymorphic variants. Individuals who were investigated for recurrent abortions showed a 9.1% rate (n=3) of polymorphic variants among 72.7% (n=24) of patients with normal karyotype and 18.2% (n=6) with abnormal karyotypes. Abnormal karyotypes included both structural/numerical and autosomic/sexual abnormalities. Phenotypes associated with polymorphic variants at prenatal diagnosis were cardiac and facial

abnormalities followed by abdominal wall defects, central nervous system and diaphragmatic hernia. Abnormal amniotic fluid volume was present in 6 cases.

Conclusion: Although polymorphic variants are considered to be silent abnormalities within karyotype analysis, our study showed elevated rates of those variants in our reference center if compared to the general population which might indicate a strong correlation between the onset of an abnormal phenotype and karyotype polymorphic variants.

P02.182

Chromosome bands specially affected in fishermen who participated in the clean-up of the Prestige oil spill

G. Monyarch Gros¹, G. Rodríguez Trigo², J. P. Zock², F. Gómez², H. Vereá², J. A. Barberá², M. D. Coll¹, F. Pozo-Rodríguez², C. Fuster¹;

¹Universitat Autònoma de Barcelona, Bellaterra, Spain, ²Grupo SEPAR-Prestige, Barcelona, Spain.

Context The oil tanker Prestige wrecked and produced contamination of the coast of Galicia (Spain), in 2002. A great number of people participated in the cleaning-up tasks.

Objectives To evaluate potential genotoxic effects in lymphocytes of the fishermen exposed, we analyzed the presence of chromosome alterations.

Methodology We analyzed 50 clean-up work and 46 non-exposed fishermen from 800 fishermen that were previously interviewed about the details of their cleaning-up tasks. The fishermen who were non-smokers and in good health were included in exposed (E) group (>15 days of cleaning-up tasks at least four hours per day) and non-exposed (NE) group. The collection of the samples was performed between July 2004 and February 2005. Peripheral lymphocytes were cultured. Breakpoints implicated in chromosomal abnormalities were identified by G-banding.

Results Comparison of cytogenetic data between the E and NE groups showed significant differences for: (i) the proportion of total chromosome lesions (E:67 lesions /4,521 metaphases; NE:35/4,859; $P=0.0079$), and (ii) the proportion of structural chromosome alterations (E:92 structural alterations/1,368 metaphases karyotyped; NE:32/1,285; $P<0.0001$). Statistical analysis of the 112 breakpoints implicated in these chromosomal abnormalities showed that seven bands were specially affected in the E group: 7p15, 7q33, 9q34, 13q32, 16p13.3, 18q23 and Xq21. In addition, in the NE group the bands most affected by the 60 breakpoints found were: 1q21, 11q23 and 14q23.

Conclusion Participation in clean-up tasks of oil spills may result in prolonged genotoxic effects lasting two years after exposure.

P02.183

Primary ovarian failure associated with pericentric inversion of chromosome 3

V. B. Chernykh, V. A. Galkina, O. V. Barkova, T. V. Zolotukhina; Research Centre for Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russian Federation.

We report on a patient with primary ovarian failure and pericentric inversion of chromosome 3. Female was referred for genetic examination because of secondary amenorrhea. Menarche occurred at the age of 14 years; menses were irregular and stopped three years later. Patient had no additional clinical signs. At the age of 19 years she's height was 167 cm, weight 54 kg. Hormone tests revealed a high level of LH and FSH, with low level of estradiol (hypergonadotropic hypogonadism). Pelvic ultrasonography displayed the hypoplasia of uterus and ovaries; fallopian tubes were normal. Histopathology of gonads revealed dysgenetic ovarian tissue with single follicles. Her lymphocyte karyotype was 46,XX,inv(3)(p24.2;q21).

The patient's mother with similar inversion had irregular menstrual cycle. She was reported to have seven pregnancies, two of which have ended with births, and five pregnancies - medical abortions. The oldest sister of the patient was healthy and had regular menses. The karyotypes of she's eldest sister and father was normal.

A number of genes involved in female germ cells differentiation and ovarian cancer have been mapped in both short and long arms of the human chromosome 3. Probably, ovarian failure was resulted from this pericentric inversion.

P02.184

Prenatal diagnosis by QF-PCR: a case with partial trisomy of chromosome 13

C. Curcio¹, C. Lodrini², A. Biasi², C. Melles¹, L. Spaccini², D. A. Coviello¹;

¹Fondazione IRCCS, Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy, ²Istituti Clinici di Perfezionamento, Ospedale Buzzi, Milan, Italy.

QF-PCR is a well established method for the rapid prenatal diagnosis of the most common chromosomal aneuploidies (chromosomes 13, 18, 21 and sexual).

This technique provides fast results and it is coupled with the conventional cytogenetic analysis on samples of women with ultrasound abnormalities at different gestational weeks, failure of long term culture and in order to differentiate twins.

Here we report a case of pregnancy with ultrasound findings of multiple fetal malformations: QF-PCR performed on amniotic fluid didn't show numerical anomalies for chromosomes 18 and 21; it also identified the presence of two X chromosomes, associated to female sex.

About chromosome 13, the three specific chromosome polymorphic STR markers gave different results: D13S631 and D13S258 located in 13q31-32 and 13q21 respectively, suggested a possible trisomy, while the STR D13S742, located in 13q11-13q12.1, showed a normal chromosomal pattern.

The cytogenetic analysis confirmed the presence of an additional marker belonging to chromosome 13. Although we agree that QF-PCR cannot substitute the traditional cytogenetic analysis, this case brings out its ability to provide reliable and rapid results even in case of partial chromosomal aneuploidies of the examined chromosomes.

P02.185

Genomic instability in blood and fibroblasts submitted to controlled cell phone radiation levels.

J. K. R. Heinrich¹, A. M. Almeida²;

¹CAISM/UNICAMP, Campinas, Brazil, ²Foundation CPqD, Campinas, Brazil.

OBJECTIVE To evaluate genomic instability characterized by multiple targets of investigation both in conventional and molecular cytogenetics and apoptosis. The results comprise a 4-year joint project between a University and a Research Foundation.

METHODS: We have investigated the effects of AMPS, CDMA and GSM cell phone radiation in cultured blood samples and skin fibroblasts cell lines after radiation exposure in a specially designed exposition set up (TEM CELL) at SAR levels from 0,8 to 10W/kg. After the exposition, the cells were applied into different assays such as conventional cytogenetic analysis for structural and numerical abnormalities, micronuclei frequency, HER-2, C-MYC and TP53 gene status through FISH, CGH profile and apoptosis-related proteins.

RESULTS: Genomic changes such as chromosomal breaks, translocations, marker chromosomes and aneuploidy, when compared to the controls, were detected in SAR levels above 5W/kg as well as the increase of micronuclei frequency above 10W/kg. CGH profiles and FISH analysis did not show a significant difference between the controls and the exposed samples. It was observed a trend for the detection of different genomic instability processes above SAR limits of 5 and 10W/kg.

CONCLUSION: As genomic instability and chromosome damage are frequently related to tumorigenesis, our findings support the hypothesis of a dose-dependent positive effect of RF radiation on the genome of cells and also give further evidence to suggest continuous cytogenetic investigation of occupationally exposed individuals to SAR levels above the accepted international limits. P02.186

Radioinduced bystander effect revealed in vitro and in vivo in mixed human lymphocytes culture

O. V. Shemetun, O. A. Talan, M. A. Pilinskaya;

Research Centre of Radiation Medicine, Kijiv, Ukraine.

The new methodic approach to investigation of radioinduced bystander effect in somatic human cells with help of G-banding cytogenetics had been elaborated. The frequency of chromosome aberrations in proposed by us model system - "mixed human peripheral blood lymphocytes culture" consisted of cells differed on cytogenetic sex markers (XX, XY) and some morphological chromosome peculiarities had been studied. It had been shown that joint cultivation of intact lymphocytes

did not influence upon their background frequency of chromosome aberrations. Under joint incubation of X-irradiated *in vitro* (in doses 250 and 1000 mGy) and intact lymphocytes the dose-dependent interaction between targeted and untargeted cells had been discovered - cytogenetic effect in bystander cells (4.31 and 6.13 of aberrations per 100 metaphases, accordingly) cultivated with irradiated ones (6.99 and 21.19 of aberrations per 100 metaphases, accordingly) elevated their background level (2.27 aberrations per 100 metaphases). In mixed cultures established from unexposed donors and Chernobyl liquidators (with radiation doses in range 1010-2370 mGy) the mean-group frequencies of aberrations in irradiated cells were 5.21 ± 0.89 per 100 metaphases, in bystander cells - 4.05 ± 0.64 per 100 metaphases. The difference between spectrum of aberrations in exposed and intact cells had been revealed both *in vitro* and *in vivo* - in targeted cells specific cytogenetic markers of irradiation dominated (unstable and stable chromosome exchanges), as well as in "bystander" cells simple aberrations (chromatid breaks and terminal deletions that can be considered as the markers of chromosome instability) mainly induced. All cytogenetic effects had been characterized by essential interindividual fluctuations.

P02.187

Can segregation analysis in spermatozoa of male carriers of a reciprocal translocation help in genetic counselling?

E. Van Assche¹, W. Vegetti², M. Bonduelle³, G. Verheyen⁴, A. Van Steirteghem⁴, I. Liebaers³;

¹Center for Medical Genetics- UZA, Antwerp, Belgium, ²First Department of Obstetrics and Gynecology, Milan, Italy, ³Center for Medical Genetics UZ-Brussel, Brussels, Belgium, ⁴Center for Reproductive Medicine UZ-Brussel, Brussels, Belgium.

Balanced reciprocal translocations (Rcp), the most frequent chromosomal rearrangements in humans are mainly transmitted by one of the parents. We used the FISH technique to analyse the chromosomal content of spermatozoa from 20 Rcp carriers. A total of 15375 sperm nuclei were analysed. The mean frequency of normal/balanced and unbalanced gametes in the carriers was 47.4% (range 20.4-89.6%) and 52.6% respectively. In 11/20 carriers the frequency of normal/balanced and unbalanced sperm differed statistically ($p < 0.05$). In one carrier the frequency of balanced/normal sperm exceeded 75%. In literature, reviewed by Benet et al. (2005), 2/84 carriers showed also such a high %. In our series we observed 3/20 carriers who produced ≥ 70 % of unbalanced sperm. On the other hand, in literature only one such carrier was found. Based on this information we can tell couples, with a male Rcp carrier and with normal fertility, that they have a chance of 50% at each conception of giving birth to a child with a balanced/normal chromosome complement. If however recurrent miscarriages keep occurring, sperm analysis may be offered in order to see if they belong to the carriers who produce ≥ 70 % of unbalanced sperm. In this case PGD may improve their conception and delivery rate. In couples where the translocation carrier has fertility problems (e.g. OAT) PGD will probably increase their chance to become pregnant of a child with a normal/balanced karyotype. After repeated failures, however, sperm analysis may help these couples to decide to use rather donor sperm.

P02.188

A balanced reciprocal translocation t(3;16)(q21;p13.3) transmitted from mother to her offspring

A. R. Stana¹, F. M. Nedelea¹, G. Peltecu¹, M. Bari¹, V. Stoian², B. Guenther³, H. C. Duba³;

¹Clinical Hospital Filantropia, Bucharest, Romania, ²University of Bucharest, Bucharest, Romania, ³General Women and Children Hospital, Linz, Austria.

We report a case with a maternal balanced translocation t(3;16)(q21;p13.3) detected by prenatal diagnosis at a male fetus. Prenatal karyotype from cultured amniocytes was performed due to increased risk for Down syndrome at serological test, without ultrasonographic anomalies.

For checking if the translocation in the child is *de novo* or inherited we performed chromosome analysis in the parents. Those are young and healthy, at the first pregnancy, achieved after a period of apparent sterility.

We have performed karyotypes of the parents and we found the same translocation in the mother. The breakpoints were established using GTG and QFQ staining methods. The karyotypes of the maternal par-

ents revealed a normal chromosomal constitution, suggesting a *de novo* rearrangement in the child's mother.

As there is obviously no genetic disease known in the child's mother, the translocation is apparently balanced and is high probability for the child not to suffer from a genetic disease caused by the translocation inherited from his mother. After genetic counseling the parents decided to continue pregnancy.

It is known that for the above translocation the total risk for an abnormal pregnancy is about 39% (33,33% abortion; 4,17% stillbirth or early death; 1,40% unbalanced offspring at birth) and the chance for an uneventful pregnancy and birth of a chromosomally normal or chromosomally balanced child about 61%. Due to the existing risk for birth of an unbalanced offspring we recommend an early chorionic villus sampling to perform chromosome analysis as soon as possible in a next pregnancy.

P02.189

Case Report: Family reciprocal translocation (8;16)

M. Burek, L. Letica, I. Tonkovic Durisevic, K. Crkvenac Gornik, R. Lasan, D. Muzinic, D. Begovic;

Division of Genetics and Metabolism, Department of Pediatrics, University Hospital Centre, Zagreb, Croatia.

Amniotic fluid sample from 32 year old pregnant woman was taken and send in our laboratory to perform prenatal cytogenetic diagnosis by standard techniques with GTG staining. Result was karyotype with reciprocal balanced translocation 46,XY,t(8;16)(p21.3;q22).

Parents were referred to our outpatient clinic for genetic counselling. They presented the following family history: two female children 8,5 and 6 years old with mental retardation, husband's brother and aunt are also mentally retarded. Blood samples were taken from both parents and chromosome analysis had been carried out on peripheral lymphocytes by standard techniques with GTG staining. Mother had normal female karyotype. Father had karyotype with the same balanced translocation as fetus. It was recommended to refer their two daughters and husband's brother for cytogenetic study.

Clinical findings of girls were: mental retardation and facial dysmorphism. Blood samples were taken from both girls for chromosome analysis by standard techniques with GTG staining and Fluorescence in situ hybridization. Karyotypes of both girls were pathologic with derivative chromosome 8, resulting from translocation (8;16) in father: 46,XX,der(8)t(8;16)(p21.3;q22)pat. It means that girls have partial trisomy of chromosome 16 and partial monosomy of chromosome 8, which is the reason for their mental retardation.

P02.190

Translocation (8;12)(p21;p11.2) found at Prenatal Diagnosis

R. Pinto Leite¹, M. Souto¹, P. Botelho¹, A. Nogueira², M. Martins¹, E. Ribeiro¹;

¹Centro Hospitalar de Tras-os-Montes e Alto Douro, Vila Real, Portugal, ²UTAD, Vila Real, Portugal.

The translocations are considered the most frequent chromosomal changes in the human species. Simple reciprocal translocations arises when a two-way exchange of material takes place between two non-homologous chromosomes. They can be "*de novo*" or familial, with a prevalence of 1:50000 and 1:500 births, respectively. The great majority of familial translocations between autosomes have no phenotypically effects.

We report a case of a 37-year-old pregnant woman with a normal obstetric history. Amniocentesis for cytogenetic evaluation was performed at 16 weeks of gestation.

Chromosome analysis of cultured amniocytes with GTL banding showed a apparently balance reciprocal translocation 46,XY,t(8;12)(p21;p11.2)mat - karyotype of parents were referred and demonstrated that the mother was carrier of the same translocation. FISH with painting probes confirmed the translocation.

Few chromosomal translocations that involve chromosome 8 and 12 were reported, but to our knowledge, all are related with other breakpoints. A bibliographic review is presented.

P02.191**Reciprocal translocations 10;18 in a patient with miscarriages, menstrual and speech problems****A. Faraj Pour**, C. Azimi;*Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran.*

Reciprocal translocations are usually an exchange of material between nonhomologous chromosomes. They are found in about 1 in 600 human newborns. Such translocations are usually harmless and may be found through prenatal diagnosis. However, carriers of balanced reciprocal translocations have increased risks of creating gametes with unbalanced chromosome translocations leading to miscarriages or children with abnormalities. Translocation between chromosomes 10 and 18 is very rare. A few reports have been published up to now including one in a patient with two miscarriages and another in a patient with juvenile neuronal ceroid-lipofuscinosis (Batten disease). Our case was a 24 year-old woman who was referred to our Department due to two miscarriages. She had also speech problems including stuttering and irregular menstrual periods. She has no problems in lips, teeth, jaw, nose, palate and hearing. Sonography of her uterus and ovaries was normal, and also her hormones were within normal range.

Family information revealed only stuttering in her uncle. Chromosomal analysis was made on her lymphocytes, using the standard banding techniques. Her karyotype was: 46, XX, t(10;18)(p11;p11).

P02.192**Structural chromosome rearrangements in couples with recurrent spontaneous abortions****F. Farzanfar**¹, S. Morovvat²;*¹Imam Khomeini Hospital, Tehran, Islamic Republic of Iran, ²Research Center of Molecular Biology, Baqiyatallah Medical Sciences University, Tehran, Islamic Republic of Iran.*

Introduction: Several studies have been done to determine the contribution of chromosome abnormalities in patient with recurrent spontaneous abortions. In this study we present a retrospective study of the cytogenetic data in 310 couples with recurrent spontaneous abortions registered in Imam Khomeini hospital in Tehran.

Materials and Methods: Giemsa-banding and Reverse-banding techniques according to standard procedures were routinely applied on peripheral lymphocytes in all patients.

Results: In our 310 couples with recurrent spontaneous abortions, the incidence of chromosomal rearrangements was 19 (6.1%). Of all chromosomal abnormalities detected, 42% (8/19) were balanced reciprocal translocations, 21% (4/19) were Robertsonian translocations, 16% (3/19) were para- or pericentric inversions, 10.5% (2/19) were X chromosome aneuploidies, and 10.5% (2/19) were marker chromosomes. Pericentric inv(9)(p11;q13) were excluded because they were considered as a normal population variant.

Conclusion: In this study we found chromosomal rearrangements in 6.1% of our patients with recurrent spontaneous abortions which is much higher than the incidence of chromosomal abnormalities in general population. Also in current study the prevalence of autosomal rearrangements in females was slightly more than males.

P02.193**Clinical features of a case with ring chromosome 18****M. Zamanian**¹, F. Mahjoubi²;*¹The Blood Transfusion Organization Research Center, Tehran, Iran., Tehran, Islamic Republic of Iran, ²The Blood Transfusion Organization Research Center, Tehran, Iran. & National Institute for Genetic Engineering and Biotechnology, Tehran, Iran, Tehran, Islamic Republic of Iran.*

Chromosome 18 Ring is a rare disorder in which there is loss (deletion) of genetic material from one or both ends of the 18th chromosome and joining of the chromosomal ends to form a ring. Associated symptoms and findings may vary greatly in range and severity from case to case, depending upon the amount and location of lost genetic material and other factors. A ring may also be formed without the loss of any genetic material.

Here we report an additional case of a 14 months girl with r(18). The girl was born at term after an uncomplicated pregnancy and delivery. Birth weight was about 1.5 kg, length 48cm, and head circumference

36cm. The girls presented hypertelorism, hypotonia, epicanthal folds, abnormal fingers, low set ears, and abnormally growth teeth. Echocardiography indicated dilation of the aorta.

Karyotyping after lymphocyte culture at the age of 14 months revealed 46,XX,r(18)(q21.2qter). The parent had normal karyotype.

The clinical feature of our case is mostly compatible with the other reported cases of r(18) except the presence of abnormal teeth and heart problem. This report further contribute to the clinical of the r(18).

P02.194**A girl with ring chromosome 5****E. Dagytė**^{1,2}, L. Cimbalistienė^{1,2}, V. Kučinskas^{1,2};*¹Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania, ²Center for Medical Genetics at Vilnius University Hospital Santariskiu Klinikos, Vilnius, Lithuania.*

We report a girl presenting ring chromosome 5. The girl was born of the second pregnancy of healthy, 25 year old mother and 28 year old father. The pedigree is otherwise unremarkable with respect to stillbirths, malformations and mental handicap. The first pregnancy resulted in spontaneous abortion.

The girl was born at 37 weeks of gestation. Birth weight was 1895 g, length was 43 cm, head circumference was 29 cm and chest circumference was 26 cm. Dysmorphic features included microcephaly, upslanting palpebral fissures, hypotelorism, microstomia, high palate, micrognathia, short neck, hirsutism. Abdominal ultrasonography revealed no abnormalities.

Clinical examination at 5 years of age showed weight 11,6 kg (<3 ‰), length 90 cm (<3 ‰), head circumference 43 cm (<3 ‰). Dysmorphic features included microcephaly, upslanting palpebral fissures, microstomia, mild micrognathia, long smooth philtrum, narrow vermilion, neck webbing, low posterior hairline, short toes, broad thumb, mild hirsutism. Mental development was normal. Cytogenetic analysis of peripheral blood lymphocytes revealed 46,XX,r(5)(pterq35) karyotype. Both parents had a normal karyotype. Cytogenetic analysis was performed from GTG banded metaphases.

P02.195**Observation of satellite association in couples with history of habitual abortion****F. Manoochehry**¹, F. Mahjoubi^{1,2}, S. Abdollahy¹;*¹Iran blood Transfusion Organization Research Centre (IBTO), Tehran, Iran, Tehran, Islamic Republic of Iran, ²Iran blood Transfusion Organization Research Centre (IBTO), Tehran, Iran & Clinical Genetic Dept. National Institute for Genetic Engineering and Biotechnology, Tehran, Iran, Tehran, Islamic Republic of Iran.*

Chromosomal aberrations account for approximately 50% of fetal losses prior to 15 weeks. Human acrocentric chromosomes are frequently found in association. This satellite association has been reported to be random by some researchers. However, there are some new reports of possible association between this phenomenon and idiopathic recurrent abortions. In our institute in order to identify the role of chromosomal rearrangements in aetiology of habitual abortions, we analyzed chromosomes of some couples with the history of miscarriages. Chromosomal karyotyping analysis was performed on cultures of peripheral blood lymphocytes by using the GTG-banding method. Sixteen metaphase cells were analyzed for their chromosome constitution in each sample. We found that in 4 patients with idiopathic recurrent abortion the incidence of satellite association is quite high in each cells and in overall. Thus the observation in the present study shows that there might be possible association between satellite associations and recurrent miscarriages at least in subpopulations of the patients.

P02.196**Molecular Cytogenetic Characterization and Genetic Counseling in Some Rare Cases of Sex Chromosomes Abnormalities****A. M. Mohamed**¹, A. K. Kamel¹, I. Mazen¹, N. Dessouk², H. A. Hussein¹, M. O. El-Rouby¹;*¹National Research centre, Cairo, Egypt, ²Faculty of Medicine, Cairo, Egypt.*

We reported on six cases with rare sex chromosomal abnormalities. Our aim was to use molecular cytogenetics to correlate karyotype findings to phenotype for proper genetic counseling. Two cases pre-

sented with ambiguous genitalia. The 1st case was reared as male and had right palpable gonad, uterus and left streak gonad. Its karyotype was 45,X/45,der(X)/46,X,der(X).ish der(X)t(X;Y)(p22.3;p11.3)(DXZ1+,DYZ3+,SRY+,KAL+,telXp-/Yp-). The second case reared as a female and had right testis, a uterus and left ovary with some follicles. The karyotype was 45,X/46,X,+mar.ish idic(Y)(qter→p11.3::p11.3→qter)(wcpY+,DYZ3++,SRY+,telYp-).The 1st case diagnosed as mixed gonadal dysgenesis and the second as true hermaphroditism.To our knowledge this is the 1st case of true hermaphroditism with this distal break points. The other 4 cases presented with primary amenorrhea and short stature. Karyotype of 3rd case was 45,X/46,X,+mar.ish idic(Y)(pter→q11::q11→pter)(DYZ3++,SRY++).The 4th case had 46,X,der(X) ish. Der(X)(pter→q21::p22.1→pter)(DXZ1+,XIST+,telXp+++,STS+++), the 5th case had severe short stature and her karyotype was 46,X,der(X). ish der(X)(qter→p11.2::p11.2→qter)(wcp X+, DXZ1+++).The 6th case had 46,X,der(X).ish idic(X)(pter→q25::q25→pter)(wcpX+DXZ1+++XIST+++telXp+++).

A team of specialists collaborated together to give the proper genetic counseling and follow-up specially for cases with Y chromosome who had the risk of gonadoblastoma.We recommend further investigations using Array CGH for identification of duplication / deletion in different regions of sex chromosomes.

P02.197

Molecular cytogenetic characterization of a small supernumerary marker chromosome derived from chromosome 11 in a mother and a child with distinct phenotypes

J. B. Melo¹, E. Matoso¹, M. R. Lima², L. Backx³, J. R. Vermeesch³, N. Kosyakova⁴, T. Liehr⁴, I. M. Carreira¹;

¹Laboratório de Citogenética and Centro de Neurociências e Biologia Celular, Faculdade de Medicina, Universidade de Coimbra, Coimbra, Portugal, ²Instituto Genética Médica Jacinto Magalhães, Porto, Portugal, ³Center for Human Genetics, University Hospital Leuven, Leuven, Belgium, ⁴Institut für Humangenetik und Anthropologie, Jena, Germany.

Small supernumerary marker chromosomes (sSMC) are defined as structurally abnormal chromosomes that cannot be identified or characterized unambiguously by conventional banding cytogenetics alone, and are generally equal in size or smaller than a chromosome 20 of the same metaphase spread. sSMC derived from chromosome 11 are rare and, so far, it is not yet clear which regions of chromosome 11 are critical and have clinical consequences.

We report a mother and a child with a karyotype 47,XX,+mar[21]/46,XX[9] and 47,XY,+mar[25]/46,XY[5], respectively. After centromeric FISH the origin of the sSMC was ascertained as derived from chromosome 11. Subcentromeric FISH revealed the presence of two different shapes of the sSMC in the mother, with apparently the following breakpoints - ish r(11)::p11.12-11.2->q12::[2]/min(11)(p:11.12-11.2->q12::[7]; and three different shapes of the sSMC in the child - ish r(11)::p11.12-11.2->q12::[6]/r(11;11)::p11.12-11.2->q12::p11.12-11.2->q12::[3]/min(11)(p:11.12-11.2->q12::[4]. The sSMC was microdissected and amplified by DOP-PCR. The amplified DNA was analysed by array painting, using fulltilling array specific for chromosome 11 (with 100-150 kB resolution). An unexpected result revealed an unusual sSMC. A maternal uniparental disomy of chromosome 11 was excluded. The child presents a more severe phenotype, with facial dysmorphisms, strabism, ptosis, mental retardation and developmental delay. The mother has a congenital cardiopathy and no apparent mental retardation.

Molecular cytogenetics techniques are a valuable tool for the accurate identification of the genetic origin and content of sSMC, contributing to a better genotype/phenotype correlation.

Supported in parts by the Erwin-Riesch Stiftung.

P02.198

Three de novo deletions, one transposition, and one inversion of chromosome 6 in a patient with complete absence of expressive speech and reduced pain perception

M. Poot¹, R. van 't Slot¹, R. Leuper², V. Beyer², E. Passarge³, T. Haaf⁴;

¹Department of Medical Genetics, Utrecht, The Netherlands, ²Institut für Humangenetik, Johannes Gutenberg-Universität Mainz, Mainz, Germany, ³Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany.

Using the Infinium HumanHap300 Genotyping BeadChip SNP array and BAC-based FISH we found three adjacent, but non-contiguous

de novo deletions, one transposition and one pericentric inversion of a chromosome 6 in a patient whose karyotype was previously described by banding analysis as 46,XX,del(6)(q13q15),inv(6)(p11.2q15). In addition to the deletion of band 6q14 detected previously by classic cytogenetics, we found two additional microdeletions. The most distal one is a 360 kb deletion in band 6p12.3, containing the genes *RHAG*, *CRISP1*, 2, and 3, and *PGK2*. The second deletion in 6p12.2-p12.1, containing the genes *PKHD1*, *IL17*, *MCM3*, *EFHC1*, and *TRAM2* genes is 1.15 Mb in size. The deletion in region 6q14.3-q16.1, reported previously, was mapped more precisely and determined to be 11.9 Mb in size. It contains 27 genes, some of which are involved in pain sensation, growth regulation, and tissue modeling during development. The refined karyotype is 46,XX,der(6)(pter→p12.3::p12.1→p12.1::q14.3→p12.1::p12.3→p12.2::q16.1→qter) or (pter→p12.3::p12.1→p12.1::q14.3→p12.1::p12.2→p12.3::q16.1→qter).The main clinical features of this 31-year-old woman are dysmorphic facial features consisting of a broad face, prominent glabella, broad nose, and hypertelorism, non-progressive deficit of motor control, in particular a broad-based slow-motion-like gait, absence of speech development, inability to acquire and to comprehend theoretical knowledge, and reduced sensitivity to pain. The rearrangement of chromosome 6 presumably originated in a paternal meiosis. By combining the SNP array and FISH data we were able to completely map and to reconstruct this highly complex rearrangement in a single chromosome.

P02.199

Characterization of a small supernumerary marker chromosomes using cytogenetic and molecular cytogenetic methods (two case reports)

M. Miskovic¹, T. Liehr², M. Guc-Scekic^{1,3}, A. Weise², K. Mrasek², T. Lalic¹, N. Lacic¹;

¹Mother and Child Health Care Institute of Serbia "Dr Vukan Cupic", Belgrade, Serbia, ²Institute of Human Genetics and Anthropology, Jena, Germany, ³Faculty of Biology, University of Belgrade, Belgrade, Serbia.

Small supernumerary marker chromosomes(sSMC),defined as additional abnormal chromosomes, too small for characterization by conventional banding cytogenetics alone,are present in 0.043% of newborns and 0.077% of prenatal cases.About 1/3 of the sSMC are correlated with a specific clinical picture,while most of the remaining sSMC have not yet been associated with clinical syndromes.

We present two cases with sSMC in karyotype which were initially studied by GTG banding technique.To define origin of sSMC,additional molecular cytogenetic methods (FISH) were performed using probe sets:cenM-FISH and subcenM-FISH Mix for the corresponding chromosomes.

Patient 1 had a diagnosis of total anomalous pulmonary venous return and facial dysmorphism.Here a mosaic karyotype 47,XX,+mar[22]/46,XX[11] was detected.The sSMC was characterized as an invdup(22)(q11.21).Similar cases were previously reported and the patient could now clinically be diagnosed as having a Cat-Eye syndrome.

Patient 2 was a prenatal diagnosis of 42-years old woman with fetal karyotype 47,XY,+mar(de novo).In this case sSMC was characterized as an invdup(15)(q11.1).According to the literature similar cases didn't show any clinical abnormalities.This type of sSMC is the most common (appears with 30% frequency).

It is difficult to predict precisely the phenotypic risk that could be associated with the presence of sSMC.The origin of sSMC is important factor in determining its possible phenotypic effect.Conventional cytogenetic techniques are limited.Molecular cytogenetic methods are necessary in terms of providing the information about marker origin and structure.It's only way to establish phenotype-karyotype correlation and discuss the results in genetic counseling.

The Effect of Chromosomal Rearrangements on Gene Expression

A. Reymond¹, F. Schütz¹, J. Chrast¹, M. Delorenzi¹, W. A. Bickmore², L. A. J. Harewood¹;

¹Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland

land, ²MRC Human Genetics Unit, Edinburgh, United Kingdom.

The t(11;22)(q23;q11) is the only recurrent non-Robertsonian translocation in humans. Carriers are phenotypically normal, but at risk of having progeny with Emanuel syndrome. It is conceivable that this large chromatin rearrangement influences the transcription levels of genes mapping both near, and distant, to chromosome breakpoints. To test this, we compared gene expression profiles of lymphoblastoid cell lines from 13 cytogenetically normal individuals, to those of 9 balanced translocation carriers and 4 unbalanced Emanuel syndrome patients. Comparison of unbalanced individuals with controls revealed twice as many gene expression changes than the balanced/control comparison. This was anticipated as individuals are partially aneuploid for both HSA11 and 22 and are phenotypically affected. Consistently, a statistically significant fraction of the differentially expressed genes mapped to these two chromosomes.

Permutation tests showed that, despite being lower, the number of differentially expressed genes between the two groups with complete genome complements is significantly higher than that observed when one compares control samples alone. This suggests that balanced rearrangements have a greater effect on gene expression than normal variation even though individuals are phenotypically normal.

Interestingly, in balanced individuals, expression of HSA11 genes is affected to a much higher degree than those on HSA22. We hypothesize that the position of the derivative chromosomes is altered within the nucleus, with derivatives chromosomes being moved to a position comparable to the normal HSA22. This would result in HSA11 genes being placed into an altered chromatin environment, thus altering their expression. We are currently investigating this possibility.

P02.201

New report of an unbalanced Xp/Yq translocation detected in a mentally retarded patient with short stature and ichthyosis

J. Oliveira, N. Oliva-Teles, M. Mota Freitas, R. Santos, M. Pinto, A. Fortuna; Centro de Genética Médica Jacinto Magalhães - INSA, Porto, Portugal.

Deletion of Xp22.3 causes different X-linked disorders in males; in females, depending on the X-inactivation patterns or gene disruptions, the phenotype may be variable (Schinzel, 2001). Patients with deletions in this region have been previously reported in a restrict number of cases, and presented with distinct combinations of usually non-related clinical manifestations such as short stature, mental retardation, ichthyosis, chondrodysplasia punctata, attention deficit hyperactivity disorder, ocular albinism and epilepsy (Lonardo et al., 2007). The phenotype is correlated with the deletion breakpoints on the X chromosome and the respectively affected genes. As a result of gene sequence similarities between Xp22 and Yq11, homologous recombination between these two regions has been suggested as the cause of X/Y translocations.

The authors report on a male patient aged 17 presenting with mild mental retardation, short stature, X-linked ichthyosis and with steroid sulphatase deficiency. High resolution GTG, QFQ and CBG banding revealed the following karyotype: 46,Y,der(X)t(X;Y)(p22.3;q11.2)mat. The study of the parents proved that the translocation was of maternal origin. PCR-based techniques positioned the centromeric breakpoint between genes VCX2 (Xp22.31) and AMELX (Xp22.2). The analysis of the DYS385 marker, located in Yq11.21, suggested that this region is duplicated in the patient.

A review of cases described in the literature with similar cytogenetic findings will be equally addressed and compared with the present case. The authors highlight the importance of careful evaluation of Xp22.3 deletions in terms of clinical prognosis, follow-up and genetic counselling.

P02.202

Telomere length and Random Aneuploidy in Hepatitis C patients

A. Amiel¹, L. Goldberg-Bittman¹, M. D. Fejgin¹, R. Hadari², Y. Kitay-Cohen²;

¹Genetic Institute, Meir Hospital, Kfar Saba, Israel, ²Liver Unit, Meir Hospital, Kfar Saba, Israel.

Hepatitis C virus (HCV) is one of the major causes of hepatocellular carcinoma and has recently been recognized to play a role in the pathogenesis of B-cell lymphoma. Random aneuploidy is one of the genetic instability parameters observed in cancer. Telomeres are the end structures of each chromosome. These structures protect from shortening at each replication cycle. Telomerase is the enzyme which

is responsible for the elongation of the telomeres, and exists only in cancer, stem and progenitor cells. A reduction in telomerase levels was observed in HCV patients lymphocytes compared to healthy individuals.

The aim of this study was: 1) Evaluating random aneuploidy rate in lymphocytes of chronically infected HCV patients compared to individuals who eradicated the virus (remission group) and to healthy controls. 2) Developing new method for measuring relative telomere length.

For random aneuploidy, we applied the FISH technique with probes from chromosome 9 and 18. For the telomere detection we used the PNA telomere kit.

A significantly higher random aneuploidy rate was found in the HCV group as compared to the control group, while the remission group had intermediate rates between the other two groups.

We observed significantly shorter telomere length in HCV patients compared to the controls and to the group in remission. We found a reverse correlation between shorter telomeres and the rate of aneuploidy.

Random aneuploidy and short telomeres are two co-existing biological phenomena found in HCV patients; it may represent pre malignant changes which could play a role in the cascade leading to neoplasia.

P02.203

A new candidate gene for mental retardation and severe central hypotonia

A. Moncla^{1,2}, C. Missirian^{1,2}, P. Cacciagli¹, B. Chabrol¹, L. Villard²;

¹La Timone Children's Hospital, Marseille, France, ²Inserm U910, Marseille, France.

We report a female patient affected by mental retardation and severe central hypotonia. At birth, the patient had normal parameters. The first clinical signs were noticed during the first months of life when she was unable to hold her head.

At first examination, CT scan, muscle enzymes, metabolic parameters (including amino acids and organic acids chromatography), mucopolysaccharides and thyroid were normal. At one year of age, she showed major axial and peripheral hypotonia and she was not able to hold her head. She was not able to sit and has no tendon reflexes. She displayed abnormal and permanent choreic movements. She does not suffer from epilepsy. Nerve conduction velocity and electromyogram are normal. She is not deaf and her EEG and MRI are normal. At age 3, her OFC is normal, she shows major hypotonia and she is still unable to hold her head or to roll-over and suffers from oculomotor dyspraxia. She has no motor autonomy. She can speak 3-4 words and has a very good eye contact.

Routine cytogenetic analysis revealed an apparently balanced de novo t(10;13)(p14;q13) translocation. The molecular characterization of the chromosomal rearrangement shows that a gene is interrupted on chromosome 13. This gene encodes a protein of unknown function. Preliminary analysis reveals that it is only expressed in brain and testis, making it a good candidate for the neurological phenotype of our patient. However, more patients need to be screened to confirm its implication in this new phenotype.

P02.204

De novo t(1;2)(q25;q21) case with various dysmorphic features and mental retardation

H. Akin¹, O. Kirbiyik¹, A. Alpman¹, E. Karaca², O. Cogulu², F. Ozkinay²;

¹Ege University Faculty of Medicine Department of Medical Genetics, Izmir, Turkey, ²Ege University Faculty of Medicine Department of Pediatrics, Izmir, Turkey.

Translocation is the most clinically significant abnormality of all the structural chromosome rearrangements. Balanced de novo chromosome rearrangements may be found in patients with mental retardation; however their role in the developmental phenotype of the patient is usually unclear. Loss of genetic material within the breakpoint regions may be responsible for the phenotype.

We describe a 9-year-old boy with various facial dysmorphic features such as telecanthus, epicanthic folds, upslanting palpebral fissures, long eyelashes, hypoplastic alae nasi, thin upper lip and high palate. In addition, mild mental retardation, developmental delay, bilateral fifth finger clinodactyly, valgus deformity in the second toe, skin syndactyly between the second and third toes and pes planus were also present. Because of the diagnosis of mental retardation and the physical ab-

normalities, cytogenetic study was performed. Balanced translocation t(1;2)(q25;q21) was detected. His parent's karyotypes were found to be normal. In the literature no similar breakpoint region has been reported. Here we point out the importance of this rare translocation that may provide a valuable clue to the phenotypic findings and identification of target loci.

P02.205

Possible post-meiotic origin of the constitutional t(11;22)

T. Kato¹, H. Inagaki¹, H. Kogo¹, T. Ohye¹, M. Tong¹, M. Tsutsumi¹, B. S. Emanuel², H. Kurahashi²;

¹Division of Molecular Genetics, Fujita Health University, Toyoake, Japan, ²Division Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA, United States.

The constitutional t(11;22) is the only known recurrent non-Robertsonian translocation in humans. The translocation breakpoints occur within palindromic AT-rich repeats on chromosomes 11q23 and 22q11. In our previous studies, we established translocation-specific PCR by using the sequence of the translocation junction fragments from both derivative translocation chromosomes. Using this method, we successfully detected de novo t(11;22)s in sperm samples from normal healthy males, but not in lymphoblasts or fibroblasts. To understand how this translocation occurs during spermatogenesis, we divided sperm samples into small aliquots prior to DNA extraction and directly performed translocation-specific PCR. Multiplex PCR allowed us to detect der(11) and der(22)-specific PCR products of de novo origin, which were amplified concomitantly from the same aliquots. This result suggests that the de novo t(11;22) occurs as a reciprocal translocation. Further, we changed the combinations of primer pairs, which allowed us to identify dicentric and acentric translocation derivative chromosomes. Interestingly, these two unusual derivative chromosomes also appear concomitantly in the same aliquots. Based on the fact that almost no unbalanced translocation products were identified, we speculate that de novo t(11;22) translocations are likely to arise at post-meiotic stages of spermatogenesis.

P02.206

A rare translocation (15;16)(p10;p10) in a normal man

H. Reshadi, C. Azimi, Z. Beheshti, Z. Saltanatpouri;

Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran.

Whole-arm translocations result from centric fusion of two chromosomes (usually nonhomologous), followed by a reciprocal exchange with fusion of entire arms in two derivatives, each with a hybrid centromere. Nevertheless, there are at least two alternatives: that both points of interchange will be juxtacentromeric and then each derivative will conserve its own whole centromere, or that one point will be centromeric and the other juxtacentromeric, so that one derivative will have a hybrid centromere and the other will conserve its original but reduced centromere. Although the underlying mechanisms are still unknown, detailed molecular analyses have provided evidence that centromere duplication may predispose to constitutional centric fusion and consequently favour the occurrence of whole-arm translocations. Constitutional whole-arm translocations are rather rare and can be identified in either a balanced or unbalanced state. Most individuals with balanced forms have a normal phenotype, but may be subfertile. In contrast, patients with unbalanced whole-arm translocations have abnormal phenotypes. Here, we describe a 34-year-old healthy married man who was referred because of consanguinity. His wife and first child were healthy and they wished to have a second child. Chromosomal studies were carried on lymphocyte cultures using G-banding. All mitoses showed a reciprocal whole-arm translocation (15;16). The karyotypes of his wife and his child were normal. Other family members were not available for study. Literature review confirmed that t(15;16) is very rare.

P02.207

A rare de novo translocation (18;21)(q23;q11.2) in a patient with Down syndrome

F. Farzanfar, C. Azimi;

Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic

Republic of Iran.

We report a 8-year-old boy with clinical features of Down syndrome: small stature, brachycephaly, flat occiput, small nose, low nasal bridge, upslanting palpebral fissures, inner epicanthal folds, Brushfield's spots, anomalous auricles, dental hypoplasia, short broad hands, Simian crease, hypoplasia of midphalanx and clinodactyly of fifth fingers, wide gap between first and second toes, and mental deficiency. Karyotyping of this patient showed: t(18;21)(q23;q11.2). Cytogenetic studies on his parents and his only sister revealed normal karyotypes. A few reports have been published concerning familial subtelomeric translocation of chromosomes 18 and 21, but we could not find any de novo translocation of 18/21 similar to our case in the literature.

P02.208

A comparison of maternal age among fetuses with trisomy 13 and trisomy 18

I. N. Machado¹, J. K. R. Heinrich¹, R. G. Paleari², C. d. Campanho³, K. C. Andrade⁴, R. Barini⁴;

¹Cell Culture and Cytogenetic Laboratory, Fetal Medicine Unit, CAISM, Unicamp, Campinas, Brazil, ²Cell Culture and Cytogenetic Laboratory, CAISM, Unicamp, Campinas, Brazil, ³Cell Culture and Cytogenetic Laboratory, CAISM, Unicamp, Campinas, Brazil, ⁴Fetal Medicine Unit, CAISM, Unicamp, Campinas, Brazil.

Objective: To evaluate the difference of maternal age among fetuses with trisomy 13 and trisomy 18.

Methods: A retrospective review of the cytogenetic laboratory databases identified all cases of prenatally diagnosed trisomy 13 and trisomy 18 from January 1997 to December 2007, and maternal age was recorded. Ages were compared by unpaired t test, with a power of 44.6% because the two groups had no normal distribution. A "p" value < 0.05 was considered statistically significant.

Results: 61 affected fetuses were included: 38 cases of trisomy 18 and 23 cases of trisomy 13. The mean maternal age in cases of trisomy 13 was 30.3 years (16-44 years, sd = 7.8 years), and in cases of trisomy 18 was 29.9 years (16-46 years, sd = 9 years). The difference in mean maternal age between these two groups shown a "p" value = 0.82. The frequency of patients younger than 35 years of age for trisomy 18 was 65.7% (n=25) and for trisomy 13 was 65.2% (n=15).

Conclusion: Our study showed that the difference in mean maternal age among fetuses affected by trisomy 13 and trisomy 18 was not significant. It was shown a trend of more cases diagnosed in patients younger than 35 years old. However, more data are needed to establish whether this is a true phenomenon or a bias of the population studied.

P02.209

A case of de novo trisomy 12p

T. G. Tsvetkova, N. V. Shilova, V. A. Galkina, N. V. Kosjakova, I. A. Mandron, T. V. Zolotukhina;

Research Centre for Medical Genetics of RAMS, Moscow, Russian Federation.

We are reporting the clinical and cytogenetic studies on a 6 months-old boy who was referred for karyotyping because of distinct craniofacial dysmorphic features. Phenotype of proband included: acrocephaly, flat occiput, mid-face hypoplasia, upslanting palpebral fissures, hypoplastic supra-orbital ridges and high narrow palate, dysplastic ears, brachydactyly, broad thorax and pectus excavatum. Psychomotor and mental retardation was marked. Conventional cytogenetic analysis of patient using GTG-banding revealed 47,XY,+mar karyotype. Supernumerary marker chromosome (SMC) resembled 21q or 12p and had AgNOR on short arm. The karyotypes of parents were normal. FISH analysis with LSI 21(21q22.13-q22.2) and WCP 12 DNA-probes (Vysis, Abbott) and DAPI counterstaining was performed. SMC was LSI 21-, WCP12+. FISH analysis showed that SMC was composed of chromosome 12p and short arm of one of acrocentric chromosomes. Inverted DAPI-staining revealed that short arm of the SMC contained only heterochromatic DNA and NOR of acrocentric chromosome. Therefore we proposed that this part of SMC has not a pathological phenotype effect. An adverse effect on the phenotype is caused of a de novo trisomy 12p. Probably this chromosome is a result of parental meiotic mutation. Use of FISH with high-specific DNA-probes increases the quality of cytogenetic diagnosis and allows one to base further recommendation for genetic counseling

P02.210**Clinical features of a case with trisomy 10q and monosomy 3p resulting from a maternal balance translocation: A case report and review of clinical features**F. Mahjoubi¹, M. Akbary², S. Kareeme³, G. Babanohammadi³;¹NIGEB, Tehran, Islamic Republic of Iran, ²Medical Genetic Dept., Tarbiat Modares University, Tehran, Iran, Tehran, Islamic Republic of Iran, ³Tehran Medical Genetic Laboratory, Taleqanee St, Tehran, Iran, Tehran, Islamic Republic of Iran.

Here we describe clinical and cytogenetic data on 2 year female child with partial trisomy for the distal part of the long arm of chromosome 10 (10q22-->qter) and a concomitant monosomy 3(p25-->pter) as a result of a maternal balanced reciprocal translocation. Her karyotype was ascertained as 46,XX,der(3)t(3;10)(p25;q22). The father had normal karyotype. The mother had an apparently balanced translocation involving chromosome 3 and 10 [46,XX,t(3;10)(p25;q22)]. To our best knowledge, this is the second reported case of partial trisomy 10q and partial trisomy 3p and first reported case from Iran. Clinical features of this case and a few published cases will be reviewed briefly.

P02.211**Partial duplication of chromosome 16p: narrowing of the critical region responsible for the common phenotype**G. Marangi¹, D. Orteschi¹, M. E. Grimaldi¹, R. Lecce¹, V. Leuzzi², G. Neri¹, M. Zollino¹;¹Institute of Medical Genetics, Università Cattolica del Sacro Cuore, Roma, Italy, ²Department of Child Neuropsychiatry, Università "La Sapienza", Roma, Italy.

Clinical descriptions of almost 50 patients with trisomy 16p, encompassing the band 16p13.3, have been reported to date in literature. Phenotypical features commonly associated to this chromosomal alteration are: severe developmental delay/psychomotor retardation, growth retardation, seizures, microcephaly, cleft palate, mild flexion contractures, clubbed feet, genitourinary abnormalities, congenital heart defects, a specific facial appearance and, usually, a poor prognosis.

We report the case of a female patient (aged 16 years) with moderate to severe mental retardation in which we disclosed, by the means of array-CGH (BAC-array at a resolution of 1 Mb) a cryptic tandem duplication of chromosomal region 16p13.3, sized about 2 Mb.

The main clinical features were: psychomotor retardation, very limited speech, relative microcephaly, narrow forehead, deep set eyes, narrow palpebral fissures, wide nasal bridge, long philtrum, rounded nasal tip, thin upper lip, midfacial hypoplasia, a protruding mandible, dysmorphic and low-set ears, tapering fingers, clubbed feet. The patient never had seizures.

Our patient's duplication is the smallest one reported to date with clinical features that resemble very closely the characteristics of larger 16p trisomy cases. We highlight, however, the relative mildness of our patient's phenotype.

We suggest that genes included in this 2 Mb region on 16p13.3 should be responsible of the main pathological findings of "trisomy 16p syndrome", such as mental retardation, typical facial appearance, microcephaly, hands and feet abnormalities.

Remarks about the possible causative role of different gene mapped in the region and comparisons with other microduplication phenotypes mapped on other regions on chromosome 16p are made.

P02.212**Prenatal findings: a foetus with trisomy of 22 chromosome**B. Aleksūnienė^{1,2}, N. Krasovskaja², V. Kučinskas^{1,2};¹Department of Human and Medical Genetics, Medical Faculty of Vilnius University, Vilnius, Lithuania, ²Center for Medical Genetics, Vilnius University Hospital Santariškių Klinikos, Vilnius, Lithuania.

Trisomy of chromosome 22 is very rare chromosomal pathology, particularly in the second or third trimester of pregnancy. We present a 33-year old para I, gravida IV woman. She was consulted at 12 weeks of gestation due to aggravated obstetric history. Her previous pregnancy was terminated at 19 weeks of gestation due to fetal meningocele. After three years patient delivered a normal boy. The recurrent risk for meningocele was about 2%. For other congenital malformations risk was the same as population risk. Fetal NT and maternal serum biochemistry (PAPP-A and β-hCG) was assessed at 12 weeks of gesta-

tion. NT thickness was 2,92 mm (1,95 MoM), PAPP-A was 0,31 MoM and β-hCG was 0,6 MoM. The combined risk for trisomy 21 was >1:50 and for trisomy 18-1:61. The ultrasound scan at 16 weeks showed asymmetrical fetal growth restriction and congenital heart disease - tricuspid valve atresia, pulmonary atresia, hypoplastic right ventricle. The parents opted for termination of pregnancy at 20 weeks of gestation.

The amniocentesis was performed for quantitative fluorescent polymerase chain reaction and karyotype analysis. QF-PCR tests results were negative for chromosomes 13, 18 and 21 trisomies. Chromosome analysis of lymphocytes revealed 47,XY,+22 karyotype. Fluorescent in situ hybridization (FISH) was performed using microdeletion probe localized to 22q11.2. FISH analysis confirmed the trisomy of chromosome 22 in the proposita. In view of these results parental chromosome analysis was not requested.

P02.213**Complete trisomy 5p due to paternal transmission of chromosome 5 centric fission products**

G. Kalnberza, I. Teilane, Z. Krūmina, A. Dzalbs, R. Lūgovska; Medical Genetics Clinic, University Children's Hospital, Riga, Latvia.

In humans stable centric fission of chromosomes are rare event, and only few families are reported with this chromosomal aberration. To our opinion this is the first report of centric fission of chromosome 5 in several generations. Complete trisomy 5p also is very rare chromosomal abnormality. Clinical findings of trisomy 5p are macrocephaly, facial dysmorphism, hypotonia, tracheobronchial abnormalities and heart defects. We describe a newborn boy was born in 40 weeks of gestation from the third pregnancy as second child in the family. The first child was healthy girl, and the second pregnancy ended with spontaneous abortion during 10 weeks of gestation. Birth weight was 3700 g, height 54 cm, HC - 40 cm. After delivery hypotonia, some respiratory difficulties, cephalohaematoma in parietooccipital region were observed. All sutures of head were widely opened. Phenotypically the patient had low situated ears, short palpebral fissures, a single crease. The patient died from respiratory infection at 5 month.

Routine chromosome analyses (GTG-banding) were performed on peripheral blood lymphocytes of proband, his parents and grandparents. The karyotype of proband showed complete telocentric trisomy 5p: 47,XY,+der(5)(pter→p10:). The cytogenetic analyses of father and his mother (proband's grandmother) revealed centric fission of chromosome 5, thus the karyotypes was 47,XY,-5,+fis(5)(p10),+fis(5)(q10) and 47,XX,-5,+fis(5)(p10),+fis(5)(q10), respectively.

P02.214**Atypical Turner syndrome due to structural chromosomal rearrangements - clinical and cytogenetic study of 9 patients**I. C. Ivanov¹, C. Rusu², M. Volosciuc², M. Gramescu², V. E. Gorduza², R. Popescu³, C. Bujoran³, L. Negura¹, E. Carasevici¹, M. Covic²;¹Immunology and Genetics Laboratory-St Spiridon Hospital, Iasi, Romania, ²(2) University of Medicine and Pharmacy, Medical Genetics Department, Iasi, Romania, ³(3) Sf Maria Children's Hospital - Medical Genetics Center, Iasi, Romania.

Turner's syndrome is the most common chromosomal abnormality in females, affecting 1:2,500 live female births. It is due to the total or partial absence of an X chromosome in a female. The most consistent clinical features are short stature and ovarian failure. A variety of chromosomal abnormalities are associated with Turner syndrome.

We present the cases diagnosed in Iasi Medical Genetics Center between 2000-2008 with atypical Turner syndrome due to structural chromosomal rearrangements, in order to discuss cytogenetic diversity of Turner syndrome. Cytogenetic study was performed using peripheral lymphocytes with G banding.

Between 2000-2008, our Cytogenetics lab has performed 1380 karyotypes, 27 being recorded with the diagnosis of Turner syndrome. Out of these, 9(33.3%) were due to structural chromosomal rearrangements. Abnormalities identified were: iXq (7cases) and r(X) (2cases).

Clinical and cytogenetic data are compared with literature data for each case. Typical and particular features are discussed.

In conclusion, we present 9 cases diagnosed with atypical Turner syndrome due to structural X chromosome abnormalities, in order to illustrate some rare variants and to discuss particularities and cytogenetic diversity of Turner syndrome.

P02.215

Cytogenetic analysis of Turner syndrome

L. Letica, R. Lasan, I. Tonković Đurišević, K. Crkvenac Gornik, M. Burek, D. Begović;

Division of Genetics and Metabolism, Department of Pediatrics, University Hospital Centre, Zagreb, Croatia.

Turner syndrome is caused by the absence of all or part of the second sex chromosome. In our study on 100 female patients clinically diagnosed with Turner syndrome:

46 patients were 45,X

10 patients were mos 45,X/46, XX

2 patients were mos 45,X/47, XXX/46,XX

8 patients were mos 45,X/47, XXX

31 patients had a structurally abnormal X chromosome (mainly iso-chromosome, deletion p or q arm, ring X chromosome) and 2 patients had a structurally changed Y chromosome

The phenotype is variable and includes short stature and gonadal dysgenesis. Mental retardation is not a feature of Turner syndrome.

Conventional cytogenetical G-banding method and Fluorescence in situ hybridization technique were considered in cultured peripheral blood.

Postnatal recognition of the syndrome requires genetic counselling of parents and supportive multidisciplinary treatment.

P02.216

The importance of women karyotyping in assisted reproduction

G. Ozgon¹, O. Oner¹, C. Aslan¹, B. Onal¹, F. Fiorentino¹, G. Karlikaya², H. Karagozolu², S. Kahraman²;

¹Genoma Turkey, Istanbul, Turkey, ²Memorial hospital, Istanbul, Turkey.

INTRODUCTION: Recent researches show that the infertility is related to both male and female genetics. Patients, who applied to our center, evaluated according to their indication and karyotypes.

Karyotype analysis was applied for the patients with the indication such as; recurrent implantation failure (RIF), recurrent pregnancy lost (RPL), male factor and abnormal fetus history, female factors (primary amenore).

In this study, we aimed to demonstrate karyotypes evaluation of the women who were referred to our cytogenetics laboratory.

MATERIAL- METHOD: Chromosome preparations were made from 72-h PHA-stimulated cell cultures from peripheral blood. Cell division was synchronized by a pulse of thymidine administered 21 h prior to harvesting. The thymidine block was released by washing the cells in fresh culture medium (RPMI 1640), also prewarmed to 37°C, for 3,5 h prior to harvesting. The culture was harvested using colcemid for 50 min prior to harvesting. At least 20 GTG-banded (Giemsa stain) metaphase cells were analyzed for each patient.

RESULTS:

Table 1

Indications	Total	Normal	
RIF	360	342	Mosaic X (n=15) inv(9) (n=7) inv(10) (n=1) balanced translocation (n=4)
RPL	308	282	Translocation carrier (n=10) Inversion (n=6) Mosaic X (n=8) mar (n=1)
Male Factor	44	43	Mosaic X (n=1)
Abnormal Fetus Story	24	23	Balanced translocation (n=1)
Female Factor	18	18	

Table 2

PGD Candidates' Indications(n=261)	Total	Normal Karyotype	
AMA	60	56	Mosaic X (n=4)
RPL	24	23	Mosaic X (n=1)
RIF	82	77	Mosaic X (n=5)
Male Factor	27	27	
Translocation Carrier	43	6	Mosaic X(n=2) Translocation carriers (n=37)

DISCUSSION: This study provides the importance of chromosome analysis for female patients applied to IVF center who had the infertility indications mentioned above. According to results, patients who were resulted as translocation carriers were suggested to undergo PGD.

P02.217

Case report: a balanced translocation between chromosome X and 13

L. Minaycheva, N. Sukhanova, L. Nazarenko, S. Vovk, V. Timoshevsky, I. Lebedev;

Institute of Medical Genetics, Tomsk, Russian Federation.

We report a 1 year and 9 months patient who was referred to the Tomsk Institute of Medical Genetics with the diagnosis of multiple congenital malformations and neuropsychic development delay. She had microcephaly, deformation and asymmetry of the skull, absence of the part of the left parietal bone. Flat, wide and protuberant bridge of nose («the Greek profile»), hypertelorism, epicanthus and bilateral cleft palate were observed. Palpebral fissures of the various size were located asymmetrically. The philtrum was short and exposed the upper incisors that were set in a «rabbitlike» forward slant. Deep neurologic and behavioral development delay and epilepsy were noted. Standard cytogenetic analysis have revealed a balanced rearrangement: 46,X,der(X)(pter→Xcen),t(X;13)(Xqter→Xq12::13cen→13qter), -13. Dual-colour FISH with DXZ1 and D13Z1/D21Z1 probes allowed to refine localization of centromeres in chromosomes involved. As a result two derivatives were described. The first was presented by der(X) with short arm of X-chromosomes and centromeric heterochromatin. The second one was a consequence of translocation between long arms of chromosomes X and 13. The influence of both derivatives to phenotype can be realized through two mechanisms, including manifestation of X-linked recessive mutations under releasing of X-inactivation and spreading of X-inactivation to autosomal segment with subsequent functional monosomy. Our patient has not revealed any symptoms of X-linked disease but clinical features of partial monosomy 13. This finding allows to suggest X-inactivation spreading mechanism that is under investigation.

P02.218

A report of a XYY man with mental retardation, prognathism, and short stature

S. Akbaroghli¹, F. Mahjoubi^{2,3}, M. Akbary⁴;

¹Dr. Akbaroghli Genetic Counseling Centre, Tehran, Iran, Tehran, Islamic Republic of Iran, ²NIGEB, Tehran, Islamic Republic of Iran, ³Tehran Medical Genetic Laboratory, Taleganeh St, Tehran, Iran, Tehran, Islamic Republic of Iran, ⁴Medical Genetic Dept., Tarbiat Modares University, Tehran, Iran, Tehran, Islamic Republic of Iran.

Here we report a 24-year-old man referred to our laboratory for evaluation of possible Fragile X syndrome on the basis of mental retardation. The patient was found to be negative for Fragile X. But he was found to be 47 XYY from chromosomal examinations. On clinical examination the patient was found to have dysmorphic facial features, prominent ears, long fingers, short stature, crowded teeth, high arched palate, prognathism, low nasal bridge, large testes, and speech problem. We have reported previously another case of XYY male with mild mental retardation, prognathism and malformation of nails and hands. The common features of this new case with the previous one are mental retardation and prognathism.

P02.219

Prevalence of gr/gr deletion among Iranian azoospermic infertile men

S. Rahmani¹, H. Fazli², R. Mirfakhraie^{1,3}, M. Montazeri¹, M. Golalipoor⁴, J. Jafari Aghdam⁵, S. M. Kalantar⁶, F. Mirzajani²;

¹Islamic Azad University of Tehran, Science & Research Campus, Tehran, Islamic Republic of Iran, ²Research & Clinical Centre for Infertility, Yazd, Islamic Republic of Iran, ³National Institute For Genetic Engineering & Biotechnology, Tehran, Islamic Republic of Iran, ⁴Grgan University of Agricultural Sciences & Natural Sciences, Gorgan, Islamic Republic of Iran, ⁵Islamic Azad University, Tehran North Unit, Tehran, Islamic Republic of Iran.

Number of microdeletion in the AZF locus of Y chromosome which itself is divided in to three discrete regions (AZFa, AZFb and AZFc) has been demonstrated to play important role in impaired spermatogenesis. The most frequent deletions are known to be occurred in AZFc

region of AZF locus and different prevalence of the partial deletions were reported in different populations.

In present study, we have screened 50 nonobstructive azoospermia men and 50 fertile men for gr/gr deletion of DAZ gene. Tow AZFc-specific sequence-tagged sites were examined using multiplex PCR method. The prevalence of gr/gr deletions in patients and controls samples were 32% (16/50 cases) and 6% (3/50 cases) respectively. The difference between two groups was significant (p-value: 0.011) Our results suggest that gr/gr partial deletion is more frequent in infertile men and may be correlated to the Iranian male infertility.

P02.220

Y chromosome microdeletion screening in infertile men in Serbia

M. L. Ristanovic¹, V. Bunjevacki¹, I. Novakovic¹, A. Nikolic², C. Tulic³, M. Majkic¹, A. Mircic⁴, D. Radojkovic²;

¹Institute of Human Genetics, Medical faculty, University of Belgrade, Belgrade, Serbia, ²Institute of Molecular Genetics and Genetic Engineering, Belgrade, Serbia, ³Institute of Urology and Nephrology, Medical faculty, University of Belgrade, Belgrade, Serbia, ⁴Institute of Histology and embryology, Medical faculty, University of Belgrade, Belgrade, Serbia.

The purpose of this study was to evaluate frequency Y chromosome microdeletions in Serbian men with azoospermia and severe oligozoospermia. Initially, 206 infertile patients were included in the study and spermogram has been performed in order to determine the sperm density. Patients were excluded if clinical evidence of obstructive azoospermia or known cytogenetic defects were present. The screening for Y chromosome microdeletion was performed in 176 selected patients by multiplex polymerase chain reaction (PCR) method on DNA extracted from peripheral blood. The following STS markers were tested: sY 84, sY 86 (AZFa); sY 127, sY134 (AZFb); sY 254, sY 255 (AZFc). Amplification found to be negative were repeated at least two times to confirm the deletion of given marker. The presence of deletions was correlated with patient's sperm concentration, and hormonal parameters. In 6,1 % men with sperm concentration less than 1×10^6 /ml a Y chromosome microdeletions were detected, comparing to 8,5 % in azoospermic men. The most frequent deletion was AZFc. Conclusion: The clinical correlation of spermatogenic impairment to the different AZF region deletions may provide the useful information for genetic counseling of infertile couples.

P02.221

Genetic studies in 50 patients with Functional Azoospermia

C. J. Trujillo¹, S. Ashour^{1,2}, S. B. El-Badawi¹;

¹Erfan & Bagedo, Jeddah, Saudi Arabia, ²Cairo University, Cairo, Egypt.

The present study investigates the number of molecular and cytogenetic defects in a population of 50 azoospermic men, (age 33.36 range 26 to 50) from the Western Region of Saudi Arabia from January 2006 to December 2007. Functional azoospermia was defined as total absence of spermatozoa in ejaculate, with normal vas deferens and without obstruction.

Cytogenetic analysis was performed in peripheral blood culture. GTG-banding of 20 metaphases was done. FISH with X centromeric (CEP X), Y centromeric (CEPY), SRY LSI probes was used. In all cases of mosaicism 500 cells were scored by FISH.

Y microdeletions were detected by multiplex PCR according to the European Molecular Genetics Quality Network guidelines for Yq deletion testing, using gene-specific primers that covered all three regions of the azoospermic factor (AZFa, AZFb and AZFc). This included sY84, sY86 for AZFa; sY127, sY134, for AZFb; sY254, sY255 for AZFc. Chromosome abnormalities were observed in 16 cases (32%), including 47,XXY karyotype in 11 cases, three mosaic (one 47,XXY/46,XY/45, one 47,XXY/46,XY and one 46,XY/45,X). One patient was 46,XX male, SRY gene was detected by FISH. One patient had a terminal deletion of chromosome 19p13. Y microdeletions were found in three cases (6%): two with AZFc, and one with both AZFc and AZFb. Genetic abnormalities were determined in 38% of azoospermic cases, which is higher than the usual reported figures between 15% to 30%. Genetic testing is indicated to determine etiology of azoospermia and to choose ART strategies and the offering of prenatal diagnosis in the indicated cases.

P02.222

An azoospermic man with a rare sex chromosome mosaicism

S. Afshar, C. Azimi, F. Farzanfar;

Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran.

Among numerous etiologic factors, chromosomal aberrations play a prime role in male infertility accompanied by abnormal semen. The patients with most severely compromised sperm counts have sex chromosome aberrations including aneuploidy and the presence of marker chromosomes. Some patients have evidence of mosaicism as detected in their peripheral blood karyotypes. Here, we report a 28-year-old patient with a rare sex chromosome mosaicism. His chief complaint was infertility secondary to azoospermia. Chromosome investigations were performed on cultures of peripheral blood lymphocytes using GTG-banding and HR-banding techniques. His karyotype showed: 47, XXY / 47, XYY / 48, XXYY. The origin of the error that leads to this mosaicism is likely to be paternal nondisjunction at meiosis I in one cell lineage, at meiosis II in the second line, and at both meiosis I and meiosis II in the third cell lineage. This was the only case with this kind of mosaicism observed during the last 20-years of work in our Department, and no similar cases were found in the literature.

P02.223

20-year chromosomal studies among the Iranian infertile men

C. Azimi, M. Khaleghian, F. Farzanfar;

Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran.

Chromosomal aberrations have been postulated to be as one of the principal genetic factors in male infertility and occur in about 2-3 % of unselected patients with proven subfertility. This rate is estimated to be 5-7 % in patients with oligozoospermia and increasing to 10-15 % in patients with azoospermia. In this 20-year retrospective study we investigated 829 men which were referred to our Department due to infertility. Karyotyping was performed on peripheral blood lymphocytes according to standard methods. Out of 829 patients, 557 patients (67.19 %) had a normal karyotype and 272 patients (32.81 %) showed abnormal chromosomes. Klinefelter syndrome, found in 195 patients (23.52 %), was the most frequent aberration in our study. The remaining 77 cases (9.29 %) showed the following abnormal karyotypes:

Karyotype	Number
47, XXY	195
48, XXYY	4
mos48, XXYY/47, XXY/47, XYY	1
mos48, XXXY/47, XXY/46, XY	4
mos47, XXY/46, XY	9
mos45, X/46, XY	7
mos47, XXY/ 46, XX/46.XY	7
mos46,XX/46.XY	5
mos45, X/46, X, del(Y)(q10)	2
mos47, XXY/45, X/46.XY	4
mos46,XY, t(7;13)/46, XY	1
47, X, i(X)(q10)Y	3
46, X, add(Y)(p11.3)	7
46, X, del(Y)(q11)	6
46, X, r(Y)	2
47, X, t(X;Y)(q10 q10)	2
46, X, t(Y;14)	2
46, XY, t(14;22)	1
47, XYY	2
46, XX (sex reversal)	5
46, XY, inv(9)	3
Total	272

P02.224

Analysis of heteroploidy frequency in sperm from man with chromosome rearrangements

I. Fedorova^{1,2}, E. Shilnikova², O. Chiryayeva¹, L. Petrova¹, V. Dudkina¹, T. Smirnova³, M. Bogdanova³;

¹Ott's Institute of Obstetrics and Gynecology, St-Petersburg, Russian Federation, ²St-Petersburg State University, St-Petersburg, Russian Federation, ³Medical centre "InAlMed", St-Petersburg, Russian Federation.

Structural chromosome aberrations detected on metaphase plates from peripheral blood lymphocytes lead to increased risk of chromosome abnormal progeny. Analysis of chromosome segregation in sper-

matozoa from carriers of chromosome aberrations allows to understand peculiarities of meiotic divisions and get information about risk of conceiving chromosome imbalanced offspring.

FISH with specific DNA probes heteroploidy frequency was scored in decondensed sperm from 3 patients with chromosome aberrations: 46,XY,t(2;3)(q33;q29) - case 1; 46,XY,inv(4)(p12q21),inv(10)(p11q21) - case 2 and 45,XY,der(13;14)(q10;q10) - case 3.

In case 1 disomy frequency of chromosome involved in this rearrangement increased (up to 3,01%). In case 2 disomy frequency of inverted chromosome (0,9%) was compared to this one the of other autosomes (1,06% for chromosome 7; 0,9% for chromosome 9). Frequency of diploidy was higher in patients with robertsonian (case 3) and reciprocal translocations (case1) (1,48% and 2,05%, respectively) compared to patient with inversions (0,54%). Frequency of heteroploidy are in agreement with spermological analysis (WHO standard): patients 46,XY,t(2;3)(q33;q29) and 45,XY,der(13;14)(q10;q10) feature oligoasthenozoospermia, in contrast to patient 46,XY,inv(4)(p12q21),inv(10)(p11q21) having asthenospermia.

Our data suggest that spermological analysis can be linked to the karyotype aberrations and carriers of chromosome aberrations with decrease of sperm concentration have poor fertility prognosis. Supported by CRDF and RFBR.

P02.225

A Y chromosome with three short arms in a male with a 45,X/46,X,psu dic(Y) karyotype

K. Hansson, K. Suzhai, J. Knijnenburg, F. Hes, E. Bakker, J. Smit, W. vd Ende, M. Hoogenboom, C. Kneplé, K. Madan;

Leiden University Medical Center, Leiden, The Netherlands.

We report a case with an unusual pseudo-dicentric Y chromosome with three short arm segments. When the male patient was first referred for karyotyping because of hypogonadism and mental retardation more than 30 years ago, he was found to have a mosaic karyotype with two cell lines, one 45,X and the other with an abnormal non-fluorescent Y chromosome. The father had a normal Y chromosome. At the age of 47, the patient was referred again for cytogenetic analysis because of his mental retardation. Mutation analysis in connection with thyroid dysfunction revealed a thyroid hormone receptor beta (TRb) germline mutation. FISH studies revealed a complex rearrangement with an alternating pattern of Y short and long arm material: short-long-short-long-short. Using probes for the subtelomeric regions two signals with the Ypter probe was found whereas no signal was observed with the subtelomeric Yq probe. Two signals were also found using probes for the centromeric region and the SHOX gene. In contrast, FISH with a probe for the SRY gene revealed three signals on the abnormal Y chromosome: two on the short arms of the dicentric and an extra signal in the short arm segment situated in the middle of the rearranged Y chromosome. DNA-studies are in progress to further elucidate the nature of this complex Y chromosome rearrangement.

P02.226

Cytogenetic Analysis of Infertile Iranian men

S. Soleimani¹, M. Zamaniyan¹, M. Montazeri², F. Nasiri¹, F. Mortezaipoor¹, M. Rahnama¹, F. Mahjoobi¹;

¹The Blood Transfusion Organization Research Center, Tehran, Islamic Republic of Iran, ²NRCGEB, Tehran, Islamic Republic of Iran.

Male infertility factor accounts for about half the cases of couple infertility.

Some of the chromosomal changes (aberrations) which seem effective in men infertility include:

1. Balanced chromosomal translocation
2. Chromosome inversion
3. Marker chromosome
4. Sex chromosome abnormality

Our investigation provides the circumstantial and direct evidences which confirm the importance of the sex chromosome in reproductive disorders. We have analyzed (7years study) 845 blood samples from infertile men which 617 of them were oligospermic and azospermic. Constitutional chromosome aberrations were diagnosed in 278 of these patients. We have observed 29.2% chromosomal abnormality in azospermia men that is compatible with the data from literature.

The following abnormal chromosome complements were found:

46,XX;47,XXY;47,YYY;48,XXXXY;45,X[10]/46,XY[134];46,XY[4]/

47,XXY[82];

46,XX[11]/47,XXY[36];46,XY[6]/47,YYY[38];46,XY[10]/46,XX[26]/47,XXY[61];

46,X,del(Y)(q_{11.23});46,X,inv(Y)(p_{11.2};q_{11.22}).

We have found some patients with complex structural and aneuploidy abnormalities:

× 46,XX,inv(9)(p_{11.13})/47,XXY,inv(9)(p_{11.13})[4]

× 47,XXY[93]/48,XXY+mar[4]/48,XXXXY[2]

× 47,XXY,inv(9)(p_{11.13})

× 47,XXY,t(1;17)(p_{36.1};q₂₁)

× 46,X,del(Y)(q_{11.2})[98]/45,X[6]

× 47,XXY,inv(9)(p_{11.13})/t(10;22)(q_{26.3};q_{13.1})

× 46,X,idel(Y)(p_{11.32};q_{11.32})[27]/45,X[36]/46,XY[2]

We believe that many infertilities especially severe oligospermic and azospermic cases raise the need for a cytogenetic analysis besides molecular techniques to reveal the existence of any genetic abnormalities.

P02.227

Meiotic studies in spermatocytes from fertile males

L. Uroz¹, O. Rajmil², C. Templado¹;

¹Unitat de Biologia Cel·lular i Genètica Mèdica, Facultat de Medicina, Universitat Autònoma de Barcelona, Bellaterra, Spain, ²Servei d'Andrologia, Fundació Puigvert, Barcelona, Spain.

BACKGROUND: Meiotic chromosome abnormalities are associated with male infertility. However, little is known about meiotic process in men of proven fertility. We carried out meiotic studies in spermatocytes to establish the base line level of meiotic abnormalities in fertile males. **MATERIAL AND METHODS:** Testicular biopsies were obtained from 11 fertile males aged 30-47. Meiotic spreads were prepared by the air-drying technique and cells were stained with DAPI. **RESULTS:** Meiotic progression was analysed at pachytene, metaphase I and metaphase II stages, counting 1,000 pachytene spermatocytes per individual. All males showed a normal meiotic progression, with a proportion of metaphase II to metaphase I higher than 0.5. A total of 848 spermatocytes at metaphase I was studied. The overall percentage of dissociated sex chromosomes was 21.7%. Autosomal synaptic abnormalities were found in 0.9% of spermatocytes I (medium-sized bivalents with one chiasmata or small bivalents as two separated univalents). Only 0.2% of the spermatocytes I analysed were hyperploid. Hypoploidy was not evaluated, since it could be due to technical artefacts. The percentage of structural chromosome aberrations per individual ranged from 0% to 5.8%. The total mean chiasma frequency was 51.0, ranging from 48.7 to 53.0. **CONCLUSION:** The incidence of meiotic abnormalities (both chromosomal and synaptic abnormalities), as well as spermatocyte distribution and chiasma count in fertile males could be used as reference data in further studies on males with idiopathic infertility.

P02.228

Increased autosomal structural aberrations in human spermatozoa regarding age

C. Templado¹, A. Donate¹, J. Giraldo², O. Rajmil², M. Bosch¹;

¹Unitat de Biologia Cel·lular i Genètica Mèdica, Facultat de Medicina, Universitat Autònoma de Barcelona, Bellaterra, Spain, ²Unitat de Bioestadística and Institut de Neurociències, Universitat Autònoma de Barcelona, Bellaterra, Spain, ³Servei d'Andrologia, Fundació Puigvert, Barcelona, Spain.

Background: Although most of *de novo* structural aberrations are paternal in origin, little information is available on the relationship between advanced paternal age and structural chromosome abnormalities in human spermatozoa. **Objective:** To explore the age effect on the frequency of structural abnormalities in human spermatozoa. **Methods:** Fluorescence *in situ* hybridisation (FISH) with a panel of 62 specific probes was used in spermatozoa to screen all 22 autosomes for duplications and deletions. Sperm samples were collected from 10 healthy males: five males aged 24-37 (mean age 27.8 years) and five males aged 60-74 (mean age 66.4 years). A total of 150,000 sperm nuclei were scored by multicolour FISH, analysing 1,000 spermatozoa per donor and per autosome. **Results:** The frequency of structural abnormalities per individual ranged from 4.2% to 7.8%. The mean percentage of autosomal duplications was significantly greater ($P < .05$) in older donors (4.5%) when compared with that in younger donors

(3.3%). This increased frequency of duplications in older donors could correspond, at least in part, to an excess of acentric fragments in their spermatozoa. Chromosome 12 was the only autosome with an increased level ($P < .05$) of structural aberrations in relation to age.

Conclusions: Our results indicate an association between advanced paternal age and increased risk in offspring for *de novo* autosomal unbalanced structural aberrations.

P02.229

A two chromosome inversions 46,XY,inv(4)(p12q21),inv(10)(p11q21) associated with spermatogenic failures

E. Shilnikova¹, I. Fedorova^{2,1}, N. Sadik²;

¹Saint-Petersburg State University, Saint-Petersburg, Russian Federation, ²Ott's Institute of Obstetrics and Gynecology, Saint-Petersburg, Russian Federation.

Chromosome aberrations carriers are often affected by reproductive failures, including spontaneous abortion and newborns with chromosome abnormalities, due to production of genetically unbalanced gametes. But such patients do not exhibit any particular phenotypes. A man from infertile couple was studied to determine the karyotype and spermatogenesis failures.

Using QFH-banding technique and FISH with DNA probes specific to chromosome 4 and 10, we detected karyotype with two pericentric inversions: 46,XY,inv(4)(p12q21),inv(10)(p11q21). There were no chromosome anomalies in the karyotype of his twin brother (46,XY), their parents were not available for genetic analysis.

Semen parameters (concentration, motility and morphology) were analyzed according to WHO criteria. Motile spermatozoa amounted to 25% with other parameters being normal (asthenozoospermia). Also Quantitative Karyological Analysis of Immature Sex Cells (QKAISK) in ejaculate was performed to determine the stage of spermatogenesis block. Partial block of spermatogenesis after MI division and delay of karyokinesis was detected. Frequency of diploid and disomic spermatozoa was identified using multicolour FISH with specific DNA probes to chromosomes 9 and 10. Frequency of aberrant chromosome disomy did not differ from that of normal one and totaled 0,9%. Frequency of diploid spermatozoa was 0,54%.

This study confirms the necessity of complex cytogenetic somatic cells and gametes analysis for patients with chromosome aberrations to calculate the risk of genetically unbalanced offspring more precisely.

Correlation of Antioxidant Enzyme level with Mitochondrial Mutations in North Indian Infertile Men

M. B. Shamsi, S. Venkatesh, R. Kumar, S. Arora, D. Arya, R. Dada;

AIIMS, New Delhi, India.

Oxidative damage to spermatozoa is a well known potential cause of infertility. The balance between antioxidants and pro-oxidants is essential. Optimum levels of free radicals (Reactive Oxygen Species) are important physiological mediators in normal sperm functioning. Antioxidants as Glutathione Peroxides, Glutathione Reductase (prostatic origin), Superoxide Dismutase (prostatic and epididymal origin) and Catalase (multiglandular origin) prevent oxidative stress (OS). Free radicals induce mitochondrial DNA damage especially in genes regulating Oxidative Phosphorylation (OXPHOS) and result in impaired sperm function and spermatogenesis.

In an ongoing study the correlation between the enzymatic antioxidants, malonaldehyde (product of lipid peroxidation) in the seminal plasma and in blood serum was done, the results were further correlated with semen parameters and mitochondrial DNA integrity. Results showed significant correlation between SOD in blood serum and sperm concentration ($r=0.699$, and $p=0.008$). Positive correlation was observed between the seminal SOD, sperm count and progressive motility. These results are in accordance with several previous studies. No correlations could be established between the seminal MDA, blood serum MDA and semen parameters. In these cases a significant number of mitochondrial mutations in the OXPHOS genes were observed. This may explain for low sperm count and motility defects in our patients.

The analysis of antioxidant levels in seminal plasma and blood and

their impact on the semen parameters corroborated with mitochondrial mutations and DNA integrity would help to provide a deep insight into the understanding of the OS induced infertility and thus in better management of such cases.

P02.231

CFTR gene mutations and TT-polymorphism in infertile men of Russia

T. M. Sorokina, L. F. Kurilo, S. A. Kazakova, A. A. Stepanova, V. B. Chernykh;

Research Centre for Medical Genetics of RAMS, Moscow, Russian Federation. Cystic fibrosis conductance transmembrane regulator (CFTR) gene mutations are common genetic cause of male infertility. Cystic fibrosis, congenital bilateral and unilateral absence of the vas deferens (CBAVD and CUAVD syndromes) lead to azoospermia or severe oligozoospermia. Also CFTR mutations are associated with reduced sperm quality in men who do not present CF phenotype.

We investigated a cohort of 568 men from Russian infertile couples. Fourteen common CFTR mutations (del21kb, ΔF508, ΔI507, 1677delTA, 2143delT, 2184insA, 394delTT, 3821delT, L138ins, G542X, W1282X, N1303K, R334W, 3849+10kbC>T) and TT-polymorphism in the intron 8 (IVS8T) have been analyzed.

CFTR mutations were found in 25 out of 568 (4.4%) patients. Following mutations have been revealed: ΔF508 (n=9), del21kb (n=5), W1282X (n=5), 2143delT (n=2), 2184insA (n=1), G542X (n=1), R334W (n=1), 1677delTA (n=1). The 5T allele frequency was 10.6% in examined patients. This allelic variant has been revealed in the heterozygous (n=52 cases), in the homozygous (n=3 cases) and in the compound heterozygote state with common CFTR mutation (n=5 cases). The combined frequency of CFTR mutations and 5T allele was 7.6% in infertile men cohort.

All patients with CFTR mut/5T and 5T/5T genotypes had a diagnosis of azoospermia or severe oligozoospermia. Two azoospermic men with CFTR mutations had extragenital features of cystic fibrosis (chronic bronchitis or a chronic pancreatitis). In one severe oligozoospermic patient with CFTR mutation the CUAVD syndrome associated with renal abnormalities has been diagnosed.

P02.232

Modelling reduced male fertility in mice

E. Bolcun-Filas, R. Speed, M. Taggart, H. J. Cooke;

MRC Human Genetics Unit, Edinburgh, United Kingdom.

Human fertility is highly variable and a substantial part of that variation is genetic. The phenotype is hard to measure and involves input from two individuals making whole genome association studies difficult if not impossible to design robustly. Candidate gene approaches based on a knowledge of the underlying processes of gametogenesis have had only limited success. This is a reflection both of the large number of genes thought to be required, particularly for sperm production, and the likelihood that the majority of mutations are recessive requiring rare homozygosity for a mutation at any one locus to produce a phenotype.

Recognising this we have asked if compound heterozygosity at genes encoding proteins required for meiosis can be a factor. SYCE1 and SYCE2 are proteins of the meiotic Synaptonemal Complex. We have shown that SYCE2 is essential for male and female fertility in mice and here we show that this is also true for SYCE1. Heterozygous null animals are fertile in the case of both genes. Mice heterozygous for both null alleles have a ten fold elevation in XY asynapsis and also an increase in unpaired autosomes. Lack of pairing is predicted to result in cell death and a consequent reduction in sperm count. We observe a reduction in sperm count of up to 40% showing that compound hemizygosity in genes involved in the same pathway can have a significant impact.

P02.233

Gene expression profiling of normal and pathological testis by microarray analysis

V. Gatta¹, F. Raicu¹, A. Scioletti¹, A. Ferlin², G. Palka¹, C. Foresta², L. Stuppia¹;

¹G. D'Annunzio University Foundation, Chieti, Italy, ²University of Padova, Padova, Italy.

Microdeletions of the AZFa, AZFb and AZFc loci on Yq are detected in about 10% of infertile males. Despite the large amount of data collected in the last years, the biological mechanisms leading to the disruption

of spermatogenesis in Yq deleted patients are still largely unknown. In this study we analyzed by microarray technology the testis expression profiles of patients with idiopathic infertility, patients carries of AZFc deletion and controls (patients with obstructive azoospermia), in order to obtain useful information about the specific genes involved in each different pathological condition. Using the hierarchical clustering average method in 27 microarray experiments we identified in AZFc deleted patients two main gene clusters showing different expression patterns as compared to normal controls and patients with idiopathic infertility. Analysis of these gene clusters using IPA software revealed an interesting down-regulated gene network directly related with spermatogenesis, with the most significant network centred around YBX2 gene (Y box binding protein 2), involved in RNA storage during gametogenesis. This alteration is responsible for the downregulation of the protamine1 and 2 genes evidenced in the same network analysis. In the expression profiles comparative analysis between controls and AZFc deleted patients we also observed an interesting downregulation of the CREM pathway, which is a master controller gene for spermatogenesis. This suggests that impairment of RNA storage and dysregulation of the CREM pathway could represent two of the biological mechanisms underlying spermatogenesis failure in patients with Yq microdeletion.

P02.234

Identification candidate genes and proteins involved in male infertility through proteomic analysis of human sperm proteins

R. Oliva¹, S. de Mateo¹, J. Martínez-Heredia¹, T. Botta-Orfila¹, S. Blescia¹, J. Oriola¹, J. Estanyof¹, J. Balleca²;

¹Human Genetics Research Group, Biochemistry and Molecular Genetics Service, Faculty of Medicine, Univ. Barcelona, and Hospital Clínic, Barcelona, Spain, ²Proteomics Unit, Faculty of Medicine, Univ. Barcelona, Barcelona, Spain, ³Institut Clínic de Ginecologia, Obstetricia i Neonatologia, Hospital Clínic, Barcelona, Spain.

Proteomics offers at present the opportunity to compare the relative abundance of the different proteins present in patients and controls with the potential to identify diagnostic markers and candidate proteins to be used in genetic association studies. Towards this goal the proteins present in the sperm cells from sperm samples from infertile patients and from semen donors were analyzed by 2D gel electrophoresis. In each of the 2D maps the intensity of 101 spots previously identified by MALDI-TOF analysis was measured. Additionally, the protamine content and DNA integrity were also determined in each independent sample. Several interesting proteins such as transcription factors, prohibitin, heat shock and proteasome proteins have been identified. Of relevance the expression of an important number of proteins (55 different 2D spots) correlated in independent sperm samples at high statistical significance. Some of the proteins have been found to correlate with DNA integrity and protamine content in infertile patients. Therefore this is proving to be a useful approach leading to the identification of candidate proteins and therefore candidate genes which may harbour mutations or polymorphisms involved in the pathogenic mechanisms present in infertile patients. Supported by BMC006-03479.

P02.235

Primary male infertility in Izmir / Turkey: a cytogenetic and molecular study of 187 infertile Turkish patients

H. Akin, H. Onay, E. Turker, F. F. Ozkinay;

Ege University Medical Faculty Medical Genetics Department, Izmir, Turkey.

Infertility is an important health problem affecting 10-15% of couples. The contribution of male factors to patients is about 30-50%. The main genetic factors in male infertility are somatic chromosomal abnormalities and Y chromosomal microdeletions within Yq11 region. The genes which control spermatogenesis are located in Yq11 region and are known as azoospermia factor genes (AZF). The AZF region has 3 non-overlapping loci-AZFa, AZFb, AZFc which are required for normal spermatogenesis. All these genes are expressed in testicular tissue showing that they play roles in human spermatogenesis. Here, we aimed to detect somatic cytogenetic abnormalities and AZF microdeletions in a sample of 187 Turkish infertile men and to evaluate the frequencies and the characteristics of our primary male infertility data in order to perform appropriate genetic counseling. Cytogenetic study revealed chromosomal abnormality in 9 subjects (4.8%). In remaining 178 subjects, 7 subjects (3.93%) were detected

to have Y chromosome microdeletions. The AZFc region was the most frequently involved region in affected subjects. One of these subjects showed microdeletion in all 3 regions (AZFa, AZFb, AZFc) and one subject had microdeletions in both AZFb and AZFc regions. Other 5 subjects had microdeletions in only AZFc region. All subjects having microdeletion were azoospermic.

In conclusion, cytogenetic and molecular study should be performed to obtain reliable genetic information for the genetic counseling of primary infertile man. Y chromosome microdeletion diagnosis is useful in decision making for assisted reproductive techniques because the association between some deletions and residual spermatogenesis capacity has been proven.

P02.236

Oxidative stress and mitochondrial DNA mutations in Oligoasthenoteratozoospermic patients

S. Venkatesh, R. Kumar, M. B. Shamsi, M. Tanwar, D. Pathak, R. Dada;

Laboratory for Molecular reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India.

Excess production of reactive oxygen species (ROS) establishes oxidative stress (OS) in the semen. Mitochondria are suspected to be the source and target of ROS where mutation in mitochondria can impair the formation/function of mature spermatozoa. So the present study was aimed to correlate the oxidative stress and mtDNA mutation with the sperm parameters of infertile patients. Study includes 62 infertile subjects and 30 fertile controls attending AIIMS, New Delhi, India. Complete semen analysis was performed according to WHO criteria (1999). OS was evaluated by malonaldehyde estimation and sperm mitochondrial DNA mutations by standard PCR-DNA sequencing. Infertile group showed significantly ($p < 0.001$) higher MDA levels (0.18 ± 0.03 nmol / 10^6 spermatozoa) compared to fertile controls (0.10 ± 0.02 nmol / 10^6 spermatozoa). The mean sperm count of infertile group was $12.78 \pm 11.81 \times 10^6$ /ml, whereas the fertile group had $55.73 \pm 20.57 \times 10^6$ /ml. DNA sequencing revealed that 66% ($n=41$) of the infertile group harboured one or more mutations (T4672A, C10165T, C10207T, A10470G, T13946A) in the mitochondrial genome where no mutations were detected in the fertile group inspite some common nucleotide changes (A750G, A4769G) in both the groups. All the mean sperm parameters of infertile subjects were negatively correlated with the malonaldehyde level. Higher MDA levels in the infertile subjects compared to the controls may be correlated with the change in the gene sequence of sperm mtDNA of infertile subjects. Thus mtDNA mutation harboured in the infertile groups may be due to oxidative stress.

P02.237

Mutations and polymorphisms in the cystic fibrosis gene in men with severe oligozoospermia.

M. Teder-Laving¹, M. Punab², E. Oitmaa³, A. Belousova⁴, K. Haller^{5,6}, O. Poolamets², E. Raukas⁷, A. Metspalu⁸, A. Salumets^{4,9};

¹Estonian Biocentre, Tartu, Estonia, ²Andrology Unit of Tartu University Hospital, Tartu, Estonia, ³Asper Biotech, Tartu, Estonia, ⁴Institute of Molecular and Cell Biology, Department of Biotechnology, University of Tartu, Tartu, Estonia, ⁵Department of Obstetrics and Gynaecology, University of Tartu, Tartu, Estonia, ⁶Institute of General and Molecular Pathology, Department of Immunology, University of Tartu, Tartu, Estonia, ⁷United Laboratories, Tartu University Hospital, Tartu, Estonia, ⁸Institute of Molecular and Cell Biology, Department of Biotechnology, Tartu, Estonia, ⁹Department of Obstetrics and Gynaecology, University of Tartu, Tartu, Estonia.

Background: Majority of male cystic fibrosis (CF) patients are infertile because of congenital bilateral absence of vas deferens (CBAVD). In addition, male infertility as a result of isolated CBAVD is also recognized as a primary genital form of CF. Mutations in cystic fibrosis transmembrane conductance regulator (CFTR) gene have been found in more than 85% of CBAVD cases. Possible involvements of CFTR mutations in other forms of male infertility have been suggested but remain controversial. In sperm, CFTR may be important in transport of various anions and sperm capacitation, hence making it possible that certain CFTR mutations may lead to reduced sperm fertilizing capacity and male infertility in other forms of male infertility rather than CBAVD.

Objective: To compare the frequency of CFTR gene mutations between oligozoospermic and healthy fertile men.

Materials and Methods: The study populations consisted of 124 oligo-

and 90 normozoospermic men. We screened simultaneously for 254 different CFTR mutations and variations using arrayed primer extension (APEX) genotyping microarray (Asper Biotech Ltd).

Results: CFTR mutations and variants were demonstrated in 22 (17.7%) of 124 oligozoospermic patients and in 13 (14.4%) of 90 control men. In addition, the total frequency of mutant/variant alleles in infertility group was slightly, but not significantly higher than in controls (9.7 vs 7.2%). Similar trend was also observed for IVS8-5T allele frequencies (3.6 vs 2.2%, respectively). Although we demonstrate comparable CFTR mutation/variation frequencies in both groups, the causal relationships between specific CFTR mutations and male infertility cannot be completely ruled out.

P02.238

Simultaneous inactivation of the transcription factors Sox9 and Sox8 in murine testis development leads to complete infertility

F. J. Barrionuevo¹, H. Scherthar², C. Lécureil³, F. Guillou³, M. Wegner⁴, G. Scherer¹;

¹Institute of Human Genetics, University of Freiburg, Freiburg, Germany, ²Institut für Radiobiologie der Bundeswehr, München, Germany, ³Institut National de la Recherche Agronomique, Université de Tours, Nouzilly, France, ⁴Institute of Biochemistry, University of Erlangen, Erlangen, Germany.

Heterozygous loss-of-function mutations of the HMG-box transcription factor SOX9 result in campomelic dysplasia, a human skeletal malformation syndrome associated with XY sex reversal. The murine Sox9 gene is expressed in embryonic and postnatal Sertoli cells of the mouse testis, and inactivation of Sox9 before the sex determination stage at E11.5 leads to complete XY sex reversal. To see whether Sox9 is required for testis development after testis induction, we crossed Sox9^{lox} mice with an AMH(Anti-Müllerian Hormone)-Cre transgenic line. Conditional Sox9 null mutants, SOX9-negative at E14.0, are initially fertile, but become sterile from complete meiotic arrest at around 5 months. As Sox8, a Sox9 related transcription factor, i) is expressed similar to Sox9 during murine testis development, ii) has been shown *in vitro* to activate AMH, a Sox9 target during testis development, iii) is expressed normally in AMH-Cre;Sox9^{lox/lox} mutants, and iv) as homozygous Sox8 null mutants show no obvious early gonadal phenotype, we hypothesized that Sox8 may compensate for the absence of Sox9. We therefore generated a Sox9 conditional knockout on a Sox8 mutant background. In double mutants heterozygous for Sox8, testes develop normally up to post-natal day 10 (P10), but subsequently show spermatogenic arrest. Homozygous double mutants show normal testis cord formation at E15.5, but subsequent testis cord development is impaired; at P6, testis cords are completely irregular in shape and appear fibrotic, resulting in complete infertility. In summary, concerted function of Sox9 and Sox8 in post E14.0 Sertoli cells is essential for the maintenance of testicular function.

P02.239

Real-Time PCR evaluation of TSPY copy number in infertile and seminoma patients.

R. Vodicka¹, K. Krizova¹, R. Vrtel¹, L. Dusek², J. Santavy¹;

¹University Hospital and Palacky University Olomouc, Olomouc, Czech Republic, ²Institute of Biostatistik and Analyses, Masaryk University Brno, Brno, Czech Republic.

Introduction: Multicopy TSPY gene is localized on chromosome Y in MSY region in gene clusters. Total number of the gene copies is estimated from 20 to 40. Testis specific expression indicates a role in meiotic or post meiotic processes during spermatogenesis.

The aims of this work are:

- 1) Confirmation of our previous findings (Vodicka R, et al., TSPY gene copy number as a potential new risk factor for male infertility. *Reprod Biomed Online*. 2007 May;14(5):579-87.)
- 2) Analyses and comparison of a new DNA samples from infertile and seminoma patients.

Material and method: There were included 104 infertile and 6 seminoma patients and 50 healthy controls into study.

Copy number relative quantification was measured using the combination of two Real-Time PCRs by Y quantifier kit and by SYBR green kit.

Results: Our results confirmed increasing copy number in infertile patients (in average 53 relative TSPY copies) compare to controls (in average 31 relative copies) even after enlarged collection of samples.

In addition the seminoma patients showed twice as many copy number compare to the infertile patients (in average 102 relative copies).

Conclusion: The main importance of our findings lies in great diagnostic potential in male infertility genetic background testing. Number of TSPY copies could be also significant tumor marker in relation to testicular tumorigenesis.

P02.240

AZF microdeletions on the Y chromosome of Iranian infertile men with non-obstructive azoospermia

R. Mirfakhraie^{1,2}, S. M. Kalantar³, M. Montazeri², N. Salsabil⁴, G. Modabber², S. M. Seyed Hassani³, M. Houshmand⁴, F. Mirzajani²;

¹Islamic Azad University of Tehran, Science & Research Campus, Tehran, Islamic Republic of Iran, ²National Institute for Genetic Engineering & Biotechnology, Tehran, Islamic Republic of Iran, ³Research & Clinical Centre for Infertility, Yazd, Islamic Republic of Iran, ⁴Mirza Kouchak Khan Hospital, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran.

The human Y chromosome contains genes that are essential for spermatogenesis specially those that are located on three major intervals defined as AZFa, AZFb and AZFc.

Deletions in these genes may result in spermatogenic failure in patients with non-obstructive azoospermia and oligozoospermia. Widely different frequencies of such deletions (0-55%) have been reported from different populations.

The main purpose of this study is to detect the frequency of Y chromosome microdeletions in Iranian patients with non-obstructive azoospermia and fertile control subjects. Multiplex polymerase chain reaction (PCR) was applied using several sequence-tagged site (STS) primer sets, in order to determine Y chromosome microdeletions in 100 infertile males and 50 fertile controls.

Microdeletions in AZFa, AZFb and AZFc (DAZ gene) regions were only detected in seventeen of the patients (17%) with the frequency of 15%, 49%, and 36% respectively.

Our findings suggest that knowing the prevalence of AZF microdeletions in Iranian infertile men will be informative before starting assisted reproductive treatments.

P02.241

Male infertility and biotransformation enzyme gene polymorphisms

M. Volk¹, A. Kastrin¹, H. Jaklič¹, B. Zorn², B. Peterlin¹;

¹Institute of Medical Genetics, University Medical Center Ljubljana, Ljubljana, Slovenia, ²Department of Andrology, University Medical Center Ljubljana, Ljubljana, Slovenia.

Environmental xenobiotics such as organophosphate pesticides are known to be involved in male infertility. Interindividual genetic variations in biotransformation enzyme activities can lead to differences in the susceptibility to male infertility. In this case-control study, PCR was used to investigate the association between polymorphisms in the PON and GST genes (PON1-55/192, PON2-311, GSTM1/T1) and male infertility in 381 Slovenian participants (the study group of 187 infertile male participants: 86 with azoospermia, 101 with oligoasthenoteratozoospermia; the control group of 194 fertile males).

We found statistical significant difference in the PON1-55 genotype distribution between the infertile and fertile men ($\chi^2(2) = 7.37$; $p = 0.02$), which after applying Bonferroni correction was no longer significant. Likewise, no significant differences in frequencies of genotypes of other tested polymorphisms, PON1-192, PON2-311, GSTM1/T1, respectively, and the occurrence of male infertility were observed (Table 1).

In this case-control study we didn't confirm the association between PON1/2 or GSTM1/T1 genetic variations and male infertility in Slovenian participants. However, limitations of the genetic association studies, namely, the relatively small sample size and population specific genotype effects which make results difficult to reproduce, should be considered when interpreting and generalizing the results.

Table 1. Genotype frequencies of the PON and GST polymorphisms in infertile and control group.

P02.242

Detection of the most common genetic causes of male infertility by QF-PCR analysis

D. Plaseska-Karanfilska¹, T. Plaseska², P. Noveski¹, S. Trivodalieva¹, G. D. Eremov¹;

¹Macedonian Academy of Sciences and Arts, Research Centre for Genetic Engineering and Biotechnology, Skopje, The former Yugoslav Republic of Macedonia, ²Faculty of Medicine, Clinic of Endocrinology and Metabolic Disorders, Skopje, The former Yugoslav Republic of Macedonia.

The most common genetic causes of spermatogenic failure are sex chromosomal abnormalities (most importantly Klinefelter's syndrome) and deletions of the azoospermia factor (AZF) regions (AZFa, AZFb, AZFc) of the Y chromosome. Recently, several studies have proposed that partial AZFc deletions/duplications may represent a risk factor for spermatogenic impairment. Here we describe a multiplex quantitative fluorescent (QF)-PCR method that allows detection of these common genetic causes and risk factors of male infertility. The 11-plex QF-PCR included the amplification of amelogenine gene; four polymorphic X-specific short tandem repeats (STR) markers (XHPRT, DXS6803, DXS981 and exon 1 of the AR gene), non-polymorphic Y-specific marker (SRY gene), polymorphic Y-specific STR marker (DYS448), as well as co-amplification of DAZL/DAZ, MYPT2/MYPT2Y and two CDY1/CDY2 fragments that allowed for the determination of the DAZ, MYPT2Y and CDY gene copy number. A total of 348 DNA samples from infertile/subfertile patients (n=204) and fertile controls (n=144) were included in the study. We detected 14 infertile males with sex chromosomal aneuploidies (10 individuals with Klinefelter's syndrome, two XX and two XYY males). All previously detected AZF deletions; AZFc (n8), AZFb (n1), AZFb+c (n1), gr/gr (n11), gr/gr with b2/b4 duplication (n3) and b2/b3 (n5) gave a specific pattern with the 11-plex QF-PCR. In addition, 29 DNA samples showed pattern consistent with the presence of gr/gr and two with b2/b3 duplication. In conclusion, multiplex QF-PCR is a rapid, simple, reliable and inexpensive method that can be used as a first-step genetic analysis in infertile/subfertile patients.

P03. Prenatal diagnostics

P03.01

Use of array CGH in prenatal diagnosis

H. Raussi¹, P. Myny², K. Heinimann², F. Wenzel¹, I. Filges², A. Godenhjelm¹, P. Ollikka¹;

¹PerkinElmer LAS, Wallac, Turku, Finland, ²Division of Medical Genetics, University Children's Hospital, Basel, Switzerland.

OBJECTIVE: Microarray based comparative genomic hybridization (aCGH) is relatively widely used in genetic diagnosis of children, but true potential is still unexplored in prenatal diagnosis. The objective of

our study is to evaluate the feasibility of BAC arrays in the analysis of prenatal samples.

METHODS: Chorionic villus and amniotic fluid samples are obtained using standard clinical procedures. DNA is extracted and labelled for the aCGH analysis. For samples with limited amounts of DNA, we perform whole genome amplification (WGA). Two types of arrays are used: arrays targeted to constitutional syndromes (Constitutional Chip[®] 3.0), and 1 Mb resolution-arrays covering whole genome (Spectral Chip[™]). The arrays are scanned with ScanArray[®], and data is analysed with SpectralWare[®]. All samples are also analysed by conventional karyotyping. Potential aCGH findings are confirmed with FISH using the corresponding BAC DNA as probe.

RESULTS: To reduce the turn-around time, DNA is extracted directly from the samples. For direct amplification, we have compared three suppliers for their WGA performance. In addition, some cases have been tested both with native and amplified DNA to address potential bias caused by amplification. Results are promising, and a larger set of samples will confirm the best practices.

CONCLUSION: The use of samples without cell culturing combined with simultaneous detection numerous genomic imbalances can have great benefit to prenatal diagnosis. The difficulty in discriminating the pathologic and benign copy-number variations and the possibility to detect potentially unwanted information will undoubtedly be challenging for the professionals interpreting the data but also for array manufacturers.

P03.02

Sequential and Integrated prenatal screening for Down syndrome

T. K. Kascheeva, Y. A. Nikolaeva, T. V. Kuznetsova, V. S. Baranov;

Ott Institute of Obstetrics & Gynecology, Saint-Petersburg, Russian Federation.

Objective. To compare the integrated test in three variants screening for prenatal Down syndrome detection: the first trimester combined screening, sequential screening and integrated screening.

Methods. Ultrasound scanners Aloka SSD-2000 and Medison SA-8000 Live was applied for 716 singleton pregnancies on 10-13 weeks of gestation with 265 of them (37%) were after 35. First trimester biochemical markers were studied on 9 to 13 weeks of gestation with Life Cycle system for prenatal screening (Wallac/Perkin Elmer Life and Analytical Sciences, Finland). 644 second trimester samples (89.9%) were tested by test-systems products of "Alkor-Bio", Saint-Petersburg.

Detection rates (DR) and false-positive rates (FPR) were estimated. Results. Integrated screening has the lowest FPR. All 27 cases of chromosomal anomalies (including 22 DS cases) were revealed after prenatal diagnostics with FPR value 13.6% (1st trimester). FPR in the second trimester screening was 23.4%. FPR for integrated screening in this group was twice lower - 11.3%. For young pregnant women FPR was 2.9% comparing to 5.8% FPR after combining screening.

Conclusion. Integrated screening was the safest policy in the high risk pregnancies. Interpreting the second test but ignoring the first-trimester markers measurements leads to false risk estimation.

P03.03

An assessment of the use of interphase FISH in prenatal diagnosis

N. V. Shilova, T. V. Zolotukhina;

Research Centre for Medical Genetics of RAMS, Moscow, Russian Federation.

Interphase fluorescence *in situ* hybridization (FISH) with different DNA-probes has been provided more ability to perform chromosomal enumeration. In our study FISH with AneuVysion kit (Vysis, Abbott) was applied for detecting of more commonly aneuploidies in 67 (8,6%) from 779 cases of prenatal diagnosis after CVS. Interphase FISH analysis was carried out when absence or small amount of metaphases took place in semi-direct samples to avoid of repeated invasive procedure. Different aneuploidies were diagnosed correctly and rapidly by FISH in 14 fetuses with phenotypic abnormalities on ultrasound. In other 53 cases fetal aneuploidies were not detected by FISH analysis. In 49 of them fetuses did not have any ultrasound abnormalities and appeared normal at birth. Normal fetal karyotypes were confirmed by conventional cytogenetic analysis on cord blood lymphocytes in 2 cases with abnormal ultrasound screening (intrauterine growth retardation). There was spontaneous termination of pregnancy at 18-19 weeks gestation in one case with fetal cystic hygroma. In remainder case with

abnormal nuchal translucency (7mm) cordocentesis was performed and 46,XX,r(13)(p11q22) karyotype was detected by conventional cytogenetics. Obtained data suggest that FISH may be a satisfactory alternative test in women undergoing prenatal diagnosis because of advanced maternal age, abnormal maternal serum screening, a previous pregnancy with a trisomy 21 and parental anxiety when high quality ultrasound examination is provided. For the other indications, especially for fetal abnormalities, detected on ultrasound scan, it is necessary to follow FISH with conventional cytogenetics.

P03.04

Prenatal DNA Detection of Down Syndrome

K. Thilakavathy, R. Rosli;

Faculty of Medicine and Health Sciences, Universiti Putra Malaysia, Serdang, Malaysia.

It has been shown that fetal cells and circulating cell-free fetal DNA increases in the maternal circulation in women carrying Down syndrome fetus. The current technology in non-invasive screening methods of fetal aneuploidies is focused on detecting Y-chromosomal sequences which is not practical to be used for pregnancies involving female fetuses. Hence, it is vital to develop an assay that is universal for both male and female fetus pregnancies. We attempted the use of superoxide dismutase (SOD-1) gene, which is located at the Down Syndrome Critical Region, to overcome this situation for the prenatal detection of Down syndrome. The prospective of the gene using real-time quantitative polymerase chain reaction was explored. Our results show that the level of SOD-1 sequences is significantly elevated in the third trimester normal pregnancies (mean = 11728 copies/ μ l) when compared to the second trimester (mean = 5705.6 copies/ μ l), $p < 0.005$ and non-pregnant normal women (mean = 3580.2 copies/ μ l), $p < 0.0001$. Down syndrome pregnancies have the greatest elevation compared to all the three trimesters of normal singleton pregnancies and twin pregnancies, $p < 0.05$. These data indicate that a quantitative analysis using a gene associated with a disorder could be used in screening for the prenatal diagnosis of fetal aneuploidies regardless of the sex of the fetus.

P03.05

Chromosome 21-specific STR markers can effectively diagnose fetal Down syndrome: a comparison to traditional karyotyping

D. Chu¹, C. Yeh¹, J. Liou², J. Hsu²;

¹Chang Gung University, Tao-Yuan, Taiwan, ²Chang Gung Memorial Hospital, Taipei, Taiwan.

Short tandem repeats (STR) have been proposed to be useful in identifying chromosome aneuploidies. In this study, it was our goal to test the sensitivity and specificity of the combination of 3 chromosome 21-specific STR loci in rapid determination of the number of fetal chromosome 21 prenatally. Six hundred and two amniotic fluid samples from increased risk pregnancies (either with abnormal maternal serum screening results or with advanced maternal age) were analyzed. Specific primers with fluorescent dye labeled on the 5' ends were applied to PCR-amplify these three STR loci following denaturing polyacrylamide gel electrophoresis in a DNA sequencer. Data revealed that 588 amniotic fluid samples showed two chromosome 21s in the fetal cells. However, two of them with 3 chromosome 21s in the fetal cells. These data were 100% concordant to the fetal karyotyping results from the clinical cytogenetic laboratory. In conclusion, this protocol could provide a very rapid yet accurate detection of fetal Down syndrome, comparing to traditional chromosome karyotyping. It is especially useful for those late second trimester pregnancy women that if amniocentesis is pursued and confirmed fetal Down syndrome by karyotyping yet not able to meet the 24 week deadline for therapeutic abortion. This molecular approach could be their alternative for karyotyping.

P03.06

A comparison between first and second trimester pregnancy screening for Down Syndrome

G. Popescu¹, M. Bari^{1,2}, F. Nedelea¹, A. Stana^{1,3};

¹Filantropia Hospital, Bucharest, Romania, ²University "Carol Davila", Bucharest, Romania, ³University "Titu Maiorescu", Bucharest, Romania.

We wanted to ascertain which prenatal screening method should be used in practice to detect more cases of Down syndrome, with a lower false positive rates.

For this purpose, we made a retrospective study among the 570 sec-

ond trimester pregnant women and 104 first trimester pregnant women, which underwent triple/double test screening for Down syndrome. Estimating with Prisca 4.0 software: β -HCG, AFP and free-estriol values, obtained by chemiluminescent assay, it was selected a group of 115 second trimester pregnant women with elevated risk for Down syndrome. Among these women, 88 chose not to have amniocentesis. We analysed the outcome of children born by these women and we found a high rate of "false" positive results - about 20%. Of the 27 women with high risk which accepted amniocentesis, 26 cases presented normal fetal karyotypes and one showed a pseudomosaicism.

In contrast, first trimester screening, which means maternal serum PAPP-A and free-HCG measurements, combined with nuchal translucency thickness, showed a much lower "false" positive rates, for about 5%.

We concluded that first trimester screening is more effective than triple test screening in early detection of Down syndrome

P03.07

Implementation of a combined screening of aneuploidies

E. Martínez, L. Cardo, A. Benavides, I. Hernandez, F. Moreno, B. Prieto, F. Alvarez;

Hospital Central de Asturias, Oviedo, Spain.

Multiple strategies of chromosomal anomalies screening have been developed, aimed to reduce the number of invasive techniques.

The first trimester combined test has been widely considered as one of the most efficient approaches.

Objective: A retrospective observational study has been carried out in order to evaluate the first year of a multicentric screening program in Asturias.

Material and methods: 3630 pregnant women were screened, from 7 hospitals of Asturias. Maternal serum free B-hCG and PAPP-A concentrations were measured in our reference laboratory (HUCA), in a Delfia Xpress analyzer from Perkin Elmer (PE). Nuchal translucency measurement (NT) was performed at every hospital.

Results from genetic analysis in amniotic fluid as well as the outcome of the delivery were also registered in order to evaluate the efficiency. Results: 3630 women during the 9-13⁶ weeks of pregnancy participated in the screening (mean age 31.1 years, 23% older than 35 years). There were 9 Down syndrome cases. Combined screening detection rate was 66.7% (3.97% false positive); 56% of the amniocentesis corresponded to pregnant women older than 35 years, but only 29% were indicated for a positive screening result.

Conclusions: The screening program allowed us to offer a prenatal diagnosis to 77% of our pregnant women population, which is under 35 years old.

The false positive rate decreased from 14.2% (maternal age) to 4% (combined test).

Two main points of this program have to be highlighted: the total control of the pregnancy and the continuous optimization based on the multicenter collaboration

P03.08

Proteomic screening techniques used in maternal plasma reveal potential biomarkers for Trisomy 21 pregnancies.

W. E. Heywood¹, T. E. Madgett², A. Wallington², J. Hogg³, K. Mills¹, N. D.

Avenel, L. S. Chitty¹;

¹Institute of Child Health, London, United Kingdom, ²University of the West of England, Bristol, United Kingdom, ³University College Hospital, London, United Kingdom.

Objective: To use proteomic methods to search for biomarkers for trisomy 21 (T21) in maternal plasma.

Methods: Surface Enhanced Laser Desorption Ionisation Mass Spectrometry (SELDI) was used to compare gestationally aged matched maternal plasma samples from normal and T21 pregnancies to detect differentially expressed proteins optimally <30kDa. Analysis was performed using Q10 cation exchange arrays. Two Dimensional Difference Gel Electrophoresis (2D DiGE) which is optimal at screening for larger molecular weight proteins was performed at three expanded pH ranges.

Results: SELDI analysis demonstrated significant differences across gestational ages in normal pregnancies, and changes in T21 pregnancies. First trimester T21 samples showed a small peak at ~100kDa that was significantly elevated by 1.3 fold ($p = 0.00026$). Second trimester

T21 samples showed significant changes, with similarities to the protein profile of normal first trimester pregnancies. Two protein peak masses in the ranges 5-10kDa ($p=0.028$) and 20-25kDa ($p=0.004$) were more than 2 fold different. The 2D DIGE first trimester study revealed two spots in the 5.3-6.5 pH range, increased by 1.4 fold ($p=0.019$) and 1.2 fold ($p=0.017$). Analysis of second trimester samples showed two further significant spots in the 5.3-6.5 pH range and two in the 6-9 pH range ($p<0.05$).

Conclusions: Proteomic screening methods have revealed a potential first trimester marker for T21 and have demonstrated changes in the normal maternal plasma proteome related to gestational age which do not occur in T21 pregnancies. These proteins may be useful as biomarkers to improve on current screening for T21, reducing the need for invasive testing

P03.09

Fetal sex determination service using real time PCR and pyrophosphorolysis-activated polymerization on free fetal DNA

S. E. Tobí¹, H. B. Schlecht¹, J. A. Shorto¹, E. M. Boor², R. Elles¹;

¹National Genetics Reference Laboratory, Manchester, United Kingdom,

²Leiden University Medical Center, Leiden, The Netherlands.

Routine genetic prenatal diagnosis is currently based on an invasive sampling procedure, which carries a significant risk (1-2%) of fetal loss. Therefore, the possibility for non-invasive sampling has been pursued for several years particularly following the discovery of free fetal DNA (ffDNA) present in maternal plasma. Two techniques, Real Time PCR, that can detect very low levels of Y chromosomal sequence, and a new and highly specific PCR technique, pyrophosphorolysis-activated polymerisation (PAP), were validated for fetal sex determination using free fetal DNA (ffDNA) as a substrate (Prenat Diagn. 2007 27: 932-7). Both Real Time PCR and PAP can be used to detect the very low levels of Y chromosome DNA present in ffDNA during a male gestation and in combination offer more reliable early prenatal sexing. Using these two techniques combined a service for fetal sex determination from maternal blood is now offered in the NW Regional Molecular Genetics Laboratory, St Mary's Hospital, Manchester. In the 8 months that the service has been running 27 patients have been tested (9 male, 11 female and 7 fail). The predicted sex of the fetus was subsequently confirmed as correct in 8 of the 27 samples tested, and we are not aware that any of the remaining 12 results were incorrect. The failure rate is currently 15%, which is partly due to the strict test acceptance criteria we impose on this new service. The test acceptance criteria are that 4/4 PAP replicates and 7/8 Real Time Ct values must be in agreement.

P03.10

Introduction of MAQ technique for autosomal aneuploidies detection

R. Raynova¹, L. Heyrmar^{2,3}, S. Andonova^{1,4}, D. Goossens^{2,3}, J. Genova⁴, A. Jordanova^{1,2}, I. Kremensky^{1,4}, J. Del-Favero^{2,3};

¹National Genetic Laboratory, Sofia, Bulgaria, ²Applied Molecular Genomics Group, Department of Molecular Genetics, VIB, Antwerp, Belgium, ³University of Antwerp (UA), Antwerp, Belgium, ⁴Molecular Medicine Center, Sofia Medical University, Sofia, Bulgaria.

Multiplex Amplicon Quantification (MAQ) is a multiplex PCR based method for the detection and analysis of CNVs. The method consists of the simultaneous PCR amplification of several fluorescently labeled target and reference sequences. The comparison of normalized intensities between the test individual and control individuals results in a dosage quotient indicating the copy number of the target amplicon.

The Trisomy MAQ for the detection of autosomal aneuploidies contains 42 amplicons divided over 34 test amplicons: 7 on chromosome 21, 7 on chromosome 18, 8 on chromosome 13, 9 on X and 3 on Y chromosomes and 8 control amplicons. The MAQ assay was applied on 615 DNA samples derived from amniotic fluid or chorionic villi of which 535 samples had normal karyotypes and 80 samples had abnormal karyotypes. All investigated samples were previously diagnosed by STR based QF-PCR and cytogenetic analysis.

Genescan was performed on ABI 3700 DNA sequencer (Applied Biosystems) data was analyzed with MAQs software (www.vibgeneticservicefacility.be/index.htm?soft/maq.php).

The influence of the input DNA quality, concentration and solvents used for extraction on the efficiency of MAQ was estimated. The optimal concentration was found to be between 24 and 44 ng/µl.

The obtained results confirm that MAQ is highly sensitive technique that requires DNA samples of good purity and minimum concentration. MAQ's experimental setup solely consists of a standard (multiplex) PCR reaction followed by fluorescent fragment analysis, together resulting in a considerable reduction of labor and time.

P03.11

Reliability of results obtained using subtelomeric MLPA in prenatal samples. Our experience

J. Bruguera¹, I. Madrigal¹, L. Rodriguez-Revenga², N. Clusellas³, E. Margarit^{3,4}, A. Sánchez^{3,4}, A. Soler^{3,4};

¹Fundació Clínic per a la Recerca Biomèdica, Barcelona, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain, ³Servei de Bioquímica i Genètica Molecular. Hospital Clínic., Barcelona, Spain, ⁴IDIBAPS (Institut d'Investigació Biomèdica August Pi i Sunyer), Barcelona, Spain.

MLPA (Multiplex Ligation-dependent Probe Amplification) is a technique which allows to analyze large numbers of samples simultaneously and has proven to be accurate for identifying deletions, duplications, and amplifications in several diseases and for the screening of subtelomeric rearrangements. The aim of our study is the diagnosis and characterization of cryptic subtelomeric chromosomal abnormalities in a series of pregnancies in which ultrasound examination discloses major fetal malformations, using a specific set of probes for subtelomeric chromosomal imbalances, SALSA P036B,D human telomere kit (MRC-Holland). It was performed on fetal DNA obtained from cultured amniocytes. To exclude false positives we use the complementary kit P070 (MRC-Holland). We have collected 173 amniotic fluid samples from pregnancies in which fetuses present different phenotype abnormalities and show a normal karyotype. Investigation revealed 23 cases that presented subtelomeric imbalances. These submicroscopic chromosomal anomalies include deletions and/or duplications of several chromosomes. Tests performed with both kits gave 3 confirmed imbalances (3pter deletion, 13qter duplication plus 20pter deletion) and 21 discordant results. These controversial results may be due to different reasons. Some P036 imbalances have been previously reported as polymorphisms. Another reason is that P036 and P070 kits contain different probes and some imbalances are located very close to the telomere region so the P070 kit does not confirm the results and FISH is not enough sensible to detect them. These discordant results need more accurate techniques for confirming some subtelomeric imbalances.

Supported by the grant PI05/0096 to A.S. from F.I.S., Ministerio de Sanidad y Consumo, Spain.

P03.12

Multi-colour FISH in 17 minutes: Towards 24 chromosome aneuploidy screening in under 24 hours

D. Ioannou¹, M. Vetter¹, L. Thomas¹, K. Finch², A. Abogrein¹, A. R. Thornhill¹, A. H. Handyside², D. K. Griffin¹;

¹University of Kent, Canterbury, United Kingdom, ²The London Bridge Fertility, Gynaecology and Genetics Centre, London, United Kingdom.

Preimplantation genetic screening (PGS) for chromosomal aneuploidy has become widespread for women of advanced maternal age in recent years. The 'gold standard' technique (multicolour fluorescence in situ hybridisation (FISH) to identify up to 12 specific chromosomes after multiple rounds of hybridization) has received criticism owing to the possibility of false positives and the possible omission of key chromosomes not included. Any successful PGS test needs to be quick, simple, cheap and accurate. We describe preliminary results using fast FISH to simultaneously screen multiple chromosomes in lymphocytes as a prelude for clinical application. 5 colour FISH was achieved in only 17 minutes from slide preparation to final post-hybridization wash (including a 5 minute hybridisation time). In the initial experiments, probes for X, Y, 15, 17 and 20 have been successfully applied to control lymphocytes. In a second set of experiments, four hitherto poorly studied chromosomes (1, 8, 11 and 17) in human embryos and sperm were analysed. Finally we have applied 4 sequential layers of probes (14 probes in total) in approximately 7 hours. Despite moves to develop microarray approaches to simultaneously analyse 24 chromosomes conventional FISH analysis should still be useful for single cell diagnosis and will certainly be useful on a per cell basis for any 'abnormal' embryos to confirm the single cell diagnosis.

P03.13

Inconsistent findings between QF-PCR and karyotype analysis for the prenatal diagnosis of common trisomies in amniocentesis

S. Y. Park¹, D. J. Kim¹, M. H. Lee¹, B. Y. Lee¹, J. Y. Park¹, H. M. Ryu², J. Y. Han²;

¹Laboratory of medical genetics, Medical research institution, Cheil general hospital and women's healthcare center, Kwandong university School of medicine, Seoul, Republic of Korea, ²Department of Obstetrics and Gynecology, Cheil general hospital and women's healthcare center, Kwandong university School of medicine, Seoul, Republic of Korea.

We report an amniocentesis case of discrepant results between QF-PCR and karyotype analysis in the prenatal diagnosis of trisomy 18 and 21. The result of rapid QF-PCR analysis from uncultured amniotic fluid cells indicated double autosomal aneuploidy for chromosome 18 and 21. However, subsequent cytogenetic analysis from the in situ cultures showed only trisomy 21 karyotype with no evidence of mosaicism. Follow-up studies were performed on the repeated amniocentesis, fetal cord blood and placental tissue after termination of the pregnancy. QF-PCR and karyotype results showed trisomy 21 from all samples. For chromosome 18, both QF-PCR and karyotyping from placental tissue revealed a normal disomic chromosome 18. Cord blood and repeated amniotic fluid cells indicated the aneuploidy of chromosome 18 in QF-PCR, but normal disomy 18 with no evidence of mosaicism in karyotyping. We supposed that this inconsistent finding was the result of duplication of the paternal chromosome 18 in mitosis after the loss of the homologous maternal chromosome 18 at an early postzygotic stage.

P03.14

QF-PCR on native chorionic villous for false positive and negative detection is a useful tool in fetal karyotyping by direct method

F. R. Grati, B. Grimi, B. Malvestiti, F. Dulcetti, G. Frascoli, S. De Toffol, A. M. Di Mecco, A. M. Ruggeri, R. Liuti, S. Milani, A. Trotta, F. Maggi, G. Simoni; Research and Development, Cytogenetics and Molecular Biology, TOMA Laboratory, Busto Arsizio, Italy.

The prenatal diagnosis (PD) on chorionic villi (CV) more reliable for the identification of fetal karyotype combines the cytotrophoblast (direct method, STC) and mesenchyme (long term culture, LTC) analyses. However, when the sample available is poor (5-10mg) the diagnosis is generally performed liking better for the direct method in order to avoid the maternal cell contamination. This condition is associated with a higher false negative risk. In our 7 years experience on 24'237 CV prenatal diagnosis, we recognised 18 cases of type V True Fetal Mosaicism (TFM) that, if they have been analysed only with STC they would have been subject to a false negative result. The abnormality found in mesenchyme of 17/18 was an aneuploidy for chromosomes 13,18,21,X,Y. In 11 of them the abnormal cell line was present in a homogeneous form, hence, possibly recognizable by QF-PCR. On these basis we performed a study to calculate in our survey the false positive and negative risk if PD would have been performed only with direct method and to evaluate in 267 poor samples (5-10mg) if QF-PCR on a minor fragment allows detection of false positive and negative cases. We evidenced 1 false negative and 2 false positive cases and in 14 instances the abnormality found in cytotrophoblast was confirmed by QF-PCR. In conclusion, QF-PCR could be an additional useful tool, which doesn't jeopardize the result of direct method, to decrease the false negative risk from 1/1136 to 1/2941.

P03.15

Rapid prenatal diagnosis of aneuploidies by QF-PCR: evaluation of large scale clinical application

V. Cirigliano^{1,2}, G. Voglino³, E. Ordoñez^{1,2}, A. Plaja⁴, C. Fuster⁵, M. Adinolfi⁵;

¹Dept. Genetica Molecular, General Lab, Barcelona, Spain, ²Departament de Biologia Cel·lular, Universitat Autònoma de Barcelona, Barcelona, Spain,

³Molecular Genetics and Cytogenetics Lab. Promea-Day Surgery, Torino, Italy,

⁴Dept. Genetica, General Lab, Barcelona, Spain, ⁵University College London, London, United Kingdom.

Introduction: Recently it has been shown that rapid QF-PCR can detect the great majority of chromosome abnormalities in prenatal samples despite being deliberately targeted to chromosomes 21, 18, 13, X and Y. Main advantages of the assay are low cost, speed and automation

allowing large scale application.

Methods: We developed a QF-PCR assay that has been applied on 38.000 clinical samples. Most frequent indications were increased biochemical risk (32%) and advanced maternal age (30%), 6% of these cases were also associated with increased nuchal translucency; parental anxiety and abnormal ultrasound were present in 22% and 7% of samples respectively. Cytogenetic analysis was performed in all cases and results compared.

Results: All 1278 non mosaic aneuploidies involving chromosomes 21, 18, 13 X and Y were detected with 100% sensitivity and specificity; several cases of mosaicism and partial trisomies were also identified. QF-PCR detected 95% of clinically significant abnormalities diagnosed by cytogenetic analysis in samples referred for abnormal ultrasound. Affected pregnancies could be terminated without further waiting for completion of fetal karyotype

Conclusions: Large scale application of QF-PCR could reduce the load of prenatal cytogenetics if all pregnancies are carefully monitored by non invasive methods. In cases of negative QF-PCR results cytogenetic analyses might only be performed for fetuses with abnormal ultrasound; affected pregnancies identified by QF-PCR can be terminated in a few hours from sampling. In countries where large scale cytogenetics is hampered by its cost and lack of technical expertise QF-PCR may be used as the only prenatal diagnostic test.

P03.16

Prenatal diagnosis of trisomy 21 by real-time PCR on fetal DNA from amniotic fluid

T. Gunel¹, K. Şahin¹, I. Kalelioglu², R. Has², H. Ermis², K. Aydinli²;

¹Istanbul University, Faculty of Science, Department of Molecular Biology and Genetics, Istanbul, Turkey, ²Istanbul University, Faculty of Medicine, Istanbul, Turkey, ³Istanbul University, Cerrahpaşa Faculty of Medicine, Istanbul, Turkey.

Trisomy 21 is the most common congenital anomaly. A region called Down Syndrome Critical Region (DSCR), extending from DNA marker D21S55 on chromosome 21, is critical for Down syndrome phenotype such as morphological features, hypotonia and mental retardation. Recently, there have been major advances performing in the screening and prenatal diagnosis of Down Syndrome. With the advent of real-time PCR, it is now possible to measure the nucleic acid concentrations with high accuracy. This study was undertaken to establish a rapid prenatal diagnosis of trisomy 21 using real-time PCR of fetal DNA from amniotic fluid. Fetal DNA's from the amniotic fluid of a mother expecting a baby with regular trisomy 21 and 9 mothers at high risk for regular trisomy 21 were isolated. Real-time PCR technique was used to measure the dosage of *DSCR3* gene. The amplification plots of 40 cycles for each sample was determined by the real-time PCR using fetal DNA's from the amniotic fluid. C_t ("cycle threshold": the PCR cycle number at which a significant increase in the components of the reaction is first detected) values for each sample were obtained and the average C_t values were calculated. The *DSCR3* and *GAPDH* gene dosage were statistically determined and a comparison was made between the results of the risk group and the one with regular trisomy 21. The real-time PCR results showed the *DSCR3* gene dosage of one of 9 samples from the risk group was higher than the one with regular trisomy 21.

P03.17

Introducing new methods in prenatal diagnosis can do harm more than good. The need for a national strategy

I. A. Dhalfalah, V. Curtisova, J. Santavy;

Palacky universtij, Olomouc, Czech Republic.

Screening programs (SP) is indispensable part of health care systems in many countries. During the past 50 years new SP are becoming available. The innovation in this filed have been transformed into applicable medical strategies and procedures with great benefits for patients. Approval of a test obligates its use. Missing guidelines and legitimate to identify centers and laboratories performing the SP have lead to more harm than good in some places.

There is an increasing need for a single national body which provides authoritative, objective decisions on whether, and under what circumstances new SP or diagnostic tests should be made available. Country's health system care, culture, demography and resources should be evaluated. Approval of a test should be accompanied by how the test might most efficiently be provided and when outdated tests can

be withdrawn.

Czech Republic have an old tradition in the field of prenatal screening programs with the first amniocentesis at 1971. Women aged 40 and than of 35 was the indications tell the late 80s. when the triple test have been introduced. Regular and detailed registration started at 1985. In the year 1990 the number of invasive testes were 3 % for about 20% detection rate for Down syndrome and 20 % other chromosomal abnormalities, in 1998 and 2006 it was 10% for 60 % and 18% for 80% respectively.

From this point of view a short description of the effect of implementing the new SP on our center and that over the country will be presented.

P03.18

Proteomic analysis of amniotic fluid in pregnancies with Turner and Klinefelter Syndrome fetuses

A. Kolialexi¹, A. Anagnostopoulos², G. Tsangaris², K. Vougas², N. Papantoniou³, V. Bagiokos¹, A. Antsaklis², A. Mavrou¹;

¹Medical Genetics, Athens University, Athens, Greece, ²Proteomics Research Unit, Centre of Basic Research II, Biomedical Research Foundation of the Academy of Athens, Athens, Greece, ³1st Department of Obstetrics & Gynecology, Athens University School of Medicine, Athens, Greece.

Objectives: To determine the protein composition of amniotic fluid coming from pregnancies with normal, Turner and Klinefelter syndrome fetuses.

Material & Methods: Proteomic analysis was performed in stored amniotic fluid samples of eighteen 2nd trimester pregnancies. In five cases routine cytogenetic analysis had shown that the fetus had Turner syndrome, in four Klinefelter syndrome and in nine cases the fetal karyotype was normal (5 females and 4 males). Samples were analysed by Two-Dimensional Gel Electrophoresis (2DE), coupled with Matrix-Assisted Laser Desorption/ Ionization Time of Flight Mass Spectrometry (MALDI-TOF-MS). Selected proteins were further evaluated by Western blotting.

Results: As compared to controls TRFE, LUM, RETBP and ApoA1 were significantly increased in Turner syndrome cases, whereas KNG1, THBR and ApoA4 were decreased.

Four proteins (Apo A1, ZINCA2, LUM and A1AG) were found to be up-regulated in samples obtained from pregnancies with Klinefelter syndrome fetuses and three (RETBP, A1AT and VDBP) were down regulated.

Conclusions: Different sets of proteins were differentially expressed in the various sex chromosome abnormalities. Since these proteins are likely to cross the placenta and be detected in maternal plasma, if the specificity of our results is verified, they may be used as biomarkers for the noninvasive prenatal diagnosis of sex chromosome aneuploidies.

P03.19

Noninvasive prenatal diagnosis of fetal trisomy

F. Crea¹, W. M. Puszyk¹, V. Cirigliano², M. A. Hulten³, M. Vatish³, R. W. Old¹;

¹University of Warwick Department of Biological Sciences, Coventry, United Kingdom, ²General Lab, Genetica Molecular, Barcelona, Spain, ³University of Warwick Medical School, Coventry, United Kingdom.

The discovery of fetal DNA as a small component of cell-free DNA in the maternal blood circulation has driven developments in non-invasive prenatal diagnosis (NIPD) for the past decade. Interest has focused upon NIPD of fetal trisomy 21, Down syndrome. We have explored DNA regions on human chromosome 21 with the aim of identifying DNA regions that are differentially methylated between adult leukocytes and placenta. These two tissues represent a model system for cell-free fetal and cell-free maternal DNA, respectively, in the blood plasma of pregnant women. Among 46 DNA regions analysed in this model system, a single differentially methylated region located in the *AIRE* gene promoter, was identified. Further analysis of the methylation of this DNA in the blood plasma of pregnant women indicated that its placental epigenetic signature was not consistently maintained in cell-free fetal DNA. The inconsistency exposes an apparent limitation of the adult leukocyte/placenta model system as a means of discovering epigenetic DNA biomarkers for use in the NIPD of fetal aneuploidies. Our data indicate that more direct strategies are required, using cell-free plasma DNA.

P03.20

Optimization of blood collection, fetal DNA isolation, concentration and analysis of fetal DNA present in maternal blood

G. Minarik^{1,2}, B. Vlkova², T. Szemes^{1,2}, P. Celec^{1,3};

¹Comenius University in Bratislava Faculty of Natural Sciences, Department of Molecular Biology, Bratislava, Slovakia, ²Geneton s.r.o., Bratislava, Slovakia,

³Comenius University in Bratislava Faculty of Medicine, Institute of Pathological Physiology, Bratislava, Slovakia.

Invasive methods currently used in prenatal genetic diagnostics represent a not negligible risk for the health of both the subjected pregnant woman and fetus. Not surprisingly, the detection and analysis of fetal DNA in maternal plasma, representing a non-invasive alternative, attracted much attention in the past few years. In our study, we focused on comparing protocols for blood collection, isolation, concentration and detection of fetal DNA present in maternal plasma of pregnant women at various phases of pregnancy. We analyzed effects of addition or omission of 4% formaldehyde solution during blood collection and surveyed the implementation of DNA concentration after isolation procedure using either ethanol precipitation or vacuum concentration. We screened for presence of Y-chromosome specific sequences employing three different methods. Two were based on qPCR (one designed in our laboratory, one with commercial system specifically used for identification and quantification of degraded human DNA sequences) and one was based on PCR and fragment analysis of amelogenin loci on automated genetic analyzer. We have successfully prepared fetal DNA suitable for reliable qPCR and PCR analysis of Y-chromosomal sequences with all three tested detection systems. The comparison of the collection, isolation, purification and concentration approaches as well as detection methods can be observed in detail on our poster presentation.

P03.21

Early first trimester detection of fetal cells and DNA in maternal blood

E. Guetta¹, L. Gutstein-Abo^{1,2}, A. Tulchinsky^{1,2}, M. Baum³, A. Hourvitz³, G. Barkai^{1,2};

¹Danek Gertner Institute of Human Genetics, Sheba Medical Center, Tel-Hashomer, Israel, ²Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel, ³IVF Unit, Department of Obstetrics and Gynecology, Sheba Medical Center, Tel-Hashomer, Israel, ⁴Department of Obstetrics and Gynecology, Sheba Medical Center, Tel-Hashomer, Israel.

Detection of Y-chromosome sequences in fetal cell-free DNA or cells from maternal blood are useful tools in non-invasive prenatal diagnosis that have evolved into a fetal gender test feasible at earlier pregnancy stages compared to ultra-sound screening.

The goal of this study was to determine the earliest possible time-point for trophoblast and fetal cell-free DNA detection and determination of fetal sex as a model for comprehensive prenatal diagnosis. Maternal blood samples were collected from IVF patients at 2, 3 and 4 weeks post-implantation. Fetal sex was determined in cells with FISH probes following magnetic sorting with HLA-G, a trophoblast marker. Y-chromosome SRY sequences were detected in cell-free plasma DNA with real-time PCR. The results were compared with the newborn gender. Fetal sex was accurately determined in cell-free DNA in 12/16 (85%) of the samples, with 2 false-positive and 2 false-negative results. Trophoblast testing yielded 8/15 (53%) accurate fetal gender determination with 4 false-positive and 3 false-negative results. False-positive results probably reflect the presence of a non-developing male embryo as evidenced in one sample in which this explanation was supported by PGD analysis.

The IVF samples yielded less accurate results compared with our ongoing study of late 1st trimester samples (weeks 7-13, parallel to 5-11 weeks post-implantation) in which 98% accuracy of fetal sex determination was achieved with cell-free fetal DNA and trophoblast methods. The uniqueness of the sample group - IVF patients - in which multiple embryos are usually implanted, and the early stage of pregnancy, can explain this discrepancy.

P03.22**Contamination-free analysis of single cells in cell-based non-invasive prenatal diagnosis**

T. Kroneis¹, J. B. Geig², J. Waldispuehl-Geig², M. Alunni-Fabroni³, E. Petek², W. Walcher⁴, G. Dohr¹, P. Sedlmayr¹;

¹Institute of Cell Biology, Histology and Embryology, Medical University, Graz, Austria, ²Institute of Human Genetics, Medical University, Graz, Austria, ³Olympus Life Science Research Europa, Munich, Germany, ⁴University Clinic of Obstetrics and Gynaecology, Medical University, Graz, Austria.

Analysis of very rare cells, as this is true for non-invasive prenatal diagnosis (NIPD) based upon fetal cells circulating in the peripheral blood of pregnant women present a formidable challenge in respect of the need for non-ambiguous data. Currently used marker lack the potential to exclusively discriminate fetal from maternal cells due to unspecific staining, lack of fetal specificity, or low signal intensity. Thus, pooling of fetal cells to enhance analysis efficiency in subsequent molecular genetic analysis may give ambiguous data due to contamination with maternal cells.

To circumvent maternal contamination while using the advantage of pooling cells to increase analysis significance we are working on a procedure to define a Post Identification Pool (PIP). The rationale is to use markers with inherently limited specificity to (semi-automatically) detect fetal candidate cells that are laser-microdissected and forwarded to single cell whole genome amplification (scWGA). Aliquots of the latter are then analysed by means of DNA fingerprinting using fluorescent multiplex PCR. ScWGA products whose DNA profiles differ from the maternal control sample are then pooled for further analysis.

Single fetal and maternal cells derived from one and the same intertubular material were subjected to PowerPlex 16 System® proofing the DNA fingerprinting to be sufficient for discriminating fetal from maternal cells. Currently a modified 16-fold multiplex is being set up to perform DNA fingerprinting on pre-amplified (scWGA) single cells to implement the PIP procedure.

P03.23**Clinical practice of the incorporation of the non-invasive fetal gender assessment in maternal blood**

A. Bustamante Aragonés, M. Rodríguez de Alba, I. Lorda-Sánchez, M. Trujillo-Tiebas, M. García-Hoyos, A. Avila-Fernandez, C. Ayuso, R. Carmen; Fundación Jimenez Diaz-Capio, CIBERER, Madrid, Spain.

Prenatal diagnosis is currently recommended to those pregnancies at risk of an X-linked disorder however the invasive obstetric procedures required entail a risk of miscarriage. Early fetal sex determination in maternal blood can avoid the need for conventional PD in a half of these cases. A previous large-scale validation study performed in our laboratory concluded that this methodology was 100% accurate from the 7th week of gestation.

After incorporating this analysis into the clinical routine we have diagnosed a total of 32 pregnancies at risk of an X-linked disorder including cases of Haemophilia, Duchenne Muscular Dystrophy, Norrie Disease... Two plasma samples were collected from each pregnant woman in the first trimester of gestation: one from the 7th week of gestation and another from the 9th week. Fetal gender was determined by the presence/absence criteria of the SRY gene by Real-Time PCR.

Conventional prenatal diagnosis, ultrasound scan or gender at birth confirmed that fetal sex was correctly diagnosed in maternal blood in all cases. Early diagnosis of fetal sex in maternal blood represents a great advantage for pregnancies at risk of an X-linked disease because invasive prenatal diagnosis is suppressed in a half of the cases. Since this diagnosis is performed before the 12th week of gestation, chorion villus sampling can be done in the case is required.

P03.24**Non invasive prenatal detection of two RHD gene exons and fetal sex using cell free fetal DNA in maternal plasma**

E. Ordoñez^{1,2}, L. Rueda^{1,2}, M. Lozano^{1,3}, P. Cañadas¹, C. Fuster², V. Cirigliano^{1,2};

¹General Lab, Barcelona, Spain, ²Departament de Biologia Cel·lular, Universitat Autònoma de Barcelona, Barcelona, Spain, ³Institut Universitari Dexeus, Barcelona, Spain.

Cell free fetal DNA (cffDNA) detection by Real-time PCR is routinely applied for non-invasive genotyping of the fetal RhD status in reference laboratories. The assay is easy to automate allowing high throughput.

We developed a new rtPCR for non-invasive prenatal RHD genotyping and fetal sex determination using maternal plasma.

Two Taqman MGB-probes and primers were designed to develop a Multiplex rtPCR for simultaneous amplification of exons 5 and 7 on RHD gene. The multicopy DYS14 sequence on the Y chromosome was also included in the assay. The test was evaluated blind on 50 coded plasma samples of known fetal genotype obtained from RhD negative pregnant women, archived in our lab at -20°C° over the last two years.

DYS14 products were detected in all 28 samples from male fetuses; both RHD exons 5 and 7 were detected in 39 samples (23 males and 16 females). No false positive were observed. Absence of all three products indicating female RhD negative fetuses was observed in 6 cases. Fetal sexing results were 100% concordant, only in one sample RhD exons failed to amplify resulting in an RhD negative female fetus.

Even in old archived plasma samples multiplex rtPCR detection of cffDNA was efficient and reliable allowing the assessment of fetal sex in all cases. Only one sample from a RhD⁺ female fetus was genotyped as RhD⁻ probably because of cffDNA degradation derived from repeated thaw freezing cycles of the original plasma. The procedure proved to be sensitive enough to be applied on clinical cases.

P03.25**Simple and fast isolation of cell-free circulating DNA from human plasma and serum**

M. Meusel, C. Kirsch, G. Gutzke;

Macherey-Nagel, Dueren, Germany.

The discovery of cell-free circulating DNA in plasma opened up interesting possibilities for noninvasive prenatal diagnosis as an alternative to established invasive genetic screening procedures such as amniocentesis and chorionic villus sampling. However, the isolation of circulating DNA from plasma or serum is challenging. Circulating DNA is highly fragmented and of very low concentration. Thus, established nucleic acid purification protocols and ready-to-use kits have only a very limited suitability for the extraction and purification of circulating DNA. To overcome these limitations we developed the *NucleoSpin Plasma XS* kit specially designed for the isolation of fragmented DNA ≥ 50 bp from human EDTA blood plasma. The kit exploits the benefits of a unique binding column with a minimised dead volume and allows for elution in 5-20 μ l. Using up to 240 μ l plasma the kit offers an easy and convenient way for efficient purification of circulating DNA from plasma. Data from kit development as well as application data, e.g., from fetal Rhesus D typing will be presented.

Besides prenatal genetic testing cell-free circulating DNA promises to be applicable for the screening and assessment of a variety of pathological findings such as cancer, stroke, myocardial infarction, inflammation or trauma. The use of the *NucleoSpin Plasma XS* kit for these applications will be exemplified.

P03.26**Update of ESHRE PGD Consortium Activities**

A. R. Thornhill;

The London Bridge Fertility, Gynaecology and Genetics Centre, London, United Kingdom.

Since 1997, the European Society of Human Reproduction and Embryology (ESHRE) Preimplantation Genetics Diagnosis (PGD) Consortium has collected technical and outcome data, provided referral networks, surveyed and promoted best practice. Membership increases steadily (n=91) with increasing numbers of centres reporting (16-45) and cycles reported (392-3358) between reports 1 and 7. During this time, reported cycle numbers for constitutional chromosome abnormalities and monogenic disorders have increased with disproportionately larger increases in preimplantation genetic screening (PGS) cycles reflecting the increasing tendency for IVF laboratories to select the 'best' embryo for transfer by elimination of chromosomally abnormal embryos. Methodologies for every technical aspects of PGD are becoming more sophisticated, accurate and reliable ensuring extremely low misdiagnosis rates. PGD babies are comparable to those derived from IVF with intracytoplasmic sperm injection procedures with respect to pregnancy complications and congenital malformation. The main complication, as with routine IVF, remains the risk of multiple pregnancy and concomitant higher morbidity and mortality.

The Consortium has published best practice guidelines for PGD and PGS and recently, a joint report with the European Society for Human Genetics (ESHG) broadly examining the interface between genetics and assisted reproductive technology. To further improve preimplantation testing, studies are ongoing to investigate PGD laboratory accreditation, appropriate external quality assessment, EQAS (multicentric evaluation of captured FISH images from single embryonic nuclei) and measures to facilitate real-time reporting of misdiagnoses and development of preventative action to reduce the risk of recurrence. Survey data regarding misdiagnosis, EQAS and confirmation of diagnosis on embryos will be shared.

P03.27

Preimplantation Genetic Diagnosis (PGD) for Genetic and Metabolic Disorders-The Saudi Experience

A. I. Al-Aqeel¹, W. Quabash², S. Coskur²;

¹Riyadh Military Hospital/ King Faisal Specialist Hospital, Riyadh, Saudi Arabia,

²King Faisal Specialist Hospital, Riyadh, Saudi Arabia.

Saudi Arabian culture is highly consanguineous, with the first cousin marriages accounting for 60-70% of all marriages. Given the difficulties in management of genetic disorders, reproductive option for families affected with genetic diseases in Saudi Arabia is often limited to PGD which is permissible under the law and religion whereas prenatal diagnosis with the intent of termination of pregnancy is neither widely practiced nor socially accepted, although it is accepted under certain conditions.

KFSH&RC has been offering PGD for monogenic and chromosomal disorders, since 2001. A total of 45 pregnancies initiated. Of which, 25 healthy babies were born, 13 pregnancies are ongoing and 7 pregnancies were either biochemical or ended up with abortion.

In all these families PGD was undertaken using fluorescent PCR (F-PCR) and/or nested PCR with sequencing on a single cell, or Multiple Displacement Modification (MDA) to amplify the whole genome from a single cell. A singleton pregnancy ensure after transfer of one heterozygous and one/or normal embryo and prenatal diagnosis by CVS confirmed a normal pregnancy. This is the first report of successful PGD in different genetic disorders in Saudi Arabia, and the Muslim world.

P03.28

Preimplantation Genetic Haplotyping for Duchenne/Becker muscular dystrophy-birth of first male babies

P. J. Renwick, J. Trussler, A. Lashwood, P. Braude, C. Ogilvie;

PGD Centre, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom.

Preimplantation Genetic Diagnosis for sex-linked disorders undertaken by sexing embryos is contentious as approximately 50% of the male embryos discarded will be free of the mutation. Direct diagnosis of dystrophin mutations is technically challenging due to heterogeneous mutations and recombination hotspots. Since January 2006, we have offered an alternative approach for Duchenne/Becker muscular dystrophy (D/BMD) using Preimplantation Genetic Haplotyping (PGH). The first 10 cases (9 DMD + 1 BMD) are presented with follow-up to February 2008. In this cohort, 7 of the carrier females had different exonic deletions, whilst 3 had different point/micro mutations, including a germline mosaic. 15 microsatellite markers spanning the gene were used, alongside 5 Y-chromosome markers to detect possible sex chromosome aneuploidy.

57 embryos were biopsied with 50 diagnosed (88%) and 32 (56%) suitable for transfer. The multiple displacement amplification (MDA) used in PGH had a significantly lower ($p < 0.0001$) allele drop out in male (23.1%) than in female (38.8%) embryos (average 29.9%). 11% recombination was observed but the density of markers allowed accurate location of the cross-over relative to mutation positions. All 10 cycles achieved embryo transfer with a 70% pregnancy rate and 50% clinical pregnancy rate resulting in 5 deliveries of 3 normal females, 1 carrier female and 2 normal males.

This successful PGH approach to X-linked disease is also being applied to Alport's syndrome, Haemophilia A and B, Fragile X, Adrenoleucodystrophy and Hydrocephalus.

P03.29

A new mutation in the AFP gene responsible for a total absence of alpha fetoprotein on 2nd-trimester maternal serum screening for Down syndrome

F. M. Petit, M. Hébert, O. Picone, S. Brisset, M. Maurin, F. Parisot, L. Capel, C. Benattar, M. Sénat, G. Tachdjian, P. Labrune;

Antoine Béclère hospital, Clamart, France.

Introduction

Alpha fetoprotein (AFP) is a major plasma protein produced by the yolk sac and the liver during the foetal period. During the 2nd-trimester of pregnancy, AFP combined with β hCG are commonly used for Down syndrome risk evaluation. Deficiency of AFP is a rare phenomenon (estimated to occur in 1/105000 newborns) and only one sequence alteration in AFP gene was reported. Here we report a new mutation in exon 5 of the foetal AFP gene leading to a total absence of AFP on 2nd-trimester maternal serum screening for Down syndrome, confirmed on the amniotic fluid. Despite this, foetal development and birth were normal.

Methods

After PCR-amplification, the whole AFP gene was sequenced. To determine the amniotic fluid profile, proteins were separated by electrophoresis and compared with 10 normal amniotic fluids sampled at the same gestational age (18 weeks).

Results

The new mutation observed was a guanine to adenine transition in position 543 creating a premature stop codon in position 181. A new SNP was characterised in the exon 12 (c.1641A>G). Albumin rate in the amniotic fluid was reduced compared to controls, whereas alpha1 and beta protein fractions were increased.

Discussion - Conclusion

The c.543G>A mutation is the second sequence modification identified so far in the AFP gene, responsible for its complete deficiency. Electrophoresis results suggest that deficiency may modify protein fraction repartition, particularly albumin, alpha1 and beta fractions suggesting complex molecular mechanisms of compensation. Studies on other families with AFP deficiency are necessary to confirm this observation.

P03.30

The evaluation of chromosomal abnormalities diagnosed prenatally in Cluj-Napoca, Romania

M. S. Militaru, R. A. Popp, A. Trifa, M. Militaru, F. Stamatiu;

University of Medicine and Pharmacy, Cluj-Napoca, Romania.

Prenatal diagnosis for chromosomal disorders is performed routinely in populations since most of these disorders have severe consequences such as major malformations and mental retardation. Since advanced technologies in rapid diagnostic tests have been developed to detect common trisomies prenatally it is essential that each laboratory should evaluate their own prenatal diagnosis profile. In this study we aimed to investigate the type and proportion of chromosomal abnormalities detected in cytogenetic studies prenatally and referral indications in 684 pregnant cases in Cluj-Napoca, Romania between the period of 2002-2007. The overall chromosomal abnormality rate was found to be 49/684 (7.16%). The cytogenetic analysis with GTG banding of amniotic fluid cells revealed: trisomy 21 (12 cases), trisomy 18 (7 cases), monosomy X (6 cases), trisomy 16 (1 case), trisomy 8 (1 case), trisomy 15 (1 case), Robertsonian translocations (2 cases), Klinefelter syndrome (3 cases), autosomal deletions (3 cases), autosomal monosomy (2 cases), polyploidy (3 cases), chromosome marker (6 cases), trisomy X (1 case), Fra 5q31 (1 case). Careful genetic counseling by expert geneticists regarding the patients indications is essential for determining the cost-effective prenatal diagnostic test for each patient.

P03.31

Prenatal expression of Baraitser-Winter syndrome

G. Morin¹, R. Goubet¹, E. Gailly¹, M. Mathieu¹, B. Delaby², S. Lanta², P. Naevels², A. Verloes³, J. Gondry²;

¹Unité de Génétique Clinique, Amiens, France, ²Centre de Diagnostic Prénatal, Amiens, France, ³Département de Génétique - Hôpital Robert Debré, Paris, France.

Baraitser-Winter syndrome was first reported by these two authors in 1988 in a brother and a sister, and a girl unrelated to the two others. The three patients had iris coloboma, hypertelorism, ptosis, mental re-

tardation, large nasal root, and epicanthus. Two similar observations with pericentric inversion of chromosome 2 were reported. In 1995, the possibility of gyration abnormalities and trigonocephaly was noticed. Due to the initial familial observation, an autosomal recessive mode of inheritance was suggested.

We report the observation of a young boy, presenting with this condition. His prenatal history was marked by hygroma colli with normal karyotype, persisting along the pregnancy, associated from the second trimester with renal dilatation and intestinal hyperechogenicity. At birth, Noonan syndrome was first considered. *PTPN11* analysis was performed but negative. At the age of 4, due to suggestive dysmorphic features, the diagnostic of Baraitser-Winter syndrome was made. However the patient had no iris coloboma or gyration abnormality. We discuss the similarities with Noonan syndrome, even during the prenatal period.

P03.32

Prenatal detection and molecular characterisation of two supernumerary marker chromosomes (SMC) derivatives of chromosome 22 in two unrelated patients.

S. Andreu¹, M. Jodar¹, G. Arnedo¹, O. Villa^{2,3}, B. Perez⁴, R. Villanueva⁵, N. Kosyakova⁶, L. Pérez Jurado^{2,3}, C. Fuster⁷, A. Escalona^{1,7};

¹Analisis MDB. Lab Duran Bellido, Barcelona, Spain, ²Unitat de Genètica. Universitat Pompeu Fabra, Barcelona, Spain, ³Center for Biomedical Research on Rare Diseases (CIBERER), Barcelona, Spain, ⁴Centre de Ginecologia i Reproducció, Barcelona, Spain, ⁵Centro Médico Augusta, Barcelona, Spain, ⁶Institut für Humangenetik und Anthropologie, Jena, Germany, ⁷Unitat de Biologia Cel·lular i Genètica Mèdica. Facultat Medicina. Universitat Autònoma de Barcelona, Barcelona, Spain.

SMC are 'additional markers' whose origin and composition cannot be determined by conventional cytogenetics. Genetic counseling of patients with SMC can be difficult, especially in prenatal testing, due to the complexity in establishing a karyotype-phenotype correlation. In fact, it has been estimated that about 37% of prenatal diagnosed SMC are associated with an abnormal phenotype. We report two cases of prenatal diagnosed SMC, detected by G-banding and completed by C-banding and NOR-staining. In the first case, the marker was familial, segregating from a mother with non-mosaic karyotype. In the second case, the SMC was de novo and present in the 78% of cells. The following FISH procedures were performed to confirm and specify the material present in the marker chromosomes: locus-specific identifier, 24-colour FISH, CGH, chromosomal manual microdissection and reverse FISH. These techniques identified both SMC as derivatives of chromosome 22. In the first case, the inherited SMC was an iso(22p) and the child was delivered successfully without phenotypic abnormalities. In the second case, the SMC was a der(22)(q11.2), resulting in a partial trisomy of band 22q11.2, which has been associated with Cat-eye syndrome (CES) in the literature. In this case the pregnancy was interrupted. It can be concluded with this study that familial markers representing an iso(22p) can be correlated with a normal phenotype. Also, this work proves the importance of the application of molecular cytogenetic procedures to know the origin of de novo SMC, in order to give accurate prenatal genetic counseling.

P03.33

Cell-free DNA levels during labor at term and preterm deliveries

S. Rosenberger¹, S. Reisinger¹, E. Magne², M. Bauer², A. Groselj-Strele³, U. Lang², B. Pertl¹;

¹Medical University of Graz, Graz, Austria, ²Department of Obstetrics and Gynecology, Graz, Austria, ³Center for medical research, Graz, Austria.

The aim was to evaluate the effect of uterine contractions on cell free fetal-DNA (cff) and total DNA levels in maternal plasma during term and preterm deliveries. Further we determined whether the cff-DNA concentration from maternal plasma samples during deliveries at term are different from those with preterm deliveries.

Maternal venous blood samples were collected during deliveries from 65 pregnant women with male fetuses. 46 pregnant women delivered at term and 19 delivered preterm. Cff-DNA levels were analyzed by quantitative real-time PCR using the *SRY*-assay and total DNA levels were analyzed using the *beta-Globin*-assay. 148 pregnant women at term without labor served as controls for women in labor at term. Pre-term samples (>27wks, 28-31wks, 32-36 wks, >36 wks) were matched for gestational age to control samples without labor.

Cff-DNA levels in plasma samples from women during delivery at term were statistically higher than fetal DNA levels in women without labor at term ($p=0.014$). The same results were found in the groups of preterm deliveries (28-31 wks: $p=0.048$ and 32-35wks: $p=0.003$). A statistically significant difference was not found in the lower age group (>27wks) which was probably due to the low number of samples. Furthermore, a statistically significant increase of fetal DNA during deliveries at term was found when compared to preterm deliveries ($p=0.05$).

Cff-DNA is increased during spontaneous deliveries at term and pre-term when compared to pregnant women without labor. Therefore, cff-DNA levels might be used as a marker for preterm deliveries.

P03.34

Prenatal diagnosis of chromosomal abnormalities in Tomsk population

L. P. Nazarenko, S. L. Vovk, Y. S. Yakovleva, N. B. Torchova, M. O. Filippova, M. P. Korf, N. L. Puryiskina;

State Research Institute of Medical Genetics, Tomsk, Russian Federation.

The aim of current study was to evaluate the frequency and structure of prenatally detected chromosomal abnormalities in Tomsk population. The risk for chromosomal aberrations was calculated by taking into account maternal age and gestation time, first and/or second trimester serum markers, first and/or second trimester ultrasound. Cut-off for invasive testing was risk 1 in 250. A total of 1349 chordocenteses, amniocenteses, placentocenteses and chorion biopsies were performed during the period of 5 years. Karyotype clarification was performed by conventional cytogenetic analysis. Abnormal karyotypes were found in 4.8% of cases. Numerical and structural chromosomal aberrations were detected in 73.8% and 26.2% of cases, respectively.

P03.35

Chromosome abnormalities in amniocenteses with normal fetal ultrasonography

Z. Yilmaz¹, E. Tarim², O. Ozer¹, T. Bulakbasi¹, F. Yanik², F. I. Sahin¹;

¹Baskent University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey, ²Baskent University Faculty of Medicine Department of Obstetrics and Gynecology, Ankara, Turkey.

Before 1994, maternal serum screening (MSS) was not offered to women 35 years of age or older, unless they did not choose to undergo invasive diagnostic testing for chromosomal abnormalities. MSS tests are usually performed for detecting trisomy 21 in women under 35 years of age. Their use in women 35 years of age or older has a detection rate of 67% for all chromosomal abnormalities and 87% for trisomy 21. In our study, we evaluated karyotype results of amniocenteses of women with advanced maternal age (AMA), increased risk for trisomy 21 on MSS (MSS-DS, first and/or second trimester tests) and with AMA+MSS-DS. None of the patient groups had fetal abnormalities detected during ultrasound examination. Among 2231 patients consulted between January 2002 and December 2007, 52 (2.33%) had chromosome abnormalities. 20 of 817 cases (2.44%) with AMA, 23 of 1121 cases with MSS-DS risk (2%) and 9 of 293 cases with both AMA and MSS-DS risk among (3.07%) had chromosome abnormalities. We detected trisomy 21 in 23 cases (7 AMA, 8 MSS-DS and 8 AMA+MSS-DS), mosaic trisomy 21 in one case with MSS-DS, mosaic trisomy 20 in one case with AMA, sex chromosome aneuploidies in 9 cases (6 AMA, 3 MSS-DS), unbalanced rearrangements in 3 cases (1 AMA, 2 MSS-DS), marker chromosome in 3 cases (1 AMA, 2 MSS-DS), balanced rearrangement in 12 cases (4 AMA, 7 MSS-DS, 1 AMA+MSS-DS). Although the fetuses had normal findings in fetal ultrasound examination, pregnancies with increased risks still had chromosome abnormalities.

P03.36

Hypertelorism-Microtia-Clefting syndrome, two further prenatal cases

J. Ghomid¹, H. Ansart-Franquet¹, D. Subtil¹, N. Pasz¹, L. Devisme², S. Manouvrier-Hanu¹, J. Andrieux¹, M. Holder-Espinasse¹;

¹Jeanne de Flandre, Lille, France, ²Centre de Biologie Pathologie, Lille, France.

Hypertelorism-Microtia-Clefting syndrome (HMC syndrome) is a very rare autosomal recessive condition, with only nine cases reported in the literature. It comprises hypertelorism, microtia, cleft lip and/or palate, microcephaly, variable mental retardation, renal anomalies and sometimes heart abnormalities.

Here we describe two affected fetuses.

During the first pregnancy, an increased nuchal translucency was identified at 12 WG. Chromosomes on Chorionic Villus Sample (CVS) were normal 46, XX. Secondly, heart abnormalities and a bilateral cleft lip and palate were noted.

This multiple congenital anomalies syndrome led to termination of pregnancy at 20 WG. Pathology examination revealed severe hypertelorism, microtia, bilateral cleft lip and palate.

HMC syndrome was suspected and since it is an autosomal recessive inherited defect, the genetic counselling was cautious. We recommended close detailed ultrasound follow-up for further pregnancies.

During the second pregnancy, a recurrence was observed. Indeed, the foetal ultrasound showed at 12 WG an increased nuchal translucency and a right cleft lip. Chromosomes on CVS were normal 46, XY. Pathology processed after the termination of pregnancy at 16 WG revealed hypertelorism, small ears and a right cleft of the upper lip.

The parents are non consanguineous. Their karyotypes are normal. A CGH-array study is pending on the first foetus. So far no responsible gene is known for the HMC syndrome and the hypothesis of chromosomal abnormality remains plausible.

P03.37

First successful prenatal diagnosis of MDC1A form in Tunisia revealed intrafamilial phenotypic variability in two siblings sharing the same mutation in LAMA2 gene

O. Siala¹, F. Kammour², N. Louhichi¹, I. Hadj Salem¹, M. Gribaa³, H. Eghezal⁴, A. Saad⁴, C. Triki², F. Fakhfakh¹;

¹Laboratory of Human Molecular Genetics, Sfax, Tunisia, ²Service de Neurologie, C H U Habib Bourguiba, Sfax, Tunisia, ³Laboratory of Human Molecular Genetics, Sousse, Tunisia, ⁴Department of Cytogenetics and Reproductive Biology, Farhat Hached University Teaching Hospital, Sousse, Tunisia, Sfax, Tunisia.

MDC1A is a severe congenital muscular dystrophy caused by mutations in LAMA2 gene encoding the laminin $\alpha 2$ chain. Prenatal diagnosis represents prevention for many couples given the overwhelming prospect of having another child with this incurable condition. We report the first prenatal diagnosis of MDC1A form in Tunisia and in Africa in a family with previously affected child and identified mutation in LAMA2 gene. Amniotic fluid was sampled by amniocentesis under ultrasound guidance. Molecular analyses were performed on cultured amniotic fluid cells after exclusion of maternal cell contamination by QFPCR. Postnatal clinical examination was also performed by cerebral MRI and by immunostaining on muscle biopsies using two monoclonal antibodies directed against the laminin $\alpha 2$. After exclusion of maternal cell contamination, mutation screening on fetal DNA showed that he was homozygous for the c.8007delT frameshift mutation, and the couple was counselled that the foetus would be affected. The presence of the mutation was confirmed on total DNA extracted from blood leukocytes of the newborn. Surprisingly, postnatal clinical examination showed that the younger patient who was diagnosed as affected developed widely milder phenotype of MDC1A form than his severely affected brother; and immunofluorescence showed complete deficiency of the laminin $\alpha 2$ in both patients. These findings suggest that other genetic/or epigenetic factors including modifier gene can control the course of the disease. Moreover, the intrafamilial phenotypic variability in siblings with the same molecular defect complicates the diagnoses because presymptomatic LAMA2 mutation carriers can develop a different phenotype than previous diagnosed porosities.

P03.38

Indications for cordocentesis and correlation with chromosomal aberrations

B. O. Petrovic¹, A. Ljubic¹, J. Joksimovic²;

¹Institute for gynecology and obstetrics, Belgrade, Serbia, ²Medicines and medical devices agency of Serbia, Belgrade, Serbia.

Over a 7 years period we performed 734 cytogenetic analysis of foetal blood taken by cordocentesis. Cordocenteses were performed because of late gestation. Indications for cordocentesis were advanced maternal age, increased risk determined by biochemical screening or sonographically detected foetal abnormalities. Indications and findings are given in table 1.

Table 1.

	Total	Aberrant	%
Biochemical Screening Risk	181	2	1,1%
Advanced Maternal Age	249	18	7,2%
Polyhydramnion	79	10	12,7%
Oligohydramnion	50	2	4%
IUGR	111	4	3,6%
CNS Anomaly	48	3	6,3%
Foetal Hart Defect	16	4	25%
Total	734	43	5,85%

In nearly 6% of analysed samples we found aberrant karyotypes. The most common finding was autosomal aneuploidy. Trisomy 21 correlated with advanced maternal age, polyhydramnion and foetal hart defects, while trisomy 18 was predominately found in fetuses with CNS abnormalities. Structural chromosomal abnormalities were detected only in 5 cases (0,7%), and had diferent phenotypic expression.

P03.39

Case Report: Submicroscopic duplication of D18S535 ina fetus with normal karyotype

G. Dimisianos, R. Neroutsou, E. Manolagos, P. Tsoplou, A. Metaxotou; BIOIATRIKI SA, Athens, Greece.

QF PCR (Quantitative Fluorescent PCR) was introduced only a few years ago to speed up prenatal diagnosis and act as an adjuvant to standard karyotype analysis. QF PCR utilizes length polymorphisms of Short Tandem Repeats (STR) on selected chromosomes that are amplified and then detected by automatic genetic analysers. STRs are found in abundance in the human genome and their usefulness as potential forensic markers for human identification purposes with the help of PCR has been noted almost 20 years ago. Many STRs have been utilized in the field of prenatal diagnosis leading to the development of QF PCR (Quantitative Fluorescent PCR) with the concurrent advance of technology in genetic analyzers. Here we report a case of a sub-microscopic duplication of STR D18S535 in an amniotic fluid sample screened routinely for aneuploidies. This partial trisomy involving the chromosome 18 was diagnosed by detecting this pattern only in one out of three markers used for chromosome 18. The rest of the STRs of chromosome 18 tested were normal. After screening the parents it was found that the extra allele had been inherited by the father so the pregnancy continued normally. Conventional cytogenetic analysis that was performed on this amniotic fluid had a normal karyotype. There have been reports of other such duplications in the literature and stringent screening is required to avoid false positive results when screening for aneuploidies.

P03.40

Prenatally detected trisomy of chromosome 21

I. I. Kavacan, J. Jovanovic Privrodski, M. Kolarski, A. Krstic, L. Gacina, V. Cihic, J. Rudez, T. Tarasenko;

Institute for Children and Youth Health Care Vojvodina, Novi Sad, Serbia.

We present incidence of prenatally detected trisomy of chromosome 21 during last seven years (2000-2007) in Medical Genetic Centre in Novi Sad, Vojvodina northern part of Serbia with 2.000.000 inhabitants.

Suspicion for trisomy 21 and indications for invasive prenatal diagnosis was made by Clinical Genetics according maternal age (35 and more), paternal age (42 and more), family pedigree, biochemical screening, expert ultrasound result such as enlarged nuchal translucency, absent nasal bone, echogenic bowels, short femur, and other.

During last seven years we detected 99 trisomy of chromosome 21 (full trisomy 91 cases, mosaicism 5 cases, translocations 3 cases), that is 38.98% of all prenatal detected chromosomal anomalies (N= 99/254; 38.98%).

P03.41

Screening for different Chromosome 18 methylation patterns between placenta and whole blood

L. Rueda^{1,2}, E. Ordoñez^{1,2}, P. Cañadas¹, W. Puszyk³, F. Crea³, R. Old³, C. Fuster², V. Cirigliano^{1,2};

¹General Lab, Barcelona, Spain, ²Departament de Biologia Cel·lular, Universitat Autònoma de Barcelona, Barcelona, Spain, ³University of Warwick, Warwick, United Kingdom.

Since its discovery in 1997, the presence of free fetal DNA in maternal plasma provided new approaches for non invasive prenatal diagnoses.

However, universal fetal markers would allow its diffusion to a wider number of applications and clinical cases.

More recently epigenetics has shown encouraging results toward this goal. Our aim was to investigate the methylation status of selected promoter regions of chromosome 18 genes in maternal blood and placenta samples.

A total of 36 genes on chromosome 18 were selected after database search for sequences with different expression patterns in placenta and blood. Primers were designed to analyse as much CpG islands as possible in 102 promoter sequences for the presence of different methylation patterns in fetal tissue (CVS) and whole blood (WB). Digestion with 4 methylation-dependent restriction enzymes was carried out on extracted DNA samples prior to PCR amplification to investigate the presence of differentially methylated sequences.

Two promoter regions were found hypermethylated in CVS and hypomethylated in WB. One more gene promoter was found with the opposite pattern being hypomethylated in CVS and hypermethylated in WB.

In this study we found three genes on chromosome 18 with apparently differentially methylated promoters between placenta and whole blood. We are in the process of developing assays to detect the placental form in maternal plasma. These preliminary results confirm the effectiveness of an epigenetic approach to find biomarkers for the analysis of free fetal DNA in maternal plasma.

P03.42

Screening and nuchal translucency in first and second trimester: efficiency in the selection of pregnant women at risk of chromosomopathies

A. Sánchez^{1,2}, N. Clusellas¹, C. Morales¹, J. Bruguera³, I. Mademont⁴, R. Queralt¹, V. Borobio⁵, A. Borrel^{1,2}, E. Casals¹, A. Soler^{1,2};

¹Servei de Bioquímica i Genètica Molecular, Hospital Clínic, Barcelona, Spain,

²IDIBAPS, Barcelona, Spain, ³Fundació Clínic per a la Recerca Biomèdica,

Barcelona, Spain, ⁴CIBERER, Barcelona, Spain, ⁵Servei de Medicina Materno-

fetal, Hospital Clínic, Barcelona, Spain.

First trimester screening for trisomy 21 is provided by a combination of maternal age, fetal nuchal translucency and maternal serum free β -hCG and PAPP-A concentration between 11-13 weeks of gestation. The detection rate of trisomy 21 is 90% with a false positive rate of 5% which is superior to the 65% achieved by second-trimester serum biochemistry. We report a series of 5285 gestations that were referred to maternal-fetal medicine department between 2003 and 2007 who underwent an invasive prenatal diagnosis. A total of 1986 samples were CVS and 3299 were amniotic fluid samples. In first trimester the 12,7% of the samples were referred due to positive combined screening (+SC) and the 13,7% due to increased nuchal translucency (INT) as unique abnormal parameter. In second trimester the 39% of the samples were referred for positive second trimester screening and the 2,5% for increased nuchal translucency. In the second trimester samples the 1,4% of +SC and the 9,3% of INT showed a chromosomopathy. In the first trimester samples the 12% of +SC and 25% of INT presented chromosomal abnormalities. In first trimester we must perform 5,5 invasive procedures to find a chromosomopathy in group of patients with the reported indications, whereas in the second trimester 53 invasive procedures are needed to detect a chromosomal abnormality. These results emphasise the higher efficiency of first trimester screening over the second besides the medical advantages of an early diagnosis.

P03.43

First-trimester screening protocols and their impact in cytogenetic counselling

C. Cotarelo-Pérez, R. Oancea, M. Fenollar-Cortés, M. Ortega-de-Heredia, J. Montalvo-Montes, M. Lautre-Ecenarro;

Hospital Clínico San Carlos, Madrid, Spain.

In the last few years, we have referred an increase of diagnosis prenatal (DP) due to advanced maternal age and more knowledge of the general population about possible diagnosis methods. The assumption of first-trimester screening protocols (ultrasound and biochemistry methods) has allowed to generalize the DP to all pregnant women, independently of maternal age. We present our results after seven years with the combined test and its impact on the cytogenetics prenatal diagnosis. We analyzed data from 5743 singleton pregnancies under-

going prenatal genetic counselling from the area 7 of Madrid. 4930 woman where testing by first-trimester combined biochemistry and ultrasound nuchal translucency screening. In 1998, 13% of the pregnant women renounced amniocentesis opposite a 50% of renounces in 2007. The implementing of first-trimester screening has reduced the number of amniocentesis and made an individual better earlier genetic counselling.

P03.44

Prenatal Diagnosis of a fetus with 44 chromosomes and homozygous Robertsonian translocations (14;21)

S. Sodia, W. Emberger, H. Zierler, M. Speicher;

Medical University Graz, Graz, Austria.

We report the rare finding of a human fetus with 44 chromosomes due to homozygous Robertsonian translocations (14;21). The related parents, born in Turkey, were referred to our Genetic Department for genetic counselling at 16th weeks of gestation due to advanced maternal age. Amniocentesis was performed and the analysis of amniotic fluid cells revealed 44 chromosomes with a homozygous Robertsonian translocations (14;21):

44,XX,der(14;21)(q10;q10),der(14,21)(q10;q10). At the time of amniocentesis there were no pathological ultrasound findings. Karyotyping of the consanguineous parents showed in each case the same heterozygous Robertsonian translocations(14;21). Family history revealed that the translocation has segregated through at least four generations. Because UPD testing should be considered in fetuses carrying a balanced Robertsonian translocation involving chromosomes 14 or 15, we excluded in our case UPD 14. Although Robertsonian translocations are common chromosomal rearrangements, homozygous carriers are rare. Previously reported single case reports showed no evidence for an increased risk for malformations or dysmorphic features in carriers of homozygous Robertsonian translocations.

P03.45

Prenatally detected mosaicism - 46,X,idelic(Y)(q11.2)/45,X. A case report

P. Tammur, K. Kuuse, P. Ilisson, M. Sitska;

Department of Genetics, Tartu, Estonia.

Isodicentric Y chromosomes are inherently unstable and may be lost during mitosis resulting in mosaicism, generally including a 45,X cell line. Clinical presentations in patients with mosaicism for a structurally abnormal Y chromosome can range from classical Turner phenotype through mixed gonadal dysgenesis to phenotypically normal males.

The variability in sexual phenotype is thought to be related to the tissue distribution, to the proportion of each cell line and to the location of the breakpoints. However, prenatal diagnosis of mosaic 46,X,idelic(Y)/45,X is rare, and poses a serious dilemma concerning the prognosis related to the fetal stature, sexual differentiation and the risk development of gonadoblastoma.

In our case amniocentesis was performed to a 33-year-old woman because of positive serum screening on the 15 week of pregnancy. Cultured amniocytes from two different culture flasks revealed mosaic karyotype 46,X,+mar[36]/45,X[14]. For detecting the origin of marker chromosome, fluorescence in situ hybridisation (FISH) was performed 1)with X and Y centromeric probes (AneuVysion, X, Y-alpha satellite probe) and 2) XYpter subtelomere specific probe (Cytocell). FISH analysis revealed that the marker chromosome was isodicentric Y chromosome with two short arms and a small portion of the long arm: 46,X,idelic(Y)(q11.2)[41]/45,X[44]. After further genetic counselling, the parents opted for termination of the pregnancy. Postmortem examination revealed male fetus with microanomalies and no major abnormalities. Cytogenetic analysis of the placenta showed mosaicism in a different degree 46,X,idelic(Y)(q11.2)[46]/45,X[4] and mosaicism was also found in fetal tissues.

P03.46

Is informed choice in the context of prenatal testing a universally held value?

A. van den Heuvel¹, E. Dormandy¹, L. Chitty², T. M. Marteau¹;

¹King's College London, Institute of Psychiatry, London, United Kingdom, ²Institute of Child Health and UCLH, London, United Kingdom.

Background: Informed choice is central to prenatal testing and endorsed by many national and international guidelines for prenatal

service delivery. Recent evidence suggests that there is considerable variation in the extent to which these guidelines translate into practice. This is particularly evident in cross-country comparisons. This paper presents findings from a values survey that assessed the extent to which informed choice in the context of prenatal testing is a universally held value.

Method: Values attached to choice in the context of prenatal diagnosis were assessed among 1) general populations (n=1200) and 2) obstetricians (n=1117) in Europe (UK, Netherlands, Italy and Greece) and Asia (China and India).

Results: Findings from both samples suggest that there is a sharp divide between first Northern European countries and second, Southern European and Asian countries in the extent to which choice is valued. Most respondents from Northern European countries perceived that undergoing prenatal testing should reflect a parental choice (71%-86%), compared with a minority from Southern European and Asian countries (16%-33%). Comparison across the populations suggests that health professionals are more strongly in favour of choice than general populations. Given the political endorsement of informed choice, the latter may reflect a tendency for professional identities to dominate over personal values.

Conclusion: Implications of these findings for policy and practice will be discussed within the framework of the ethical principle of 'autonomy'.

P03.47

Couple's karyotyping in recurrent miscarriage: A case report with t(13;14)

S. Shinde, B. B. Ganguly;

MGM Center for Genetic Research and Diagnosis, New Bombay, India.

An individual who is a carrier of a translocation may not have any problem with their growth, development and health but depending on the chromosomes involved, they may experience reproductive problems such as infertility, miscarriage and having a child with abnormal chromosomal complement. In the present study, chromosome study was carried out on young couple who was married for 1.5 yrs and had three consecutive missed abortions. However, chromosome study was not carried out in any of the abortus. Couples karyotyping following PHA-stimulated blood culture detected constitutive abnormality in husband with 46,XY,t(13;14)(q22.1;q24.3) pattern. The translocation between the two chromosomes was a balanced one with no significant phenotypic effect. The wife had a normal female karyotype. The possible genetic make up of the male gametes and subsequently of the fetus could be: i) both normal 13 and 14, ii) rearranged 13 with normal 14, iii) rearranged 14 with normal 13, and iv) both rearranged 13 and 14. Mathematically, she has a 1 in 4 (25%) chance of having baby entirely chromosomally normal and the others will be a translocation 'carrier' just like father or carrier of a recombinant 13 or 14. Therefore, 3/4 of her babies are at risk for being chromosomally abnormal. These babies could have severe congenital malformations and if they manage to survive birth and the neonatal period, profound metabolic disturbances and mental retardation could persist life long. However, prenatal diagnosis in CVS or amniotic fluid must be carried out for evaluation of chromosomal composition in fetus and obstetric management accordingly.

P03.48

Triploidy identified through Maternal Serum Screening in Second Trimester

F. Behjati^{1,2}, I. Bagherizadeh², M. Oveis², Z. Hadipour², A. Sarem², Y. Shafaghahi²;

¹Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran, ²Dept. of Medical Genetics, Sarem Women's Hospital, Tehran, Islamic Republic of Iran.

Amniocentesis was carried out at 17 weeks gestation on a 27 years old woman following an abnormal maternal serum screening test (MSS). MSS test was carried out primarily to estimate the risk of trisomy for chromosomes 21 and 18. The maternal serum markers used were alpha-fetoprotein (AFP), human chorionic gonadotrophin (hCG), and unconjugated estriol (UE3) together with maternal age. The fetus was identified as screen-positive for Edward's syndrome (trisomy18), with low UE3, normal AFP and hCG levels. The calculated risk for trisomy 18 was more than 1:50.

To identify any possible chromosomal abnormality, cytogenetics inves-

tigation was carried out on amniotic fluid sample. The fetus's karyotype was triploid with 69, XXX chromosome complement in all the metaphase spreads obtained from three different cultures, using GTG banding technique. Upon termination of the fetus, gross abnormalities indicative of triploidy were present in the fetus.

This is one of a few cases reported so far where abnormal maternal serum screening indicative of trisomy 18, ends up as a triploid fetus. Maternal serum screening is an essential approach for detecting chromosome abnormality prenatally, and thus helping with prevention of the birth of a genetically abnormal fetus.

P03.49

A new prenatal diagnosis of Nager syndrome on monochorionic-biamniotic twin pregnancy

H. Ansart-Franquet¹, V. Houfflin-Debarge¹, J. Ghoumid¹, N. Pasz¹, L. Devisme², S. Manouvrier-Hanu¹, J. Andrieux¹, M. Holder-Espinasse¹;

¹Jeanne de Flandre, Lille, France, ²Centre de Biologie Pathologie, Lille, France.

The Nager syndrome, also termed preaxial acrofacial dysostosis, is a rare condition characterised by limb and facial deformities. Limb anomalies consist of hypoplasia or absence of radius, radioulnar synostosis, and hypoplasia or absent thumbs. The mandibulofacial dysostosis is characterised mainly by severe micrognathia and malar hypoplasia.

Since its first description in 1948, more than 80 cases have been reported in the literature, although there are only two reports of prenatal diagnosis. We report here a further case of Nager syndrome diagnosed at 22 weeks of gestation in a monochorionic-biamniotic twin pregnancy. The prenatal diagnosis was performed on ultrasound because of severe microretrognathia and significant forearm shortening on both foeti. Termination of pregnancy was performed at 25 WG. Chromosomes were normal 46XY. The pathology report confirmed the diagnosis of Nager syndrome in both twins. Growth discordance was noted between the fetuses. Both presented a large cleft palate, ear dysplasia and a severe microretrognathia. They had bilateral thumb agenesis with single palmar crease. The X-ray confirmed the microretrognathia. One foetus had bilateral radioulnar synostosis with hypoplasia of the right radius, and bilateral thumb agenesis. The other twin presented bilateral thumb agenesis too, but only a partial radioulnar synostosis on the left side. A CGH-array analysis on fetal DNA is pending.

P03.50

Cytogenetic analysis of chorionic villi samples (CVS) in missed abortions

K. Sentija, Z. Duic, I. Krivak Bolanca, S. Katalenic Simon;

University Clinic Merkur, Zagreb, Croatia.

The aim of our study was to analyse the frequency and type of chromosomal aberrations of chorionic villi samplings (CVS) in patients with missed abortion, performed in our clinic during last three years.

Methods: CVS analyses obtained by transabdominal biopsy in first and second trimester of 57 pregnant women with ultrasonographic evidence of missed abortion were performed. For chromosome analysis conventional cultures of CVS and GTG-banding techniques were used.

Results: Of total 579 CVS analysed, 57 CVS were performed for missed abortion. The mean maternal age was 35,86 (22-46) years, and mean gestational week was 9,75 (8-16). Fetal karyotyping was successful in 54 cases, while 3 cases were excluded from study for low proliferative activity. Of 54 analysed, 36 (66.66%) cases had an abnormal karyotyp, while no chromosomal abnormalities could be diagnosed in 18 (33.33%) cases. Of 36 abnormal karyotypes, predominant abnormality were autosomal trisomies in 22 (61,11%) cases, including various chromosome groups (B,C;D,E,G), most of them represent nonviable defects. Follows 6 (16,65%) polyploidies and 4 (11,11%) X monosomies (46,XO). Relatively rare type of double abnormality in 2 cases (5,55%) (48,XY;D14+,E17+; 48XX;C7+,D13+) were observed. Mosaicism (46,XY/47,XY) was present in one case (2,77%) where autosomal trisomy could not be determined. Translocation (46,XY)t(D13,D14) was also present only in one (2,77%) case.

Conclusion: Although CVS analysis in our study did not exclude normal karyotype, our results suggest that missed abortion is strongly associated with chromosome abnormalities. The factors responsible for missed abortion with a normal karyotype are presently unknown and require further study.

P03.51**MLPA validation for prenatal diagnosis of chromosomal anomalies: retrospective study of 125 consecutive chorion villi samples**

D. Diego-Alvarez, C. Ramos, B. Gomez-Dominguez, R. Cardero-Merlo, A. Bustamante-Aragones, M. Trujillo-Tiebas, C. Auz-Alexandre, J. Gallego-Merlo, A. Gimenez-Pardo, F. Infantes, C. Ayuso, J. Diaz-Recasens, M. Garcia-Hoyos, R. Riveiro-Alvarez, E. Vallespin, A. Avila-Fernandez, D. Cantalapiedra, M. Rodriguez de Alba, I. Lorda-Sanchez;
Fundación Jiménez Díaz, Madrid, Spain.

Rapid screening for common aneuploidies (trisomy 13, 18, 21 and those involving sexual chromosomes) by interphase *nuclei* FISH or multiplex QF-PCR has become a common offer in prenatal diagnosis. Although it reduces maternal anxiety by discarding the most frequent chromosomal anomalies, some other like terminal deletions are missed. In addition, rapid detection of unbalanced products of parental balanced translocations requires the use of additional specific FISH probes. In contrast, MLPA technique with subtelomeric probe-mixes provides information about copy number changes of every chromosome in a rapid (24 h) and simple protocol requiring few material. Although specific probe-mixes for the detection of common anomalies in prenatal diagnosis have been validated, the aim of the present study was to evaluate the use of subtelomeric probe-mixes for the rapid detection of aneuploidy, unbalanced reciprocal translocations and terminal chromosomal rearrangements of every chromosome on a hundred and twenty-five consecutive *chorion villi* samples. Terminal deletion or duplication was suspected when two different probes for a chromosomal arm appeared deleted or duplicated, respectively. Aneuploidy was suspected if probes for both arms of a chromosome appear deleted (monosomy) or duplicated (trisomy). Results demonstrate the capability of MLPA on detecting not only numerical but also structural chromosomal anomalies on prenatal samples. Thus, this technique can also be a rapid and simple approach for the detection of balanced or unbalanced products of translocations.

P03.52**22p derived supernumerary marker chromosome identified prenatally by MLPA**

R. Fernandez Gonzalez¹, P. Blanco Soto¹, J. Ubeda Arades¹, B. Ferreiro¹, A. Gonzalez de la Vega², M. Sanchez Hombre², A. Gomez Pastor², M. A. Orera^{1,2};
¹Hospital Gregorio Marañon, Madrid, Spain, ²Circagen, Madrid, Spain, ³Complejo Hospitalario Universitario de Albacete, Albacete, Spain.

Supernumerary Marker Chromosomes (SMC) have a frequency of around 0.05% in prenatal diagnosis. Risk for congenital anomalies ranges from 7% for SMC derived from acrocentric chromosomes to 28% for SMC derived from autosomes.

We present a prenatally detected SMC in a 32 years old woman, with a previous spontaneous miscarriage. The ultrasound performed at 11th gestational week detected a cystic hygroma. Chorionic villus sampling was done at that time and FISH for 13, 18, 21, XY chromosomes (Aneuvysion, Vysys) was normal. No foetal karyotype could be obtained, and despite normal ultrasounds during follow up, an amniocentesis was performed at the 16th gestational week. The karyotype of the fetus was 47,XY+mar. The marker chromosome was centromeric, satellited and smaller than chromosome 21. Because of the risk of Congenital Heart Disease, we performed a FISH with TUPLE1 probe (Catch 22) (Vysys) that was normal. Parental karyotypes were also normal.

In order to identify the origin of the SMC, we performed Multiplex Ligation Probe Amplification (MLPA) with Salsa P070 for Telomeres (MRC-Holland). The result was compatible with partial trisomy of 22p. Considering the result of FISH and MLPA, we conclude that the breakpoint lied between the end of IL17R and the beginning of HIRA, carrying some or all the genes associated with Cat Eye Syndrome. The parents decided to terminate the gestation.

This case illustrates the difficulties in prenatal genetic counselling when a SMC is involved and the need to use all technologies available to better predict the outcomes of these pregnancies.

P03.53**Cell selection in culture of amniotic fluid cells: report of three cases with low level of true mosaicism**

N. Clusellas¹, C. Morales¹, I. Mademont², R. Queral¹, A. Soler¹, C. Badenas¹, A. Sánchez²;

¹Hospital Clínic de Barcelona, Barcelona, Spain, ²CIBERER, Barcelona, Spain. Mosaic aneuploidy is found in 0,3% of all amniocentesis. When detected in prenatal diagnosis is a troublesome problem on interpretation and genetic counselling. We present three cases with low level of mosaicism:

1.- Twenty cells analysed from two independent vessels showed 47,XXX, which is a good prognostic result. But a culture performed in another laboratory showed a 45,X/47,XXX with a 75% of monosomic cells. We revised our slides and found 7/40 of 45,X cells, which changed the genetic counselling.

2.- The first culture showed 1/50 of 47,XY,+21 cells, the second and the third showed 5/50 and 2/25 trisomic cells, respectively. This was an ambiguous result, with 6% of +21 cells. We performed QF-PCR analysis for common aneuploidies with a portion of fresh amniotic fluid and the result was compatible with trisomy 21.

3: The cell culture in this case was slow and poor, in order to ensure the diagnosis, we decided to perform QF-PCR. The result was a normal male. Finally, we could obtain some metaphases for cytogenetic analysis and the result was 37 cells with a 45,X karyotype. The gestation was interrupted because of ultrasound findings. We repeated cytogenetics, FISH and QF-PCR studies and the result was 45,X/46,XY. Conclusions: There is a selection in the culture that may disturb the real percentage of abnormal cells. Then, the percentage of abnormal cells does not reflect the state of the fetus. The use of complementary techniques such as QF-PCR and FISH may help to the final result.

P03.54**Identification of feto-maternal differentially methylated regions on chromosome 18 and chromosome 21. Towards the development of fetal epigenetic markers for trisomies 18 and 21**

E. Papageorgiou^{1,2}, H. Fiegler², N. P. Carter², P. C. Patsalis¹;

¹The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus, ²The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom.

The discovery of free fetal DNA in maternal plasma has raised the possibility for future development of noninvasive prenatal diagnosis (NIPD). We have been using Methylated DNA Immunoprecipitation (MeDIP) assay and DNA oligonucleotide array technology to screen for differentially methylated sequences between maternal blood and placental (fetal) DNA that could be exploited for NIPD. The oligo arrays used are specific for chromosome 18 and chromosome 21. The probes are 50-60bp long with a median spacing of 170bp for chromosome 18 and 70bp for chromosome 21.

The results have shown regions of several consecutive oligo array probes to be differentially methylated between whole blood and placenta. A detailed analysis has revealed 42 regions on chromosome 18 and 34 regions on chromosome 21 that can potentially be used as fetal DNA epigenetic markers. The methylation status of the *SERBINB5* promoter region and two additional regions on chromosome 18 as well as ten regions on chromosome 21 have been confirmed by real time quantitative PCR in six whole blood and six placental DNA samples. Furthermore a high degree of variability has been observed between first and third trimester placentas whereas a lower degree of variability has been detected between individual samples of the same gestational age. Additionally, to imitate the low percentage of fetal DNA observed in the plasma of pregnant women, we have prepared mixtures of 5% fetal DNA with maternal DNA and tested the enrichment of fetal DNA by using MeDIP. Preliminary results have shown enrichment of fetal specific methylated DNA sequences absent in whole blood DNA samples.

P03.55**Partial trisomy 3q and monosomy 15q due to paternal t(3;15)(q26.33;q26.1); paternal detection by m-CGH and FISH, prenatal USG, postnatal and autopsy findings**

K. Piotrowski¹, M. Constantinou², Z. Celewicz², J. Patalan⁴, P. Waloszczyk⁵, S. Zajączek¹, B. Kalużewski²;

¹Cytogenetics Unit, Szczecin, Poland, ²Department of Medical Genetics, Medi-

cal University, Lodz, Poland, ³Department of Obstetrics and Gynaecology, "Mother and Child Hospital", Szczecin, Poland, ⁴Dept of Pediatrics "Mother and Child Hospital", Szczecin, Poland, ⁵Dept of Pathology Specialistic Hospital "Zdunowo", Szczecin, Poland.

A 31 years old gravida was referred at 13 week of pregnancy for prenatal diagnosis due to previous four undiagnosed pregnancy loss. During non-invasive screening at 14 week of pregnancy cystic hygroma (1.33 cm), features of cardiac insufficiency, multiply bone anomalies and prune belly syndrome suspicion were noted. Urgent karyotype analyses of both parents with resolution 450 - 650 bb. not detected any anomalies. Amniocentesis (with suspicion of X's chromosomes anomaly) was performed at 15 week and didn't detect any pathologies in classical cytogenetics analyses, but mCGH investigation (2,44 OLI-GO m-CGH Agilent) showed deletion in 46XY foetus chromosomes of distal 15q26.1qter and duplication of 3q26.33qter, confirmed by FISH with use of telomeric probes (Tel Vision 3qSO and 15qSO) and described as 46XY, ish der (15)t(3;15)(qter+,qter-)pat. Aberration was result due to next detected paternal balanced subtelomeric translocation 46,XY,ish t(3;15)(qter-qter+;qter+qter-). In next USG observations Intrauterine Growth Retardation, hypoplastic long bones, feets and hands anomalies, heart defect in form of CoA, hypoplastic DA, VSD, polycystic kidneys and defect of abdominal muscle were diagnosed. After uuneventful pregnancy a boy (2130g, 40 cm, Apgar 6,6,7) was born preterm at 36 week. Due to their poor status (particularly renal anomalies and insufficiency) possibility of cardiosurgery correction was excluded and he died at 40 day of life. Autopsy confirmed and précised all detected in foetal USG anomalies and more like: in the heart aorta-truncus pulmonalis anastomoses, additional perimembranous VSD, bilateral hydronephrosis with urethral and urachal hypoplasia and polysplenia.

P03.56

Total cell free and cell free fetal DNA quantification in preeclamptic pregnant womans

L. Lazar, B. Nagy, A. Morvarecz, J. Rigó Jr.; Semmelweis University, Budapest, Hungary.

Background: Presence of cell free fetal DNA in plasma of pregnant womans is a well known phenomenon. The quantity of DNA is different in normal and pathological pregnancies. The aim of our study was to measure and to compare the quantity of total free and fetal origin DNA in the plasma of preeclamptic patients, and patient with normal pregnancy and to reveal the correlations with pregnancy age and body mass index (BMI) in both groups. **Methods:** Blood samples were collected, and plasma was separated from 71 paeclamptic and 71 patients witouth symptoms of preeclampsia. Quantitative real-time PCR analysis of the SRY region of Y chromosome and globin gene was performed in order to detect and to measure the quantity of cell free fetal DNA and total free DNA in plasma. **Results:** The mean pregnancy age in preeclamptic and control group was 37 and 34 weeks respectively, BMI ranges between 20.6-38.2 and 16.7-30. The mean value \pm SD, of total free DNA was: 6.16E-03 \pm 0.23E-03 ng/mL and 2.755E-03 \pm 0.32E-03 ng/mL, in SRY positive cases the quantity of free fetal DNA we measured 3.363E-04 \pm 1.28E-05 ng/mL and 1.04E-04 \pm 0.92E-05 ng/mL respectively. The diefference between two groups in both cases was significant ($P=$.001). **Conclusions:** The quantity of free DNA is significantly higher in preeclamptic cases than in patients with normal pregnancy and depends on mathernal weight. In concordance with other studies the quantitative measurement of total cell free and cell free fetal DNA could be a predictive marker in early diagnosis and prevention of preecalmpsia.

P03.57

Reproductive decision of Spanish families with genetic risk for peroxisomal diseases

T. Pampols^{1,2}, M. Coll^{1,2}, M. Ruiz^{2,3}, M. Girós^{1,2};

¹Institut de Bioquímica Clínica. Servei de Bioquímica i Genètica Molecular. Hospital Clínic, Barcelona, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Barcelona, Spain, ³Instituto de Investigación Biomédica de Bellvitge (IDIBELL), Barcelona, Spain.

Peroxisomal disorders are severe neurodegenerative diseases caused by defects in genes that control single steps of metabolic peroxisomal pathways as well as the proteins involved in the peroxisomal biogenesis. Since 1988 we have diagnosed 198 cases of Peroxisomal dis-

eases, 158 of them had been X-linked adrenoleukodystrophy (X-ALD), 2 other isolated defects of peroxisomal β -oxidation and 38 defects of peroxisomal biogenesis (DPB).

The 158 affected X-ALD/AMN males proceed from 95 families that requested prenatal diagnosis (PD) in 34 pregnancies. In all the affected foetuses, parents opted by termination. Couples that were against this option decided not request PD. In most cases the mother was a carrier detected in the course of family studies, who proves the relevance of the recommendation to the parents of the index cases to communicate the genetic risk to other family members. As far as we know, only in one case, the couple hide the information to the family, resulting later on in the birth of one affected child. A couple that undertake 4 pregnancies with the result of 4 affected male foetuses, requested preimplantatory sex selection, but they don't succeed in two consecutive cycles of in vitro fertilization.

Families with other Peroxisomal disorders asked for DP in 11 pregnancies, 4 at risk for an isolated defect of peroxisomal β -oxidation and 7 at risk for PDB.

P03.58

A case of de novo 16p rearrangement diagnosed prenatally

I. D. Papoulidis¹, A. P. Athanasiadis², M. B. Petersen³, E. Drosopoulou², E. Siomou¹, C. Malamaki¹, F. Partheniou¹, T. Liehr⁴, Z. G. Scouras²;

¹Eurogenetica S.A., Thessaloniki, Greece, ²Aristotle University of Thessaloniki, Thessaloniki, Greece, ³Institute of child health, Athens, Greece, ⁴Institute of human genetics and anthropology, Friedrich-Schiller-University, Jena, Germany.

A case of a terminated pregnancy of a 30-year-old woman is reported in which ultrasound examination at 22 weeks' gestation showed two umbilical cord vessels, enlarged polycystic right kidney, implying polycystic kidney disease, and a normal left kidney. Conventional chromosome analysis (GTG banding) revealed addition of chromosomal material to the long arm of chromosome 16; however the limited resolution of conventional prenatal karyotype analysis prevented the identification of the origin of the additional material. MLPA (Multiple Ligation-dependent Probe Amplification) analysis was performed, which showed neither duplication nor deletion in chromosome 16. Both parents were found to have a normal karyotype. Expected data will include Fluorescence In Situ Hybridization (FISH) analysis to identify the chromosomal origin of the additional material. Furthermore, array CGH analysis will be performed to define the chromosomal breakpoints and the size of the additional material.

P03.59

Polyploidy in early spontaneous abortions

I. Tonković Đurišević¹, D. Mužinić¹, R. Lasan¹, K. Crkvenac Gornik¹, L. Letica¹, M. Burek¹, D. Begović¹;

¹Division of Genetics and Metabolism, Department of Pediatrics, University Hospital Centre Zagreb, Zagreb, Croatia.

Polyploidy is a condition in which there is more than two sets of chromosomes. A total of 321 cases of first trimester spontaneous abortions between 4 and 13 weeks of gestation were analyzed cytogenetically by direct - preparation method using chorionic villi. Among 54% of abnormal karyotypes, trisomy was predominant. The second most common abnormality was triploidy found in 25 (7,8%) cases. Triploidy may arise from fertilization of haploid egg by two haploid sperm or by maternal or paternal meiotic errors. Tetraploidy is a rare ploidy abnormality and was detected in 3 (0,9%) cases, 92,XXYY and 92,XXXX sex chromosome complement.

Among the triploid abortions the gonosomal constitution of XXY prevailed (14 cases), followed by XXX (8cases) and XYY (3 cases). The maternal age ranged from 18 to 35 age and the gestational age from 6 to 13 weeks. In this study the frequency of poliploidy abortions decreased with maternal age, what confirms that increased maternal age is not a risk factor and mechanism of poliploidy.

Triploidy and tetraploidy together account for 18% of chromosomal abnormalities and give rise to a significant proportion of human pregnancy wastage. Poliploidyies are numerical abnormalities, are sporadic, and they do not usually recur in subsequent pregnancies.

The results of perinatal testing from Istanbul Memorial Hospital

C. Aslan¹, G. Ozgon¹, O. Oner¹, B. Onal¹, F. Fiorentino¹, C. Yilanlioglu², S. Kahraman²;

¹Genoma Turkey, istanbul, Turkey, ²Memorial hospital, istanbul, Turkey.

Introduction

The aim of this study is the retrospective data collection of patients (especially PGD patients) between 2000-2007 for amniocentesis and for cvs between 2003-2007 to understand that the PGD might be a reasonable option for translocation carriers, advanced maternal age (ama), single gene disorder (sgd) carriers, pathological USG findings, recurrent implantation failure (rif), recurrent pregnancy lost (rpl), bad obstetric history.

Mat- method: Cell cultures were used for amniotic fluid specimens and tissue culture for coryon villi sampling (CVS). Culture developments were observed and underwent harvesting steps in the optimum timing (after 10-12 days). Slides were stained with giemsa staining techniques (GTG) and 30 cells were counted.

Between years 2000-2007, amniocentesis were performed to 615 patients and 82 CVS between 2003-2007 in our center. The indications and chromosome analysis results are in the table.1 below.

Results:

Table1 Results of amniosentesis

	Normal (n=5)	
Bad Obstetric History (n=5)	Normal (n=5)	
Male Factor (n=2)	Normal (n=1) 46,--,inv(12)	
Abnormal Triple Test (n=2)	Normal (n=2)	
PGD Cases (n=12)	Single gene +HLA(n=9)	Normal (n=9)
	PGD FISH(n=3)	Normal (n=2) 46,--,t(10;12)

Discussion: In this study, we present that performing amniocentesis and cvs cultures

and karyotype analysis approve that PGD is a reliable option for the patients with several indications to have a non-affected offspring.

P03.61

Pathological cytogenetical findings in fetal prenatal diagnosis

J. Jovanovic Privrodski, I. Kavecán, A. Krstic, L. Gacina, M. Kolarski, V. Cih, J. Rudez, T. Tarasenko;

Institute for Children and Youth Health Care Vojvodina, Novi Sad, Serbia.

In Medical Genetic Centre in Novi Sad (Institute for Children and Youth Health Care Vojvodina), prenatal genetic screening of fetal abnormalities is performed using detailed analysis of pedigree, maternal and paternal age, biochemical screening (pregnancy associated plasma protein -PAPP-A, free beta-subunit of human chorionic gonadotropin -free beta hCG in 11-14th weeks of gestation; alpha-fetoprotein -AFP, unconjugated estriol -uE3, PAPP-A, in 16-18th weeks of gestation) and expert ultrasound. If married couple have risk for fetal chromosomal abnormalities, Clinical genetics indicate invasive prenatal diagnosis.

During last five years (2003-2007.) in Medical Genetics Centre in Novi Sad were made 19019 Genetic consultations, and 11488 invasive prenatal procedures (9938 amniocentesis, 1550 cordocentesis). We found 169 pathological findings (1.47%), from amniocentesis (N=145/9938; 1.46%) and from cordocentesis (N=24/1550; 1.54%). The most frequent chromosomal anomalies was Down syndrome (42.01%), Edwards syndrome (9.46%), Patau syndrome (5.32%), Turner syndrome (6.51%), Klinefelter syndrome (9.46%), and other chromosomal anomalies (27.24%).

P03.62

Karyotyping vs MLPA in spontaneous (late) pregnancy losses.

T. Dijkhuizen, H. H. Faber, G. Drok, K. B. J. Gerssen-Schoorl, B. Sikkema-Raddatz, K. Bouman;

Department of Genetics, Groningen, The Netherlands.

Early spontaneous abortions (less than 16 weeks of pregnancy) have a variety of chromosome aberrations, most of them aneuploidies of whole chromosomes. Chromosome abnormalities occur to a lesser extent in second and third trimester pregnancy losses. Chromosome analysis provides valuable information about the possible cause of fetal death and the recurrence risk. Yet it is hampered by a high rate of culture failure. Multiplex Ligation dependent Probe Amplification (MLPA) overcomes the problem of culture failure if DNA is extracted directly out of the fetal tissue before culture. Using a subtelomere dedicated test, it can provide information on the ploidy status of all chromosome (arm)s.

In the present study we compared routine chromosome with MLPA analysis in a series of more than hundred fetal tissue samples of spontaneous (late) second and third trimester pregnancy losses. Routine chromosome analysis succeeded in 20% of cases, of which 8% had an abnormal chromosome complement. For MLPA, two different subtelomere specific tests (P036 and P070) were used to examine all chromosomes for ploidy status. We obtained interpretable results in 83% of cases. Abnormal ratio spreads were observed in 6% of them. Detailed data will be presented on the poster.

In conclusion, MLPA increases the success rate for chromosome analysis dramatically by overcoming the problem of culture failure. Although it is suggested that culture failure could be caused by the fact that the fetus has a chromosome abnormality, the percentage of genetically abnormal tissue samples remains similar for both techniques, MLPA and karyotyping.

P03.63

Prenatal diagnosis of mosaicism for different structural unbalanced cell lines involving chromosome 18

A. Soler^{1,2}, J. Bruguera³, I. Mademont⁴, C. Morales¹, N. Clusellas¹, C. Badesas^{1,2}, A. Sánchez^{1,2};

¹ Servei de Bioquímica i Genètica Molecular. Hospital Clinic, Barcelona, Spain,

² IDIBAPS, Barcelona, Spain, ³ Fundació Clinic, Barcelona, Spain, ⁴ CIBERER,

Barcelona, Spain.

Confined placental mosaicism is detected in 1-2% of pregnancies undergoing first-trimester CVS. Structural mosaicism is a rare event, often difficult to interpret. However, chromosome 18 appears to be most frequently involved in these structural rearrangements, according to published cases. We report a further case detected by prenatal diagnosis. CVS was performed on a pregnant woman due to increased

nuchal translucency. Cytogenetic analysis after short-term culture showed four different abnormal cell lines involving chromosome 18, and the karyotype was described as: mos 46,XX,18p+[15]/r(18)[14]/i(18q)[1]/45,XX,-18[3]. Amniocentesis was subsequently performed. Ultrasound examination showed a septate translucency as the only abnormal finding. QF-PCR analysis showed homozygosity for all 18p markers, suggesting a 18p monosomy. The karyotype obtained was 46,XX,del(18p) in all cells. The pregnancy was terminated and pathologic studies are being performed at present. We propose a model to explain the cytogenetic findings. A first postzygotic error, probably an unequal sister chromatid exchange giving rise to a cell line with del(18p) and the complementary with 18p+, may have most likely happened before the first post-zygotic division, since no normal cells have been detected. Isochromosome(18q) and ring(18) seem to be secondary to del(18p), and monosomy 18 may have derived from the ring(18) cell line, given the instability of rings. An unequal distribution of the different cell lines between the trophoblast and the inner cell mass, and differences on the viability of each cell line in different tissues, may explain why the fetal tissues only show the 18p deletion whereas the trophoblast presents the other cell lines.

P03.64

Uptake of prenatal diagnosis after established carrier status of a balanced structural chromosome abnormality in couples with recurrent miscarriage

F. Vansenne, J. C. Korevaar, M. T. M. Franssen, N. J. Leschot, F. van der Veen, P. M. M. Bossuyt, C. A. J. M. de Borgie, M. Goddijn;
Academic Medical Centre, Amsterdam, The Netherlands.

Three to six percent of couples with recurrent miscarriage are carriers of a structural chromosome abnormality. These carriers are offered prenatal diagnosis (PND) in subsequent pregnancies. It is unknown what the effect is of disclosure of the abnormal result of karyotyping in carrier couples on the uptake of PND in subsequent pregnancies. This study evaluates the uptake of PND in carrier couples compared with non-carrier couples.

We collected data of 239 carrier and 389 non-carrier couples presenting for parental karyotyping after two or more miscarriages < 20 weeks of gestation in six centers for Clinical Genetics in the Netherlands, from 1992-2001. PND procedures in subsequent pregnancies were recorded for a minimum of 24 months.

Within the carrier couples 150 out of 239 (63%) underwent a PND-procedure in at least one subsequent pregnancy compared to 111 out of 389 non-carrier couples (29%) ($p < 0.01$). Only 60 out of 239 carrier couples (25%) underwent a PND procedure in all pregnancies.

In the maternal age group < 36 years 136 out of 206 carrier couples (66%) underwent at least one PND procedure.

In the maternal age group ≥ 36 years there was no significant difference between carrier (14 out of 33, 42%) and non-carrier couples (47 out of 98, 48%) in the uptake of at least one PND procedure ($p = 0.41$). Detection of a structural chromosome abnormality in couples with recurrent miscarriage has a marked influence on their decision to undergo PND, although one third of all carrier couples refrained from PND in all pregnancies.

P03.65

Trisomy 13: cytogenetic and prenatal findings

R. G. Paleari¹, I. N. Machado², J. K. R. Heinrich², C. L. Campanhol¹, K. C. Andrade³, R. Barin²;

¹Cell Culture and Cytogenetic Laboratory, CAISM, Unicamp, Campinas, Brazil,

²Cell Culture and Cytogenetic Laboratory, Fetal Medicine Unit, CAISM, Unicamp, Campinas, Brazil, ³Fetal Medicine Unit, CAISM, Unicamp, Campinas, Brazil.

Objective: To describe prenatal sonographic findings and cytogenetic spectrum of fetuses with trisomy 13 in a tertiary fetal medicine center. **Methods:** Retrospective review of cytogenetic laboratory databases identified cases of trisomy 13 from January 1997 to December 2007. Sonographic and cytogenetic findings were evaluated.

Results: Trisomy 13 was identified in 23 out of 298 cases referred to cytogenetic investigation. Free trisomy was identified in most cases ($n = 20$ [87%]) and chromosome structural abnormalities were identified in 3 cases [13%] of 47XY+13,der(13;14)(q10;q10). Although in 2 fetuses one isolated anomaly was detected, twenty-one cases were found

to carry multiple anomalies. The most frequent structural abnormalities detected were facial anomalies (91.3% [$n = 21$]), holoprosencephaly (60.9% [$n = 14$]) and heart defects (56.5% [$n = 13$]). Abnormal amniotic fluid volume was present in 5 cases. Common findings included urinary obstruction ($n = 10$ [43.5%]), microcephaly ($n = 7$ [30.4%]) and polydactyly ($n = 7$ [30.4%]). Following anomalies were verified in four cases (17.4%): cerebral ventriculomegaly, omphalocele, distended bladder, single umbilical artery and clubbed feet. Other findings: 3 cases of abnormal hands, abnormal feet positioning, echodense kidneys and agenesis of nasal bones; two cases of genital defects and agenesis of one ear; one case of ascitis, edema of the scalp, pleural effusion, ectopic kidney, atypical cranial ossification, bowel dilatation and abdominal mass.

Conclusion: Prenatal diagnosis of trisomy 13 may provide options regarding pregnancy management. Recent advances in sonographic imaging may lead to a frequent update of the findings, without invalidating the applicability of prior reports. Thus, this updated information can be useful for trisomy 13 prenatal characterization and diagnosis.

P03.66

Rare case of structural aberration of chromosome 18

R. Skalíkova¹, **D. Konvalinka**¹, J. Dvorackova¹, J. Vseticka², M. Uvírova¹, I. Urbanovska¹, J. Kopeckova¹;

¹CGB laborator, a.s., Ostrava, Czech Republic, ²Private ambulance of clinical genetics, Ostrava, Czech Republic.

Trisomy 18 - Edwards syndrome is the second most common aneuploidy in newborns, with a prevalence between 1 in 3,000 to 1 in 8,000. More than 80 % of cases are caused by free trisomy of chromosome 18, whereas the rest of cases are translocations and other structural aberrations. Subject of this presentation is prenatal capture of rare and special chromosomal constitution of trisomy 18.

Due to positive biochemical screening (routine biochemical screening within the second trimester of gestation) in 17th week of gestation, the amniocentesis and karyotype determination have been indicated in 24-year-old mother. Conventional karyotyping of amniotic fluid cells revealed the presence of pseudoisodicentric 18 chromosome, karyotype: 46, XY, psu idic (18)(p11.32). According to recent literature records the breakpoint at 18p11.32 has not been described yet.

Based on result of investigation, parents have decided to terminate the pregnancy in 20th week of gestation and it was fully genetically indicated. Karyotype determination of parents has been performed with normal result. It indicates to *de novo* origin of this aberration in fetus. Aborted fetus underwent bioptic investigation. Result of the biopsy confirmed diagnosis of Edwards syndrome. Nevertheless, comparison of proband's phenotypic features with clinical manifestation of free chromosome 18 trisomy is very interesting. Some of the symptoms, present almost in all trisomy 18 cases, have not been found. Most obvious is the lack of clenched hands with crossed fingers and missing congenital heart defect, which are already present during intrauterine development.

P03.67

Contribution to prenatal genetic counselling in trisomy 20 mosaicism: two new cases

S. Santucci¹, C. Menozzi², E. Racalbuto³, M. Bergamaschi⁴, M. C. Galassi⁵;

¹Sezione Genetica Medica Territoriale Dipartimento Salute Donna AUSL, Modena, Italy, ²Laboratorio Citogenetica Medica, AO Policlinico, Modena, Italy,

³Laboratorio Mendel Genetica Medica, Modena, Italy, ⁴Ostetricia-Ginecologia Ospedale Pavullo AUSL Modena, Modena, Italy, ⁵Ostetricia-Ginecologia Ospedale Carpi AUSL, Modena, Italy.

Trisomy 20 is one of the common mosaic trisomies detected in amniocentesis and it is associated with normal outcome in over than 90% of cases. However, an abnormal outcome has been observed in 5-10% of cases including fetal demise, intrauterine growth restriction and multiple congenital anomalies.

To contribute in defining fetal prognosis, we report two new cases of trisomy 20 mosaicism detected in amniocentesis requested for maternal age.

Following genetic counselling concerning fetal prognosis and on the basis of normal second level US performed at 20 weeks, couples chose to continue pregnancies without proceeding with further invasive controls.

Two healthy babies were born.

To date, follow-up failed to reveal abnormality on physical or psychomotor development at 1 month or at 1,12,18 months, respectively.

P03.68

Prenatally detected trisomy 7 mosaicism in a child with Blascholinear skin pigmentary variation and developmental delay.

M. Mori¹, F. Santos¹, A. Díaz de Bustamante², M. Palomares¹, L. Fernández¹, M. Muñoz³, P. Lapunzina¹;

¹Department of Medical Genetics, Hospital Universitario La Paz, Madrid, Spain,

²Department of Medical Genetics, Hospital de Móstoles, Madrid, Spain, ³Department of Paediatrics, Hospital de Fuenlabrada, Madrid, Spain.

We report on a girl showing Blaschkolinear skin pigmentary variation associated with developmental delay and minimal facial dimorphisms. The proband's mother was referred for prenatal diagnosis at week 15 of gestation, due to nuchal translucency of 3.5 mm and unique umbilical artery. A chromosomal analysis was performed in cultured amniocytes in two consecutive studies, both showing 46, XX [40%] / 47, XX,+7 [60%]. A study in fetal blood lymphocytes excluded uniparental disomy 7 by microsatellites analysis, and revealed a normal karyotype (46 XX). During pregnancy only intrauterine growth delay was noted. At 45 days of age, the patient was evaluated not disclosing any clinical anomaly and the chromosomal analyses were repeated revealing the previous results. The proband was periodically evaluated showing a progressive developmental delay. In the last review, at 22 months of age, Blaschkolinear skin pigmentation anomalies were detected in both lower extremities and thorax associated with sparse hair, abnormal dentition and a moderate developmental delay. This brings up the possibility that the mosaic trisomy 7 line should still be present in skin cells and it could be present in any other tissue.

When a mosaic trisomy 7 is diagnosed prenatally in cultured amniocytes, and it is not confirmed in a fetal lymphocyte karyotype, it is essential to follow up these patients postnatally to establish an early physical, occupational and language therapy in order to improve their developmental outcome. Absence of pigmentary alterations along Blaschko lines at birth is not exclusive, as they could appear any time during childhood.

P03.69

Foetal ultrasound findings in trisomy 18

A. Ljubic¹, B. Petrovic¹, J. Joksimovic²;

¹Institute for gynecology and obstetrics, Belgrade, Serbia, ²Medicines and medical devices agency of Serbia, Belgrade, Serbia.

Among liveborn children, trisomy 18 is the second most common autosomal trisomy after trisomy 21. The disorder/condition is characterised by severe psychomotor and growth retardation, microcephaly, microphthalmia, malformed ears, micrognathia or retrognathia, microstomia, distinctively clenched fingers, and other congenital malformations. Approximately 95% of conceptuses with trisomy 18 die in embryonic or foetal life; 5-10% affected children survive beyond the first year of life. The aim of this study was to estimate the correlation between pathological foetal ultrasound findings and trisomy 18.

Over the past five years (2003-2008) we analyzed fetal blood samples for chromosome abnormalities. Samples were taken by cordocentesis and processed using standard techniques. All specimens were G-banded using trypsin-Giemsa. Sixteen metaphase cells were analyzed for chromosomal constitution in each sample.

From 1248 samples of fetal blood analyzed for chromosomal abnormalities, there were 11 (0,88%) with complete trisomy 18. We found no mosaicism, or partial trisomy 18. From 11 fetuses with trisomy 18, 9 (81,8%) had some anomaly detected by ultrasound. Ultrasound findings were polyhydramnion, IUGR, oligohydramnion, heart defect, hydrocephalus and omphalocele.

In the last 5 years in our laboratory, the incidence of trisomy 18 was 0,9%. In all cases, trisomy 18 was complete. About 81% of the fetuses with trisomy 18 had ultrasonographically detected anomalies.

P03.70

STRs multiplex assay for rapid and economic detection of UPD 15

R. Cascella¹, C. Peconi¹, C. Sinibaldi¹, E. Giardina¹, A. Nardone¹, G. Novelli^{1,2,3};

¹Department of Biopathology and Centre of Excellence for Genomic risk Assessment in Multifactorial and Complex Diseases, School of Medicine, Uni-

versity of Rome "Tor Vergata", Rome, Italy, ²Department of Cardiovascular Medicine, University of Arkansas for Medical Sciences., Little Rock, AR, United States, ³Fondazione Livio Patrizi, Rome, Italy.

Uniparental disomy (UPD) describes the inheritance of both homologues of a pair of chromosomes from only one parent. The clinical impact of UPD and associated imprinting disorders, such as Prader-Willi syndrome (PWS) and Angelman syndrome (AS) increasingly have come to our attention. Chromosome 15 UPD testing is also relevant in various prenatal diagnostic conditions including apparent confined placental mosaicism (CPM), homologous and nonhomologous Robertsonian translocations involving chromosome 15 and 14, and as genomic biomarker for detecting chromosome origin. We developed and validated a two fluorescent STR multiplex assays for a rapid and economic detection of UPD 15 by capillary electrophoresis. Eight informative markers have been selected on the basis of their expected heterozygosity and chromosomal localization. We developed two different four-plex PCR: multiplex 1 containing microsatellites D15S1007, D15S205, D15S1019 and D15S130; multiplex 2 containing markers D15S988, D15S979, D15S128 and D15S131. In order to assess and validate the polymorphic information content (PIC), allele frequencies and heterozygosity of selected markers we typed 100 unrelated individuals. Statistical analysis revealed a probability to obtain an informative assay of 99.1% for multiplex 1 and 98.8% for multiplex 2. Genotyping results of the two four-plexes were compared with those generated in singleplex reactions for the same samples revealing a concordance rate of 100%. To summarize, UPD exclusion/confirmation is expected to be needed in an increasing number of cytogenetic and clinical cases and we believe that the availability of a rapid test for its recognition should be highly suitable by both genetic laboratories.

P03.71

Mild-borderline ventriculomegaly as a marker for structural chromosome abnormalities

K. Wrizli¹, A. Veble¹, M. Volk¹, V. Cerar², B. Šajina Stritar², S. Pušenjak², B. Peterlin¹;

¹Institute of Medical Genetics, UMC Ljubljana, Ljubljana, Slovenia, ²Perinatology Unit, Department of Obstetrics and Gynecology, UMC Ljubljana, Ljubljana, Slovenia.

Ventriculomegaly is a descriptive term for enlargement of the intracranial ventricular system. It is defined as a ventricular atrium at any gestation, which measures 11 mm or greater. The frequency of chromosomal anomalies reported in the literature in fetuses with ventriculomegaly ranges from 3 to 27%. Separate analysis for mild and moderate ventriculomegaly is not carried out.

We report two prenatal cases with mild ventriculomegaly and structural chromosome abnormalities.

Case 1: prenatal ultrasound at 21 weeks of gestation noted the fetus to have mild ventriculomegaly (Vhposterior = 11 mm). Chromosome analysis following amniocentesis demonstrated a 1p36 deletion, which was confirmed by fluorescence in situ hybridization (FISH). Subsequent analysis revealed an unbalanced translocation between 1p and 10q resulting in 1p36.1->pter deletion and 10q26.3->qter duplication. Case 2: at 21 weeks of gestation mild ventriculomegaly (Vhposterior = 11 mm) and intracardiac hyperechogenic focus were detected. Cytogenetic analysis of cultured amniocytes revealed an inverted duplication of the short arm of chromosome 9. The karyotype was: 46,XY,dup(9)(p13p24). In both cases parents opted for termination of pregnancy.

We conclude that borderline ventriculomegaly may occur in association with structural chromosomal abnormalities, and propose that karyotype is offered and FISH analysis is done where a cryptic rearrangement is suspected following classical G-banding techniques.

P03.72

Prenatal diagnosis of restrictive dermopathy

C. Daumer-Haas¹, L. T. T. Huong², N. T. Duong², I. Hausser³, M. Wehner², K. P. Gloning¹;

¹Pränatal-Medizin München, Munich, Germany, ²Institut für Humangenetik, Greifswald, Germany, ³Dermatologische Klinik, Universität, Heidelberg, Germany.

Restrictive dermopathy (OMIM 275210) is a rare lethal autosomal recessive disorder characterized by rigid skin, facial dysmorphism (hypertelorism, small nose, open mouth), multiple joint contractures, skel-

etal anomalies (thin ribs, hypoplastic clavicles) and lung hypoplasia. We report prenatal ultrasound findings and molecular genetic diagnosis of this disorder in a woman whose first child died a few hours after birth. From clinical appearance restrictive dermopathy was suspected. There was distant consanguinity of the parents.

Ultrasound examinations in the 29th week of a further pregnancy showed growth retardation, short extremities, reduced fetal movements and abnormal shrunken amnion membranes. Additional findings of absent clavicles, thin ribs, an abnormal face with small nose and open mouth strongly suggested the diagnosis of restrictive dermopathy. The shrunken and separated amnion membranes seem to be recorded for the first time in restrictive dermopathy. The child was born in the 32nd week of gestation after premature rupture of membranes and died 30 minutes after birth. It showed the expected facial anomalies, a very tight translucent skin with venal pattern and contractures. Morphology of the skin revealed typical findings in restrictive dermopathy with absent rete ridges of the epidermis, hypoplastic appendage structures, very thin dermis and rarefied elastic fibres.

The assumed diagnosis of restrictive dermopathy was confirmed by molecular genetic analysis. A homozygous mutation c.1085-1086insT in the ZMPSTE24 gene was detected. In the following still ongoing pregnancy early molecular genetic prenatal diagnosis could be offered after chorionic villi biopsy resulting in an unaffected fetus.

P03.73

Fraser Syndrome In Two Fetuses: Clinical, Radiological And Pathological Evaluation

F. Ekici, O. Sezer, M. Tosun, F. Karagoz, M. Ceyhan, B. Ozyilmaz, M. Ture, E. Malatyalioglu, G. Ogur;

Ondokuz Mayıs University Medical Faculty, Samsun, Turkey.

Fraser syndrome (FS; OMIM 219000) is an extremely rare autosomal recessive disorder characterized by cryptophthalmos, cutaneous syndactyly, ambiguous genitalia, laryngeal/genitourinary malformations, craniofacial dysmorphism and mental retardation. Here, we present two fetuses with FS diagnosed after termination of pregnancy because of severe fetal abnormalities.

Case1: At the 18th week a cordocentesis was performed to the first pregnancy of a consanguineous 26 year-old father and 21 year-old mother because of intraabdominal ascites, unilateral renal agenesis, and cystic adenomatoid malformation of lung (type3)[CCAML3]. Fetal karyotype was 46,XY. After genetic counselling, parents decided to terminate the pregnancy. Fetus presented bilateral cryptophthalmos, hypertelorism, ear/nose anomalies, tetramelic cutaneous syndactyly, single artery/vein, small penis, and scrotal hypoplasia. Autopsy revealed unilateral right renal agenesis, left renal dysgenesis but no CCAML3.

Case2: Amniocentesis for was performed at 25th week of gestation of a 29 year-old father and 26 year-old mother because of ultrasound abnormalities: intraabdominal ascites, bilateral renal agenesis, CCAML3, oligo-anhydramnios, nuchal edema, intracardiac hyperechogenic focus, hyperechogenic bowel. Parents were consanguineous. One previous pregnancy ended spontaneously; another was medically aborted. Karyotype was 46,XX. Parents decided to terminate the pregnancy. Fetus showed facial asymmetry, right sided cryptophthalmos, ear/nose anomalies, tetramelic cutaneous syndactyly, umbilical hernia, anterior abdominal wall defect, immature external genitalia, and anal atresia. X-ray revealed 11 ribs. Autopsy confirmed bilateral renal agenesis; gonads were immature, undifferentiated.

P03.74

Outcome of fetuses with central nervous system anomalies detected by ultrasound during pregnancy: clinical, cytogenetic, radiological and pathological data from 18 fetuses

G. Ogur, M. Tosun, Ö. Sezer, M. Ceyhan, T. Alper, F. Ekici, B. Özyilmaz, O. Aydın, M. Türe, E. Malatyalioglu;

Ondokuz Mayıs University Medical Faculty, Samsun, Turkey.

Fetal brain anomalies constitute a heterogeneous group of disorders with different prognostic outcome. Affected fetuses mostly come to attention because of ultrasound (US) and often on indication termination of pregnancy, before 24th of gestation, and with parental consent, occurs. Here we report outcome of 18 fetuses with brain malformations initially seen on routine US screening during pregnancy. After termination of pregnancy a thorough examination of the fetus, followed by

imaging (X-ray, MRI) and autopsy was done.

Out of 18 fetuses 11 were with chromosomal abnormalities(61%): der(1) (p36,1;p21,3), mosaic trisomy 8, trisomy 18 (two cases), trisomy 21 (one case), 47,XXX, 45, X, 47,XXY, 49,XXXXY, "de novo" inv(9)(p11q13), and a homozygous inv(6)(p23q23). Seven patients presented monogenic syndromes(39%):skeletal dysplasias(3 cases: Short-Rib Polydactyly Saldino-Noonan Type, Thanotophoric Dysplasia San Diego Type and Jarcho-Levin syndrome), alobar holoprosencephaly(2 cases), iniencephaly(one case), Dandy-Walker syndrome(one case) and cranial teratoma (one case). The fetus with iniencephaly showed also paracentric inversion of "both" chromosomes 6. The parents, both were carriers for inv(6q). Following clinical diagnosis all families received genetic counselling and fetal DNAs were isolated for possible Gene mutation analysis.

We believe that management of fetal malformations is an extensive, heavy "team work" yet the best way of structuring bases for phenotype-genotype correlations.

P03.75

Congenital lamellar ichthyosis: TGM1 gene mutation analysis and prenatal diagnosis of a twin pregnancy

B. Ozyilmaz¹, M. Tosun¹, B. Demir¹, C. Goktas¹, T. Oztas¹, S. Bale², G. Ogur¹;

¹Ondokuz Mayıs University Medical Faculty, Samsun, Turkey, ²GeneDx, Gaithersburg, MD, United States.

Autosomal recessive congenital ichthyosis include several subtypes: lamellar ichthyosis, Harlequin ichthyosis and non-bullous congenital ichthyosiform erythroderma. Differential diagnosis of these subtypes can be obtained with strict clinical criteria which is crucial for gene-mutation selection. In this report we present prenatal diagnosis of "Congenital Lamellar Ichthyosis" of a mother with twin pregnancy whose previous child was diagnosed with lamellar ichthyosis.

The previous affected child had a history of *erythroderma* and *ectropion* since birth. At referral to our center, he presented *dry skin* with *dark scales* over his entire body. Scales were also present over the cutaneous surfaces of *flexural accentuation*. *Hyperkeratotic fissures covering palms and soles* of the hands and feet were remarkable. Facial skin under eye level was intact and eyelids exhibited mild *ectropion*. The patient had no other medical problems, and his growth and development have been normal.

TGM1 gene analysis of the index patient showed homozygous mutation at Exon 5, G278R. Amniocentesis was performed for biamniotic twin pregnancy. TGM1 gene analysis revealed heterozygous TGM1 Exon 5 G278R mutations in both fetuses rendering both fetuses being clinical carriers. Karyotypes of the fetuses were normal. Family decided to continue the pregnancy. At birth twins were normal.

P03.76

Smith-Lemli-Opitz Syndrome, Prenatal Biochemical and Molecular Diagnosis

B. Özyilmaz¹, G. Celep¹, L. E. Kratz², M. Witsch-Baumgartner³, G. Ogur¹;

¹Ondokuz Mayıs University Medical Faculty, Samsun, Turkey, ²Kennedy Krieger Institute, Baltimore, MD, United States, ³Department of Medical Genetics, Mol. Clin. Pharmacology, Innsbruck, Austria.

Introduction: Smith-Lemli-Opitz Syndrome is an autosomal recessive disorder presented with clinical hallmarks like characteristic facial phenotype, cleft palate, thumb-toe abnormalities and ambiguous genitalia. Prenatal and postnatal diagnosis is possible by the detection of low cholesterol and high 7DHC levels in both serum and amniotic fluid. In this report we present a 40 day-old baby diagnosed SLOS Type 1 and prenatal diagnosis in the family's subsequent pregnancy.

Case Presentation: The case presented with growth retardation, cleft palate, facial dysmorphism, unilateral oligodactyly, unilateral congenital cataract and ambiguous genitalia. Biochemical parameters showed low serum cholesterol and high serum 7DHC levels. The child was diagnosed as SLOS. Due to family's demand, prenatal diagnosis during the subsequent pregnancy was performed; the parents were checked for DHCR7 gene mutations. c.384-IVS5+4del and p.S397L mutations were found to be heterozygous in the mother and father respectively. c.384-IVS5+4del is a previously unidentified mutation for SLOS.

An amniocentesis was performed at 16th week of gestation. Amniotic fluid showed normal levels of 7-Dehydrocholesterol and molecular analysis revealed normal DNA results. Cytogenetic analysis revealed

a 46,XY karyotype.

Conclusion: Biochemical analysis of the amniotic fluid through 7DHC levels is a rapid and efficient prenatal diagnosis test for SLOS and is family relieving before a results of molecular analysis is achieved. Both pre- and post-natally, association of cleft palate, ambiguous genitalia and oligodactyly in a patient should prompt the physician to evaluate SLOS.

Partial monosomy of chromosome 8p and partial trisomy of chromosome 7p associated with a Fryns syndrome-like phenotype: Prenatal diagnosis

C. Fournéau, S. Rombout, B. Grisart, C. Verellen-Dumoulin; Centre de Génétique Humaine, Institut de Pathologie et de Génétique, Gosselies, Belgium.

We wanted to insist on the importance of a good resolution chromosome analysis for finding subtle chromosomal abnormalities in prenatal diagnosis specially when there are abnormal ultrasound findings. We report a prenatal diagnosis performed following the discovery at ultrasound of a diaphragmatic hernia and a Dandy Walker malformation at 16 weeks of pregnancy.

A decision was made to interrupt the pregnancy and the fetal autopsy revealed signs of a Fryns syndrome that is thought to be inherited in an autosomal recessive way: craniofacial dysmorphism (macrocephaly, short webbed neck, coarse face, flat and broad nasal bridge, anteverted nostrils, hypertelorism, microretrognathia, large mouth with thin lips, low-set ears with posterior angulation), Dandy-Walker malformation, diaphragmatic hernia, small penis with hypospadias.

Cytogenetic analysis on the amniotic fluid showed a partial monosomy 8p associated with a partial trisomy 7p which was initially interpreted as a duplication 8p.

When the parents karyotypes were established, we discovered that the father had a terminal reciprocal translocation between the short arm of chromosome 8 and the short arm of chromosome 7 with karyotype 46,XY,t(7;8)(p21;p23).

The fetus had thus inherited an unbalanced translocation with karyotype 46,XY,der(8)t(7;8)(p21;p23)pat.

Array CGH and FISH analysis are under way in order to characterize the break points.

The APC gene mutations status in Polish FAP patients

A. Plawski¹, M. Podralska¹, D. Nowakowska², T. Banasiewicz³, J. Paszkowski³, P. Krokowicz³, E. Czkwanianc⁴, W. Cichy³, J. Lubinski⁵, G. Kurzawski⁵, A. Dobrowolska-Zachwieja³, J. Steffer³, M. Drewno³, R. Slomski¹;

¹Institute of Human Genetics, Poznan, Poland, ²Institute of Oncology, Warszawa, Poland, ³Karol Marcinkowski University of Medical Sciences, Poznan, Poland, ⁴Institute of Polish Mother's Memorial Hospital, Lodz, Poland, ⁵Department of Genetics and Pathology, Pomeranian Medical University, Szczecin, Poland.

Familial adenomatous polyposis (FAP) is a genetically conditioned predisposition to occurrence of numerous adenomatous polyps in colon and rectum. The polyps arises in second decade of life and left untreated develop to the tumor. Other extracolonic features may include polyps in the upper parts of the gastroenterological tract, desmoid tumours, ocular lesions, osteomas, dental abnormalities, and malignancies in other organs. FAP incidence is estimated at 1/10,000. FAP arises due to germ line mutations in the adenomatous polyposis coli (APC) gene, which was first described in 1991. The APC gene mutations are studied at the Institute of Human Genetics in Poznan for last 10 years. The Institute of Human Genetics in Poznan cooperates with medical centers from all country, what permitted us to create the DNA bank for Polish FAP patients. Till now samples from 340 families were collected. Seven hundred DNA samples from Polish FAP families were banked so far. The APC gene we screened for mutation in 300 probands. We identified 74 point mutations in 124 FAP families. The detected mutation can be considered characteristic for Polish population due to 34 types of them has not described in other population. Among detected mutations seven occurred in two or to the greater number of families. Occurrence of the APC gene large rearrangements was studied in 95 families. We identified rearrangements in 24 fami-

lies in two cases it were deletion of whole APC gene. This work was founded by the Ministry of Education and Science, Poland, grant number 2PO5A10728

P04.002

Frequent association of sporadic desmoid tumors with germline APC mutations

T. A. Muzaffarova¹, O. V. Novikova², I. V. Droshneva², E. K. Ginter¹, A. V. Karpuhin¹;

¹Research Centre For Medical Genetics, Moscow, Russian Federation, ²Moscow Herzen Oncology Institute, Moscow, Russian Federation.

As it is known somatic APC mutations are present in desmoid tumors. However there is no information about the role of germline APC mutations in patients with desmoid tumors and without history of familial adenomatous polyposis (FAP).

We examined 31 patients (17 female and 14 male) with apparently sporadic desmoid tumors and without clinical features or family history of FAP. Peripheral blood lymphocytes from these patients were investigated for the APC gene mutations.

Germline APC mutations were found for 6 of 31 the patients (19%). Four mutations - 1462del5, 1465delAG, 1525insT and R2505Q were found for the first time. The mutation 1465delAG was seen twice. The mutations were located predominantly between 1450 and 1525 codons of the APC gene (4 of 5 mutations).

The age of desmoid diagnosis among patients with the APC mutations was ranged from 1 month to 23 years. Colonoscopy was performed for two patients with germline APC mutations and highest age. There were no polyps in colon of 25 years old female. Another patient, 19 years old female had gastric polyps and no colon polyps. In our sample there were six patients with multiple desmoids tumors and five of them were found with germline APC mutations. One patient with APC mutation had intraabdominal desmoid at age 4 year. Thus for the first time it is shown association of sporadic desmoid tumors with APC germline mutations. The patients with germline APC mutations are characterized by early disease onset and severe desmoid phenotype.

P04.003

Molecular Analysis of the APC gene in Families Affected by FAP: 2 Novel Mutations

M. Noruzinia¹, N. Vasilj²;

¹Tarbiat Modares University, Tehran, Islamic Republic of Iran, ²Department of genetics, School of Sciences, Azad Olum Tahghighat University, Tehran, Iran, Tehran, Islamic Republic of Iran.

Introduction: Familial adenomatous polyposis (FAP) is an autosomal dominantly inherited susceptibility to colon cancer with high penetrance, characterized by more than 100 adenomatous polyps in the colon and rectum. Additional features may include desmoids tumors, polyps in the upper gastrointestinal tract, osteomas and congenital hypertrophy of the retinal pigment epithelium (CHRPE). APC (Adenomatous Polyposis Coli) gene is mutated in most of these carriers. Pre-symptomatic genetic diagnosis in this syndrome is obligatory as near 100% of carriers of deleterious mutations will present colon cancer by 40 years. The APC gene has 15 exons and an ORF with 8538 nucleotides which code a protein with 2843 amino acids.

Materials & Methods: CSGE on APC was set up and used as screening method to analyze APC alterations. Direct sequencing was used to confirm the presence of mutation or polymorphism.

Results: we found deleterious mutations in all patients. Two novel mutations c.3921_3925del AAAAG in MCR and c.1862C>G in exon 14 of APC were found in 2 families with classical FAP

Conclusion: Conformation Sensitive Gel Electrophoresis can be used as a simple, cost-effective and sensitive mutation screening test in complex genes where sequencing as the gold standard of mutation detection techniques is expensive to use in the first line.

15 years of familial adenomatous polyposis diagnostics in the Czech Republic

K. Veselá, J. Štekrová, M. Florianová, K. Zídková, J. Kotlas, M. Kohoutová;

Institute of Biology and Medical Genetics of the 1st Faculty of Medicine Charles University and General Teaching Hospital, Prague, Czech Republic.

Familial adenomatous polyposis (FAP) is an autosomal dominant syndrome with almost 100 % risk of colorectal cancer. FAP exists in two

forms. The typical FAP is characterized by hundreds to thousands of colorectal adenomatous polyps and by extracolonic manifestations. An attenuated form of FAP (AFAP) is characterized by less than 100 adenomas and later onset of the disease. Incidence of FAP/AFAP in the Czech Republic is 1/ 5000 - 7500.

Since 1993 we have detected presence of mutations in adenomatous polyposis gene (APC) and in the last 5 years also mutations in the base excision repair MUTYH gene in FAP families. The mutation in MUTYH gene leads to MUTYH associated polyposis (MAP). The MAP is an autosomal recessive form of polyposis with manifestation similar to AFAP.

We have examined 280 unrelated patients with a suspicion of FAP/AFAP. By the combination of different molecular genetic tests (DGGE, PTT, MLPA, DHPLC, and sequencing) mutation detection rate was 77 % in classical FAP and 40 % in AFAP for APC gene in case the patients met strict diagnostic criteria. For MUTYH gene was mutation detection rate lower than we supposed. In Czech population we discovered 48 unique APC mutations and 3 large deletion of gene.

If the causal mutation is identified, all carriers of the mutation undergo second genetic consultation and the results of molecular genetic testing are used both when stating the predictive diagnosis and in the clinical management of patients, eventually for the prenatal testing.

Molecular analysis of the APC and MYH genes in Galician and Catalonian FAP patients: a different spectra of mutations?

N. Gomez-Fernandez¹, S. Castellvi-Bel², C. Fernandez-Rozadilla¹, F. Balaguer², M. Magdalena¹, O. Lortes¹, J. Muñoz², I. Madrigal², M. Mila³, A. Vega¹, A. Castells², A. Carracedo¹, C. Ruiz-Ponte¹;

¹Fundacion Publica Galega de Medicina Xenomica-SERGAS, Grupo de Medicina Xenomica-USC, CIBER-ER, Santiago de Compostela, Spain, ²Department of Gastroenterology, Institut de Malalties Digestives i Metabòliques, Hospital Clínic, CIBEREHD, IDIBAPS, Barcelona, Spain, ³Biochemistry and Molecular Genetics Department, Hospital Clínic, CIBER-ER, IDIBAPS, Barcelona, Spain.

Familial adenomatous polyposis (FAP) is an autosomal dominant-inherited colorectal cancer syndrome caused by germline mutations in the APC gene. Recently, patients with multiple colorectal adenomas and also patients with FAP but without detectable germline APC mutations have been found to carry biallelic mutations in MYH.

We analysed the mutational spectrum of the APC gene in 80 unrelated patients (46 Galician and 34 Catalonian) with classical FAP or multiple polyposis, and we also investigated the contribution of MYH germline mutations in those APC-negative patients.

Germline mutations including large deletions in the APC gene were found in 38% of patients. The two commonest hotspots at codons 1061 and 1309 of the APC gene, account for 15% and 12% respectively of the APC-positive families, but were reported mainly in Catalonian families. Thus, mutation at codon 1061 represents the 23% (5/13) of the Catalonian positive families whereas was not found in 17 APC-positive Galician families. The same trend was observed for the codon 1309 mutation. Similar results had been already observed in a previous study with Galician families and could be due to the genetic isolation of this population. Haplotype analyses of these recurrent mutations should be carried out in Catalonian families to investigate the possibility of a common ancestry.

Twenty percent of the APC-negative patients carried biallelic MYH germline mutation, and the two most frequent mutations reported (p.Y165C and p.G382D) were observed. Therefore, MYH analysis is recommended for all APC-negative families, although MYH cannot explain all cases of FAP.

P04.006

Frequent identification and familial aggregation of hyperplastic polyposis syndrome in the Spanish region of Navarra

A. Alonso¹, A. Guerra², M. Montes³, S. Moreno¹, F. Garcia-Amigot¹, **M. Artigas¹**;

¹Medical Genetics Dpt. Hospital Virgen del Camino, Pamplona, Navarra, Spain, ²Gastroenterology Dpt. Hospital Virgen del Camino, Pamplona, Navarra, Spain, ³Pathology Dpt. Hospital Virgen del Camino, Pamplona, Navarra, Spain.

Background: Hyperplastic polyposis syndrome (HPS) is a rare disorder characterized by multiple hyperplastic polyps (HP), and a limited number of adenomas, serrated adenomas and colorectal cancers. Scarce previous series (1-38 patients) have reported exceptional fa-

miliar aggregation and unknown prevalence with predilection for European population.

Aim: To study the prevalence and characteristics of HPS in our region (600,000 inhabitants).

Methods: Retrospective search of patients from the familial cancer registry, gastroenterology and pathology departments fulfilling WHO criteria, or showing essential traits of HPS.

Results: 12 patients from 9 different families fulfilled WHO criteria with a mean of 39 HP per patient (pp), 75% (9/12) mainly right sided; 3.44 adenomas (pp); 2.33 serrated adenomas (pp), and an incidence of colon cancer of 33% (4/12) (mean age=41y). Remarkably, in two families HPS seemed to be transmitted as a hereditary condition. In the rest, 60% of the patients had at least one 1st degree relative with colon cancer (mean age=56y) and 30% had relatives with >5 HP. Besides, we have characterized 6 extra individuals from 5 different families not fulfilling WHO criteria but who met more than one of the essential characteristic of HPS.

Conclusion: The prominent number of patients with hyperplastic polyposis and the familial aggregation in our series support the hypothesis of a higher prevalence of this condition in our region, suggesting a common genetic background. Furthermore, in specially predisposed populations, a reassessment of WHO criteria is probably needed for the diagnosis of additional cases.

P04.007

The study of the mutations of BMPR1A and SMAD4 genes in the group of Polish JPS patients

M. Podralska¹, W. Cichy², R. Slomski¹, M. Teisseyre², P. Mankowski¹, E. Czkwanianc², D. Nowakowska², B. Kozak-Klonowska², A. Plawski¹;

¹Institute of Human Genetics, Poznan, Poland, ²Karol Marcinkowski University of Medical Sciences, Poznan, Poland, ³Department of Gastroenterology, Hepatology and Immunology, The Children's Memorial Health Institute, Warszawa, Poland, ⁴Department of Pediatrics and Gastroenterology, Institute of Polish Mother's Memorial Hospital, Lodz, Poland, ⁵Genetic Counseling Unit Cancer Center and Institute of Oncology, Warszawa, Poland, ⁶Regional Oncology Center, Kielce, Poznan, Poland.

Juvenile Polyposis Syndrome (JPS, MIM # 174900) is an autosomal dominant disorder, characterized by predisposition to developing juvenile polyps. These polyps are hamartomatous lesions of gastrointestinal tract, especially colon and rectum. The juvenile polyps are typified by markedly expanded lamina propria containing dilated cystic glands, an inflammatory infiltrate and show a normal epithelium with dense stroma. The frequency of Juvenile polyposis syndrome is estimate to occur once in every 100000 newborn. Risk of gastrointestinal malignant transformation in JPS patient is increased and ranges more than 60%. Occurrence of the colon cancer is two fold higher in the upper parts of the gastrointestinal tract. Development of the juvenile polyps is caused by mutation in one of two genes associated with JPS. First of them is bone morphogenetic protein receptor 1A gene (BMPR1A also known as ALK3), which encodes a type I cell surface receptor, a serine/threonine kinase receptor, involved in bone morphogenetic protein signaling pathway (BMP). Second one is SMAD4 gene (also known as MADH4 or DPC4). The protein product of this gene is intracellular mediator of TGFβ superfamily signaling pathway. In result of research we observed four mutations. Using screening methods were found two mutations in the BMPR1A gene and two in the SMAD4 gene. Presented results are preliminary stage study which main aim is to determine the mutation spectrum of the BMPR1A and SMAD4 genes in Polish JPS patients. The study was financed by the Ministry of Education and Science, Poland, grant number 2PO5E02630

P04.008

Timing and Importance of genomic instability in colorectal tumorigenesis and association with clinic-pathological features

A. D. Beggs^{1,2}, M. Abulafi², A. Arnaouf², I. P. M. Tomlinson³, S. V. Hodgson¹;

¹St Georges University of London, London, United Kingdom, ²Mayday University Hospital, London, United Kingdom, ³Cancer Research UK, London, United Kingdom.

Aims:

- 1) To test the hypothesis that somatic genetic instability is a necessary driver of early colorectal carcinogenesis
- 2) To investigate the sequence of molecular carcinogenic changes.

Techniques

There is good evidence for the hypothesis that colorectal carcinoma initiation is progression from benign adenoma to carcinoma via a series of sequential somatic genetic and epigenetic changes. However it is not known whether genomic instability is a necessary initiating factor.

We are currently recruiting patients with a known family history of colorectal carcinoma or who are undergoing surveillance colonoscopy for recurrent polyps. These patients attend screening colonoscopy, where polyps are identified and removed. To date, 137 patients have been recruited with a total of 195 polyps.

A pilot study, looking at markers (K-ras, BRAF, MSI, LOH) of genomic instability in 168 polyps in 107 patients demonstrated that this was technically feasible.

We will collect 50 hyperplastic polyps and 300 adenomatous polyps, including 30 serrated adenomas, and 10 polyps from patients with Lynch syndrome.

Isolated crypts will be extracted from polyps and tested for genomic instability using several parameters: chromosomal loss/gain, copy number variation, LoH, MSI and CPG-Island Promoter Methylation. We will also screen for mutations in known target genes.

Results will be compared with normal tissue, to determine when/if genomic instability occurs, and it's relationship to other (epi)genetic changes

Conclusions

We hope to elucidate the earliest drivers of colorectal carcinogenesis: when each form of genomic instability occurs, whether they initiate carcinogenesis and how this relates to family history and clinico-pathological features.

P04.009

Microsatellites instability and mismatch repair genes mutations in hereditary nonpolyposis colorectal cancer

C. IANCU¹, C. Vrabie², D. Iancu¹, G. Girbea¹, A. Constantinescu¹, C. Constantinescu¹, E. Neagu¹, L. Barbarii²;

¹National Institute of Legal Medicine, Bucharest, Romania, ²National Institute "Victor Babes", Bucharest, Romania.

Background: Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant cancer predisposition syndrome caused by germ-line mutations in DNA mismatch repair genes. Therefore diagnosis of genomic deletions of one or more exons of the MSH2 and MLH1 genes and the analyse of microsatellite instability (MSI) from a minimal amount of highly damaged DNA is difficult.

Methods. Formalin-fixed and paraffin-embedded tissue samples from 25 HNPCC patients were analysed for microsatellite instability (MSI) using a panel of 7 markers (BAT-25, BAT-26, NR-21, NR-24, MONO-27, Penta C and Penta D) included in a commercial kit. MLPA tests were also performed to screen for major mutation in the mismatch repair genes MLH1 and MSH2.

Results. The study revealed a 58% microsatellite instability pattern for the 25 unrelated Romanian HNPCC patients. 5 to 10% of major alterations detected on the MLH1 and MSH2 genes are subject for further characterization.

Conclusions. So far, family history, MSI and MMR gene mutation analysis become critical parameters for HNPCC genetic characterization and genetic counseling.

P04.010

Microsatellite instability and promotor hypermethylation of MLH1 and MSH2 in Bulgarian patients with sporadic colorectal cancer

A. V. Mitkova¹, T. Vlaykova², G. Stancheva¹, T. Kadiyska³, M. Gulubova⁴, E. Kostadinov⁵, D. Damyanov⁶, G. Cirovski⁶, Y. Yovchev⁶, I. Kremenski³, V. Mitev⁷, R. Kaneva¹;

¹Molecular Medicine Centre, Medical University-Sofia, Sofia, Bulgaria, ²Dept. Chemistry and Biochemistry, Trakia University, Stara Zagora, Bulgaria, ³National Genetic Laboratory, University Hospital of Obstetrics and Gynaecology "Majchin Dom", Medical University-Sofia, Sofia, Bulgaria, ⁴Dept. General Surgery, Medical Faculty, Trakia University, Stara Zagora, Bulgaria, ⁷Dept. Chemistry and Biochemistry, Medical University-Sofia,

Sofia, Bulgaria.

Inactivation of the genes involved in DNA mismatch repair is associated with microsatellite instability (MSI) and loss of heterozygosity (LOH). Mutations in MLH1 and MSH2 genes are usually the cause of hereditary colorectal cancers (CRC), such as HNPCC, while microsatellite instability in sporadic CRC often results from epigenetic inactivation of *hMLH1* due to DNA promotor methylation.

We examined MSI in 98 patients with sporadic CRC and the methylation status of the *MLH1* and *MSH2* promotor regions in the cases with MSI/LOH. MSI was evaluated in a panel of five microsatellite markers (*BAT26*, *D5S346*, *D18S35*, *D2S123* and *FGA*) and the hypermethylation assessed by methyl-specific PCR (MSP) of bisulfite converted DNA. The PCR products were analyzed on agarose gel electrophoresis, following by direct sequencing.

Our results demonstrated MSI/LOH in 29 patients (29.5%) with sporadic colorectal cancer. Among them the promoter hypermethylation of *MLH1* was observed in 14 (48.3%) of the cases, whereas promoter hypermethylation of *MSH2* was observed only in one case (3.4%). The epigenetic changes of *MLH1* were associated with loss of the protein expression.

Conclusions: Widespread promotor methylation of tumor suppressor genes is a common mechanism of gene inactivation during tumorigenesis. Our results suggest that microsatellite instability in Bulgarian patients with sporadic CRC and the epigenetic inactivation of *hMLH1* in association with DNA methylation occurs in similar frequency to relative studies of sporadic colorectal cancer. The promoter hypermethylation of *MSH2*, although a rare event, is also a possible cause of mismatch repair system deficiency in this type of CRC.

P04.011

Implication of MSH6 mutations in colorectal cancer (CRC) patients carrying a monoallelic MYH mutation

M. D. Giráldez¹, F. Balaguer¹, T. Caldés², N. Gómez-Fernández³, C. Ruiz-Ponte³, J. Muñoz¹, V. Gonzalo¹, T. Ocaña¹, J. Clofent⁴, A. Carracedo⁵, A. Castells¹, S. Castellvi-Bel¹, A. E. G. Gastrointestinal Oncology Group⁵;

¹Gastroenterology, Hospital Clínic, IMDiM, CIBEREHD, IDIBAPS, Barcelona, Spain, ²Oncology Molecular Lab, Hospital Clínic Universitario San Carlos, Madrid, Spain, ³Grupo de Medicina Xenómica-USC-FPGMX-CIBERER, Santiago de Compostela, Spain, ⁴Gastroenterology Department, Hospital Meixoeiro-CHUVI, Vigo, Spain, ⁵Asociación Española de Gastroenterología, Barcelona, Spain.

Background. CCR risk associated with germline monoallelic *MYH* mutations remains controversial. Nevertheless, a slight increased risk has been suggested. *MYH* and *MSH6* proteins act together during the DNA reparation process. It has been shown that individuals harboring mutations in both genes could have an increased CRC risk.

Aim. To evaluate the prevalence of *MSH6* mutations in CRC patients carrying a monoallelic mutation in *MYH*.

Patients and methods. We analyzed the prevalence of *MSH6* mutations in a CRC patients cohort with and without a monoallelic *MYH* mutation (group I, n=26 and group II, n=50, respectively), and in another cohort including healthy controls with and without a monoallelic *MYH* mutation (group III, n=21, group IV, n=21, respectively). Patients and controls were recruited from EPICOLON and Hospital Clinic, respectively. Mutational screening was performed by TaqMan, SSCP, DHPLC and sequencing.

Results. We detected three germline *MSH6* mutations in group I (11.5%), a missense variant (R635G), a change in 3'UTR region (4098A>C) and a nonsense mutation (Q982X). We did not detect any *MSH6* mutation in groups II and IV, whereas only one was found in group III (4.8%) (M1326G). *MSH6* mutations were more frequently found in CRC patients with a monoallelic *MYH* mutation than in non-carriers (11.5% vs 0%, p=0.037).

Conclusions. CRC patients harboring a monoallelic *MYH* mutation may carry more frequently a *MSH6* mutation than patients without them. We could hypothesize that the CRC predisposition associated with a mutation in each gene could add up and confer an increased risk.

P04.012

A novel PTEN mutation in an Italian family with hyperplastic polyposis of the colon in the context of Cowden Syndrome

D. Turchetti^{1,2}, L. M. Pradella¹, C. Rossi¹, A. Alberani³, F. Ferrara³, P. A. Fantì⁴, G. Romeo¹;

¹UO e Cattedra di Genetica Medica - Azienda Ospedaliero-Universitaria Poli-clinico S.Orsola-Malpighi, Bologna, Italy, ²Dipartimento di Oncologia - Presidio Ospedaliero Bellaria-Maggiore, Bologna, Italy, ³UO Gastroenterologia ed Endoscopia Digestiva - Presidio Ospedaliero Bellaria-Maggiore, Bologna, Italy, ⁴UO Dermatologia - Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy.

Clinical manifestations of Cowden Syndrome, which is caused by mutations in the PTEN gene, are extremely variable. Among gastrointestinal manifestations, hamartomatous polyps are the typical lesions, but other polyp types, including hyperplastic, have been reported.

We describe a family in which hyperplastic polyposis was the reason for referral to the genetic clinic and that was found to carry a novel PTEN mutation.

The proband, a 46 year-old man, was referred to the cancer genetic clinic because of the endoscopic finding of colonic polyposis. Histology showed the polyps to be hyperplastic. Moreover, upper gastrointestinal endoscopy detected esophageal acanthosis and papillomatosis and HP-related gastritis. Physical examination revealed the presence of macrocephaly (65cm), obesity and cutaneous papillomas. The mother, 62 year-old, had also been diagnosed with hyperplastic polyposis and with carcinoma ex-adenoma of the left colon, for which had undergone hemicolectomy at age 61. Previously, she had had hysterectomy for uterine fibroids at age 47 and mastectomy for invasive ductal carcinoma of the breast at age 51. Physical examination showed macrocephaly (59cm), obesity, cutaneous papillomas and subcutaneous lipomas.

PTEN mutational analysis in the proband revealed the germline heterozygous mutation 303delA in the exon 5, which was confirmed in the mother. This mutation, which to our knowledge has never been described before, generates a stop at codon 111, producing a truncated protein which loses three functionally relevant domains.

To help clarify the pathogenic mechanism of the mutation, we are now performing molecular studies on pathologic tissues removed from the patients.

P04.013

Dysregulation of RAS signaling in colorectal carcinomas

I. Bottillo¹, I. Torrente¹, T. Ahlquist², S. A. Danielsen², G. I. Meling³, R. A. Lothe², B. Dallapiccola^{1,4};

¹CSS-Mendel Institute, Rome, Italy, ²Department of Cancer Prevention, Institute for Cancer Research, Rikshospitalet-Radiumhospitalet Medical Centre, Oslo, Norway, ³Surgical Department, Faculty Division Akershus University Hospital, University of Oslo, Oslo, Norway, ⁴Department of Experimental Medicine, Sapienza University, Rome, Italy.

Half of all colorectal carcinomas (CRC) have dysregulation of the RAS signaling, increasing the cellular proliferative potential and resistance to apoptosis. *KRAS* is known to be commonly mutated in CRC, while mutational status of the *NF1* gene, acting as a negative regulator of RAS signaling, is not known. We analyzed a series of CRC for mutations in *KRAS*, *BRAF*, and *NF1*. *NF1* coding region screening was performed by dHPLC (denaturing high performance liquid chromatography), sequencing and MLPA (multiple ligation-dependent probe amplification). *KRAS* and *BRAF* were analyzed by sequencing. 40% (26/65) of the samples carried a mutation in *KRAS*, 22% (14/64) in *BRAF*, and 13% (3/24) in *NF1*. We found that 62% (40/65) of the samples had alterations in one or more of the components, meaning they have a dysregulation of the RAS pathway. *BRAF* and *KRAS* mutations were mutually exclusive. *BRAF* mutation was strongly associated with microsatellite instability (MSI), female gender, and proximal location. Among the 24 samples analyzed for mutations in *NF1*, we found 2 missense and 2 splicing mutations. All *NF1* mutations occurred in MSI, proximal, and female-derived tumors with *BRAF* mutation. In addition, we found that 3 of the samples had duplication of parts or the whole *NF1* gene. In conclusion RAS pathway is dysregulated by mutually exclusive mutations of *KRAS* and *BRAF* in the majority of CRC. We show that the activity of RAS signaling is likely to be enhanced in more than 10% of the tumors since they harbor mutations in both *BRAF* and *NF1*.

Age related differences in molecular profiles of colorectal cancers in patients from the Republic of Macedonia

M. Hiljadnikova - Bajro¹, T. Josifovsk², A. Kapedanovska¹, Z. Serafimovska¹, Z. Sterjev¹, N. Matevska¹, M. Panovsk¹, N. Petrusevska², L. Suturkova¹, A. J. Dimovski¹;

¹Faculty of Pharmacy, Skopje, The former Yugoslav Republic of Macedonia,

²Faculty of Medicine, Skopje, The former Yugoslav Republic of Macedonia.

Colorectal cancer (CRC) is considered a disease of elderly, though 2-3% occurs in patients <40 years of age. Published data on the differences between young and elderly patients are quite controversial. Our study aims at comparing the molecular profiles between tumors of younger (age <40y) and older (>40y) patients from the Republic of Macedonia. A total of 343 patients with sporadic (FAP & HNPCC excluded) tumors treated by surgery were enrolled in the study. DNA was isolated from peripheral blood and fresh tumor tissues obtained immediately after surgery, and paired samples were evaluated for the presence of MSI and/or LOH using Real-Time PCR or multiplex qPCR. The evaluation included 23 SNP or STR markers located at 1p, 2p, 2q, 4q, 5q, 8p, 11q, 12q, 17p, 17q, 18p, 18q, 21q from either NCI panel or located in regions harboring genes implicated in CRC pathogenesis. Younger patients comprise 6% of CRC in our population. They are predominantly males (76% vs. 57% of older patients) with tumors in proximal colon (40 vs. 27%) and with MSI-H genotype (23 vs. 9.6%). On the contrary, the frequency of LOH is higher in tumors from older patients: 59 vs. 36% at 18q, 55 vs. 20% at 8p, 42 vs. 25% at 1p and 37 vs. 30% at 5q. In 46% of younger and 30% of older patients neither MSI nor LOH was detected. Our data suggest that CRC pathogenesis evolves through different pathways in patients with early compared to patients with late onset of the disease.

Mutational analysis of the PIK3CA kinase domain in endometrial carcinoma

D. V. Konstantinova^{1,2}, R. P. Kaneva³, T. K. Kadiyska¹, R. G. Dimitrov⁴, S. I. Ivanov⁵, T. V. Dyankova⁵, E. Tiufekchieva⁶, K. P. Meinhardt⁷, N. I. Doganov⁴, I. M. Kremenski¹, V. I. Mitev^{3,8};

¹Laboratory of Molecular Pathology, Sofia, Bulgaria, ²Department of Chemistry and Biochemistry, Medical University-Sofia, Sofia, Bulgaria, ³Molecular Medicine Center, Medical University-Sofia, Sofia, Bulgaria, ⁴Clinic of Operative Gynecology, University Hospital of Obstetrics and Gynecology "Maichin Dom", Sofia, Bulgaria, Sofia, Bulgaria, ⁵Clinic of Oncogynecology, National Centre of Oncology, Sofia, Bulgaria, Sofia, Bulgaria, ⁶Department of Obstetrics and Gynecology "Maichin Dom", Sofia, Bulgaria, Sofia, Bulgaria, ⁷Department of Pathology, University Hospital "Aleksandrovska", Sofia, Bulgaria, Sofia, Bulgaria, ⁸Department of Chemistry and Biochemistry, Medical University-Sofia, Sofia, Bulgaria.

Somatic mutations in PIK3CA, which encodes the p110 α catalytic subunit of phosphatidylinositol 3-kinases (PI3K), have been identified in a wide variety of tumors including endometrial carcinoma (EC). Mutations in PIK3CA cluster to exons 1 (p85), exon 9 (helical domain), and exon 20 (kinase domain) of the gene.

Recently, mutations in exon 20 have been linked to unfavorable clinicopathological characteristics of EC patients such as grade and lymphovascular invasion.

We have determined the frequency of exon 20 PIK3CA mutations among 60 endometrial carcinomas and have related their presence to metastatic disease. Five of the patients had metastasis (to ovary, sigma and parametrium).

We performed direct cycle sequencing of PIK3CA exon 20.

We found 4 missense mutations in 6 tumors (10%). We found c.3140A>G (p.H1047R) in 3 cases. We also found c.3073 A>G (p.T1025A) and c.3145 G>C (p.G1049R). In one case we found a mutation which, to our knowledge, has not been reported previously: c.3074 C>T (p.T1025I).

Two of the patients with exon 20 PIK3CA mutations had metastatic disease (33%), while 3 of 54 (5.5%) patients with no mutations had metastasis (p=0.07). The mean age at diagnosis for patients with PIK3CA mutation was 62.8, and for patients without a mutation - 63.3.

Somatic mutations in exon 20 of PIK3CA have been shown to be oncogenic as they lead to an increased PI3K activity. The PI3K regulate signaling pathways such as cell proliferation, survival and adhesion. Our results confirm that PIK3CA alterations may play an important role

for endometrial carcinogenesis and invasion.

Identification of four new pathological mutations in HNPCC patients of the Basque Country

C. Martínez-Bouzas¹, E. Beristain¹, N. Puente-Unzueta¹, N. Viguera¹, E. Ojembarrena¹, J. Errast², K. Mugica³, M. I. Tejada¹;

¹Hospital de Cruces, Barakaldo, Spain, ²Hospital de Txagorritxu, Vitoria-Gasteiz, Spain, ³Instituto Oncológico de Gipuzkoa, San Sebastián, Spain.

Hereditary non-polyposis colorectal cancer (HNPCC) is the most common form of hereditary colorectal cancer (CRC), accounting for 1%-5% of cases and is associated with germline mutations in the mismatch repair genes (MMR). We have studied families with HNPCC for three years granted by the Public Health Department of the Basque Country. The aim of this work is to establish whether the proportion of mutation in our population is similar to others previously published. Fifty-five index cases were analysed using heteroduplex, sequencing and MLPA. Thirty patients fulfilled the Amsterdam criteria and twenty-five fulfilled the Bethesda criteria. Ninety relatives were also tested. We found in total twenty-three variations (41.8%): eight (14.5%) in MLH1; nine (16.4%) in MSH2; and six (10.9%) in MSH6. Of these variations, eighteen were pathologic mutations, four of them being novel. Furthermore, other three new variations were found, but without aminoacid change. The 43.3% of Amsterdam criteria patients had one pathological mutation and so had 28% of the Bethesda criteria. Of the thirty-nine relatives with mutation, six have only developed cancer. The majority of pathological mutations in Amsterdam criteria were found in the MLH1 and MSH2 genes. In the MSH6 the pathological mutations were found in Bethesda criteria patients, that presented many different types of cancer. In this study we haven't found any rearrangements in the MLH1 gene, as were described in other populations. In conclusion, with this work we are contributing these new mutations to the wide spectrum that already exists.

P04.017

Uncertain pathogenicity of MSH2 variants N127S and G322D challenges their classification

S. Ollila¹, D. Dermadi Bebek¹, M. Greenblatt², M. Nyström¹;

¹Department of Biosciences, Division of Genetics, University of Helsinki, Helsinki, Finland, ²Vermont Cancer Center, University of Vermont, Burlington, VT, United States.

Hereditary non-polyposis colorectal cancer (HNPCC) is associated with germline mutations in mismatch repair (MMR) genes. Inherited missense mutations, however, complicate the diagnostics since they do not always cause unambiguous predisposition to cancer. This leads to variable and contradictory interpretations of their pathogenicity. Here, we establish evidence for the functionality of the two frequently reported variations, MSH2 N127S and G322D, which have been described both as pathogenic and non-pathogenic in literature and databases. We report the results of three different functional analyses characterizing the biochemical properties of these protein variants *in vitro*. We applied an immunoprecipitation assay to assess the MSH2-MSH6 interaction, a bandshift assay to study mismatch recognition and binding, and a MMR assay for repair efficiency. None of the experiments provided evidence on reduced functionality of these proteins as compared to wild-type MSH2. Our data demonstrate that MSH2 N127S and G322D *per se* are not sufficient to trigger MMR deficiency. This together with variable clinical phenotypes in the mutation carriers suggest no or only low cancer risk *in vivo*.

P04.018

Familial and clinicopathological differences in Amsterdam-families according to their mismatch repair status

M. Pineda¹, L. Benito², C. Yagüe², M. Salinas², C. Lázaro¹, S. González¹, G. Capellá¹, I. Blanco²;

¹Laboratori de Recerca Translacional, Institut Català d'Oncologia, Hospitalet de Llobregat, Spain, ²Unitat de Consell Genètic, Institut Català d'Oncologia, Hospitalet de Llobregat, Spain.

The aim of this study was to establish the familial and clinicopathological differences within Amsterdam-families according to their mismatch repair (MMR) status.

Seventy families fulfilling Amsterdam criteria II were included. MMR status was determined by microsatellite analysis and/or immunohisto-

chemistry of MMR proteins. Families with microsatellite instability and/or loss of expression of MMR proteins were considered MMR-deficient. Families were classified in three groups: A: MMR mutation detected (Lynch syndrome) (n=36); B: MMR-deficient families with no MMR mutation detected (n=10); and C: MMR-proficient families (n=24).

Proband's age of diagnosis was younger in Lynch syndrome families (A, 40 y; B, 50; C, 46 y; p=0.028). The presence of extracolonic tumors, the absence of polyps and the number of first-degree relatives with HNPCC-associated tumors were higher in Lynch syndrome families. MMR-proficient families showed a predominance of left colon tumors with no mucinous phenotype and a lower presence of metachronous tumors.

These results confirm that the presence of a MMR mutation is associated with a specific phenotype, while MMR-deficient families with no detected mutation show a mixed phenotype likely reflecting misclassification.

P04.019

Pathogenicity analysis of six unclassified missense variations in MMR genes identified in a selected population of Castilla-León (Spain)

L. Pérez-Cabornero¹, E. Velasco¹, M. Infante¹, D. Sanz¹, N. Martínez¹, L.

Hernández², N. Martínez¹, E. Lastra², C. Miner¹, M. Durán¹;

¹IBGM, Valladolid, Spain, ²Hospital General Yagüe, Burgos, Spain.

Lynch syndrome is the most common hereditary syndrome predisposing to colorectal cancer. Mostly, it is caused by DNA variations in the DNA mismatch repair (MMR) genes MLH1, MSH2 and MSH6. Of considerable relevance in the clinical management of colorectal cancer is to know if the missense variants referred to as unclassified variants (UVs) are or not cancer-causing. We report the mutational screening of 100 index cases from the Council Genetics Unit of Castilla-León. Of the 21 (21%) who carried germline mutation, 11 (52%) were categorized as pathogenic (frameshift, large rearrangements, splicing defects) and 10 (48%) as unclassified missense variants. The focus of this report is the classification of six of these missense variants as benign or pathogenic: MLH1 c.1852_1853AA>GC **p.K618A**; MLH1 c.2146G>A **p.V716M**; MSH6 c.2633 T>C **p.V878A**; MSH6 c.431 G>T **p.S144I** and two novel variations MSH6 c.3425 C>T **p.T1142M**; MLH1 c.1574 G>A **p.S505N**. To test this, we have analyzed clinical and genetic aspects including **i**) comparison between allelic frequency of the variant in the cases and 700 unaffected controls from a National DNA Register **ii**) a co-segregation study of the mutation with the disease within pedigree **iii**) evolutionary conservation of the involved aminoacid and type of aminoacid change **iv**) **a**) prediction of the degree of affectation at the protein function by two bioinformatics programs "Sort intolerant from tolerant" (SIFT; <http://blocks.fhcr.org/sift/SIFT.html>) and Polimorphism Phenotype (PolyPhen; www.bork.embl-heidelberg.de/PolyPhen). The combination of all these approaches helps us to predict whether these contribute to the disease phenotype or merely represent rare polymorphisms

P04.020

A Database to Support the Clinical Interpretation of Human Mismatch Repair Gene Variants

R. H. Sijmons, R. M. W. Hofstra;

University Medical Center Groningen, Groningen, The Netherlands.

Germline mutations in the mismatch repair (MMR) genes *MLH1*, *MSH2*, *MSH6* and *PMS2* can cause Lynch syndrome. Truncating MMR gene mutations generally offer a clear handle for genetic counselling and allows for pre-symptomatic testing. In contrast, the clinical implications of most missense mutations and small in-frame deletions detected in patients suspected of having Lynch syndrome are unclear. We have constructed an online database dedicated to these unclassified variants (UVs) of the MMR genes. It can be easily searched for information on the results of functional assays and other findings, including tumour characteristics, segregation within families and frequency in controls. The clinical classification of MMR gene UVs will be a huge challenge. Recently formed committees within the International Society for Gastrointestinal Hereditary Tumours (InSIGHT) are working towards collecting data and developing classification algorithms. Our MMR gene missense database will be one of the tools to support that process. It can be searched at www.MMRmissense.org

Comparative scanning of polymorphisms in mitochondrial D-loop region in colorectal and breast cancer

M. Akouchekian^{1,2}, M. Houshmand^{2,3}¹Hanover university, Hanover, Germany, ²Department of Medical Genetics, National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Islamic Republic of Iran, ³Department of Genetic, Special Medical Center, Tehran, Islamic Republic of Iran.

ABSTRACT

Mitochondrial DNA (mtDNA) mutations have been found in many kinds of human cancer and especially the 1.1 kb displacement loop (D-loop) region was found to be a "hot spot" for mutation in mtDNA of tumors. Mitochondria play an important role in shifting the cell from death to abnormal cell growth thus contributing to the neoplastic process, because of their essential roles in energy metabolism and generation of reactive oxygen species (ROS) also initiation of apoptosis and aging. The purpose of this study is to scan the mutation frequencies in hypervariable regions of mitochondrial D-Loop in colorectal and breast cancer patients comparatively. The results of our investigation are summarized in the following table. when each polymorphism is tested individually using the fisher exact test the frequency of two single-nucleotide polymorphism SNPs were found to be significantly different between the colorectal cancer (CRC) and breast cancer patient ($p \leq 0.05$). while the SNP C16261T ($p=0.0005$) is significantly more in breast cancer patients than CRC patients, the frequency of SNP T16519C ($p=0.0019$) is less in breast cancer patients than CRC patients. In this contribution the fact that SNP C16261T may be a consequence for breast cancer and SNP T16519C for CRC is discussed.

Fisher's Exact Test p value	Breast cancer cases (n=6)		Colorectal cancer Cases (n=40)	
	%	Positive	%	Positive
0.0005	83.3	5	10	4
1	16.6	1	25	10
1	0	0	10	4
0.0019	0	0	70	28

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal disorder caused by mutations in DNA mismatch repair genes, most often in *MLH1*, *MSH2* and *MSH6* genes. Tumors of HNPCC-spectrum are associated with microsatellite instability and loss of mismatch repair proteins expression. In some populations, founder mutations appear to explain a substantial fraction of HNPCC cases.

We report here the identification of two mutations in *MLH1* gene, c.306+5G>A and c.1865T>A (p.Leu622His), in 12 and 11 Spanish HNPCC families, respectively. Both mutations segregate with the disease, and tumors show microsatellite instability and loss of expression of *MLH1* protein. RNA studies demonstrate that c.306+5G>A mutation generates two aberrant mRNA transcripts. Experimental approaches are being performed to elucidate the pathogenicity of the c.1865T>A (p.Leu622His) mutation.

Haplotype analysis is performed using three single nucleotide polymorphisms of *MLH1* gene, three intragenic and four extragenic microsatellite markers, located between D3S1609 and D3S3564. We identify two common haplotypes associated to c.306+5G>A and c.1865T>A, suggesting a founder effect.

Mutations c.306+5G>A and c.1865T>A (p.Leu622His) of *MLH1* gene are the first founder *MLH1* mutations identified in Spain. This fact would have important implications for the design of molecular diagnostic strategies in the HNPCC Spanish families.

ABSTRACT

Germline mutations in mismatch repair (MMR) genes, tumours with high microsatellite instability (MSI-H) and loss of MMR protein expression are the hallmarks of HNPCC (Lynch-syndrome). While somatic *MLH1* promoter hypermethylation is generally accepted in the tumorigenesis of sporadic tumours, abnormal *MLH1* promoter methylation in normal body cells is controversially discussed as a mechanism predisposing patients to HNPCC.

94 patients suspected of HNPCC-syndrome with a mean age of onset of 45.5 years, *MLH1*-deficiency in their tumours but no germline mutation underwent methylation-specific PCR-screening for *MLH1* promoter methylation.

In peripheral blood cells of twelve patients an *MLH1* promoter methylation, in seven informative cases allele-specific, was found. Normal colonic tissue, buccal mucosa, and tumour tissue available from three patients also presented abnormal hemiallelic methylation in the *MLH1* promoter. The heredity of aberrant methylation is questionable. Pro: *MLH1* promoter methylation was found in a patient and his mother giving evidence for a familial predisposition for an epimutation in *MLH1*. Contra: a de novo set-up of methylation in one patient, a mosaic or incomplete methylation pattern in six patients, and no evidence for inheritance of *MLH1* promoter methylation in the remaining families.

Our findings provide strong evidence that *MLH1* promoter methylation in normal body cells mimics HNPCC and constitutes a pathogenic prelesion in *MLH1*. The identification of hypermethylation as an epigenetic defect has important implications for surveillance recommendations, as these patients should be treated like Lynch-Syndrome patients, whereas the heritability of methylation is still under investigation.

P04.024

Founder effect of a pathogenic *MSH2* mutation identified in four Hereditary Non-Polyposis Colorectal Cancer (HNPCC) familiesM. Menéndez¹, S. Castellví-Bel¹, M. Pineda¹, R. de Cid², J. Muñoz², F. Balaguer², V. Gonzalo², M. Giráldez², I. Blanco³, G. Llort⁴, T. Ramón y Cajal⁵, S. González¹, A. Castellví², G. Capellá¹;

¹Laboratori de Recerca Translacional, Institut Català d'Oncologia, IDIBELL, Hospitalet de Llobregat, Spain, ²Servei de Gastroenterologia, Institut de Malalties Digestives i Metabòliques, Hospital Clínic, CIBEREHD, IDIBAPS, Barcelona, Spain, ³Programa Gens i Malaltia, Centre de Regulació Genòmica-UPF, Barcelona, Spain, ⁴Unitat de Consell Genètic, Institut Català d'Oncologia, IDIBELL, Hospital Duran i Reynals, Hospitalet de Llobregat, Spain, ⁵Unitat de Consell Genètic, Institut Català d'Oncologia, Hospital Universitari Germans Trias i Pujol, Badalona, Spain, ⁶Servei d'Oncologia Mèdica, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

HNPCC is caused by germline mutations in DNA mismatch repair genes *MLH1*, *MSH2*, *MSH6* and *PMS2*. The novel *MSH2* c.[2635-3T>C; 2635-5C>T] mutation was identified in 4 HNPCC families, cosegregating with the disease. This mutation, located in intron 15, was predicted to alter the correct mRNA processing by *in silico* analysis.

Our aim was to perform the c.[2635-3T>C; 2635-5C>T] mutation screening in HNPCC and control populations, to evaluate the founder effect in our population by haplotype analysis and to confirm the pathogenic effect of the mutation by *MSH2* expression studies.

Mutation screening was performed by SSCP and CSCE in genomic DNA from 256 HNPCC index cases and 239 controls. Haplotyping was performed analysing 4 *MSH2* extragenic microsatellite markers (D2S288, D2S2227, D2S1247 and D2S1248) in 50 controls and mutation carriers by using the PHASE program. We analysed the effect of the mutation in mRNA processing by RT-PCR and in *MSH2* expression by qRT-PCR using RNA from 5 mutation carriers and 18 controls.

None of the remaining HNPCC cases or controls analysed harboured the mutation. We identified a common telomeric haplotype and two centromeric haplotypes, both rare in our population. Although we were not able to identify any abnormal transcript by RT-PCR with the design used, we observed a 50% reduction of mRNA *MSH2* expression in carriers when compared with controls.

Haplotype analyses suggest a founder effect of the c.[2635-3T>C; 2635-5C>T] *MSH2* mutation and expression studies support a pathogenic role of this mutation.

P04.025

Biallelic MUTYH germline mutations and endometrial cancer

R. Tricarico¹, B. Ciambotti², P. Be³, C. Di Gregorio³, L. Varesco², M. Genuardi¹;
¹Department of Clinical Pathophysiology, Medical Genetics Unit, University of Florence, Florence, Italy, ²Center for Hereditary Tumours, National Institute for Cancer Research, Genoa, Italy, ³Division of Pathology, Hospital of Carpi, Modena, Italy.

MAP (MUTYH-Associated Polyposis) is an autosomal recessive condition predisposing to colorectal cancer, due to inherited defects of the MUTYH gene causing an excess of somatic G>T mutations in the APC and KRAS genes. To date, few extracolonic manifestations have been observed in MAP patients, and the clinical spectrum of this condition is not yet fully established. Recently, one patient with a diagnosis of endometrial cancer and biallelic MUTYH germline mutations has been described (Barnetson et al., Clin Genet 2007: 72: 551-555). However, it is not yet clear if biallelic germline mutations in MUTYH increase the risk of endometrial tumours. We report on two MAP patients with biallelic MUTYH germline mutations who developed endometrial carcinoma. In one of the patients, a diagnosis of Lynch syndrome was originally considered, and subsequently ruled out by immunohistochemical analysis of mismatch repair proteins and microsatellite instability analysis. The endometrial tumours were evaluated for PTEN, PIK3CA, KRAS, BRAF and CTNNB1 mutations. A G>T transversion at codon 12 of the KRAS gene was observed in one tumor. A single 1-bp frameshift deletion of PTEN was observed in the same sample. Overall, these results suggest that endometrial carcinoma may represent a component manifestation of MAP.

P04.026

Gene conversion rates between PMS2, a mismatch repair gene involved in Lynch syndrome, and its pseudogene PMS2CL; impact on the reliability of current mutation scanning

H. M. van der Klift¹, C. M. Tops², E. C. Bik², M. W. Boogaard², K. Pavlikova³, H. Morreau⁴, P. Devilee^{1,4}, J. T. Wijnen^{1,2};

¹Department of Human Genetics, LUMC, Leiden, The Netherlands, ²Department of Clinical Genetics, LUMC, Leiden, The Netherlands, ³Institute of biology and medical genetics, University Hospital Motol, Praha, Czech Republic, ⁴Department of Pathology, LUMC, Leiden, The Netherlands.

Mutation detection in PMS2, a Mismatch Repair gene involved in Lynch syndrome (formerly Hereditary Non Polyposis Colorectal Cancer or HNPCC), is complicated by the presence of the pseudogene PMS2CL. It has been shown that gene conversion can occur between the 3' part of PMS2 and this 700 kb proximally located pseudogene. We investigated 83 familial colorectal cancer cases and 25 healthy controls by semi-quantification of paralogous sequence variants (nucleotides that differ between PMS2 and PMS2CL) in sequence chromatograms of non-specific PCR products (amplification of PMS2 and PMS2CL sequences simultaneously) and show that, from exon 12 onwards, all PMS2 specific nucleotides on which commonly used MLPA and PMS2 specific PCR primers are based, can be subject to gene conversion with an increasing frequency of up to 50 % at the 3' end of the gene. Current mutation scanning designs are thus extremely prone to generate false-negatives or even worse false-positives in this part of the gene.

With a newly developed protocol including non-specific sequencing, cDNA analysis and Southern Blot analysis that excludes false-nega-

tive and false-positive results due to gene conversion events, we scanned colorectal cancer patients including strong candidates for a PMS2 germline mutation based on immunohistochemistry analysis of their tumours. We show that several mutations detected in the 3' part of PMS2 using the current mutation scanning designs are actually false-positives and that also mutations can be missed.

P04.027

Screening for genomic rearrangements of the MMR and APC genes in Galician families with hereditary colorectal cancer

C. Fernández-Rozadilla¹, N. Gómez-Fernández¹, I. Madrigal², O. Lortes¹, M. Mila², M. Magdalena¹, S. Castellví-Bel³, A. Vega¹, A. Castells³, A. Carracedo¹, C. Ruiz-Ponte¹;

¹Fundación Pública Galega de Medicina Xenómica-SERGAS, Grupo de Medicina Xenómica-USC, CIBER-ER, Santiago de Compostela, Spain, ²Biochemistry and Molecular Genetics Department, Hospital Clínic, CIBER-ER, IDIBAPS, Barcelona, Spain, ³Department of Gastroenterology, Institut de Malalties Digestives i Metabòliques, Hospital Clínic, CIBEREHD, IDIBAPS, Barcelona, Spain.

Lynch syndrome and Familial Adenomatous Polyposis (FAP) are two well-known inherited colorectal cancer syndromes caused by germline mutations in susceptibility genes (*MMR*, *APC*, *MYH*). Molecular diagnosis has until very recently relied only on detection of germline point mutations in these genes. Nevertheless, it is known that large rearrangements also play an important role in pathogenesis and should therefore be considered.

Thirty-nine FAP and 16 Lynch syndrome unrelated Galician families that were negative for germline mutations were analysed by MLPA to determine the frequency of large rearrangements. Positive results were further confirmed by other methods (FISH, cDNA analysis).

Three different deletions in *APC* were detected in 4 families (8% of the total *APC* families): an exon 4 deletion, an exon 1-15 deletion, and two whole gene deletions. Carriers of whole allelic deletions presented a severe polyposis phenotype with an early onset of symptoms.

In Lynch syndrome families, 3 deletions were found in *MSH2* (exon 7-16, exon 2-3 and one whole gene deletion), whereas only one deletion was found in *MLH1* (exon 4-6), making up to 14% (10% *MSH2* and 4% *MLH1*) of the Lynch syndrome germline mutations. Large rearrangements were mainly detected in families fulfilling Amsterdam criteria.

The overall results resemble those previously published in other populations and confirm that large rearrangements represent an important percentage of FAP and Lynch syndrome germline mutations. They should therefore be taken into account in molecular genetic testing of Galician families.

Background: Hereditary non-polyposis colorectal cancer (HNPCC) is an autosomal dominant syndrome predisposing to the early development of various cancers including those of colon, rectum, endometrium, ovary, small bowel, stomach and urinary tract. HNPCC is caused by germline mutations in the DNA mismatch repair genes, mostly *MLH1* and *MSH2*. The mutation spectrum in the Brazilian population is still poorly documented.

Aim: To report our experience on the mutation screening and investigation of the pathogenicity of the mutations in *MLH1* and *MSH2* genes in 20 unrelated Brazilian kindreds with suspected HNPCC.

Methods: Twenty Brazilian patients with familial clustering of CRC were genetically tested. The families were identified by applying the Amsterdam and Bethesda Criteria. Point mutations in the *MLH1* and *MSH2* genes were screened by denaturing high performance liquid chromatography (DHPLC) followed by direct sequencing.

Results: Two novel nonpathogenic mutations (2 of 20 [10%]) in *MLH1*-exon 15 (intron) nt. 1707 a->g and *MLH1*-exon 13 (intron) nt. 1632 g->a were identified in Brazilian CRC patients.

Conclusion: According to the Human Gene Mutation Database (HGMD) and the International Society of Gastrointestinal Hereditary Tumors (InSIGHT) Database, this is the first report of this mutation.

P04.029**Characterisation of familial breast tumours using array-based comparative genomic hybridisation technology: the common heterogeneity with sporadic breast tumours**

L. Melchor¹, E. Honrado¹, M. J. García¹, S. Álvarez², A. Osorio¹, K. L. Nathanson³, J. Benítez¹;

¹Human Genetics Group, Human Genetics Programme, Spanish National Cancer Centre (CNIO), Madrid, Spain, ²Molecular Cytogenetics Group, Human Genetics Programme, Spanish National Cancer Centre (CNIO), Madrid, Spain, ³Division of Medical Genetics, Department of Medicine and Abramson Cancer Center, University of Pennsylvania, Philadelphia, PA, United States.

Familial breast cancer (~5% of breast cancer cases) maybe due to mutations at the BRCA1 and BRCA2 genes (~30% of families with breast cancer) or to mutations in other unknown genes to date in the non-BRCA1/2 or BRCA1/2 families (~70%). To characterise the genomic differences amongst the distinct breast cancer classes using the array-based comparative genomic hybridization technique, we have collected 20 tumours associated with BRCA1 mutation, 24 tumours from mutation carriers in BRCA2, 32 BRCA1-tumours, and 19 sporadic samples.

Breast tumours associated with mutations in BRCA1 or BRCA2 had greater genomic instability than BRCA1 or BRCA2 or sporadic samples, and a trend to alter specific chromosomal regions. However, we have demonstrated a common heterogeneity between familial and sporadic breast cancer in terms of estrogen receptor (ER) status and breast cancer subtypes. First, ER-negative tumours showed higher genomic instability and a specific genomic aberration pattern compared with ER-positive tumours. Second, familial breast tumours have been profiled into molecular subtypes: basal, ERBB2, luminal A, and luminal B. BRCA1-tumours were associated with the basal phenotype, which presented the highest genomic instability, whereas BRCA2 samples were related to the luminal A subtype. Luminal B tumours had the greatest number of high-level DNA amplifications.

Two regions with high-level DNA amplifications in familial breast cancer have also been studied: 8p11-p12 and 13q34. The former one was related to higher cell proliferation, whereas the latter one was characteristic of basal tumours, had 1.6Mb length, and was correlated with overexpression of candidate genes such as TFDP1.

P04.030**BAX gene mutations and Breast carcinoma: A study of phenotype-genotype correlation**

M. Hosseini¹, M. Houshmand², K. Banihashemi³, M. Sayedhassani⁴;

¹Islamic Azad University, Tehran, Islamic Republic of Iran, ²National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran, ³Research and clinical center for infertility of Yazd, Yazd, Iran., ⁴Research and clinical center for infertility of Yazd, Yazd, Iran., Tehran, Islamic Republic of Iran.

It has been known for a while that the proapoptotic BAX protein induces cell death by acting on mitochondria and its gene is located on 19q13.3-q13.4. On the other hand it has been demonstrated that BAX can be essential for death receptor-mediated apoptosis in cancer cells

In this study a kind of phenotype-genotype correlation research for breast carcinoma and BAX gene mutations has been done. The correlation between breast cancer stage and its prognosis has been evaluated with the mutation types of the BAX and their statistical analyses were the matter of interest through a series of clinical and genetic variables. The sample consists of 50 female patients with mean age of 40-50. who involved with Breast Cancer compared to a healthy control group of the same race and ethnicity with approximately the same mean age who also never had a history of breast cancer in their close relatives.

Our study shows some basic findings to make a Bax mutation database phenotypically interrelated with the clinical prognoses which could be a fundamental guide to clinical treatment options through a series of genetic screening.

P04.031**Preliminary genetic investigations of BRCA genes within hereditary breast and ovarian cancer (HBOC) families in north-eastern Romania**

L. Negura¹, E. Carasevici¹, A. Negura², N. Uhrhammer³, Y. J. Bignon³;

¹Gr. T. Popa Medicine and Pharmacy University, IASI, Romania, ²Al. I. Cuza University, IASI, Romania, ³Jean Perrin Molecular Oncology Center, Clermont-Ferrand, France.

BRCA1 and BRCA2 are major cancer predisposition genes, responsible for a large percentage of hereditary breast and ovarian cancer (HBOC) families. Screening for mutations in these genes is now standard practice for HBOC cases in Europe, and permits medical follow-up and genetic counselling adapted to the needs of individuals in such families. As very little information is available in Romania, we started the first characterization of hereditary breast and ovarian cancer risk in north-eastern Romania. Our study consists in HBOC families identification and recruitment, DNA collection achievement from these patients, implementation of molecular technology for mutations analysis and oncogenetic follow-up of mutations bearers.

We managed to identify and recruit so far several HBOC families with unique features such as 5 ovarian plus 1 breast cancer, or 8 breast cancer cases within the same family line. All recruited families are now under systematic DNA sequencing for BRCA screening.

We also investigated, within HBOC families and sporadic cases, the status of three known founder mutations (185delAG and 5382insC on BRCA1 and 6174delT on BRCA2), by optimization and comparison of several multiplex-PCR techniques. This part of our study showed a very important random factor within all multiplex-PCR methods. We demonstrate that although they are cheap, rapid and easy techniques, they often generate false results like primer dimers, undesirable amplification products apparition or heteroduplexes. Therefore we always recommend combining multiplex-PCR with other pre-screening methods (SNP, heteroduplex analysis) for a good selection before DNA sequencing.

Our study was possible by financial support from Romanian Academy.

P04.032**Implementation of a comprehensive strategy for mutational analysis of BRCA1 and BRCA2 genes in our clinical setting: Description of the algorithm and preliminary results**

J. del Valle, L. Feliubadaló, E. Tornero, M. Menéndez, M. Mirete, E. Montes, M. Calaf, G. Capellà, C. Lázaro;

Laboratori Recerca Translacional, Institut Català d'Oncologia, Hospitalet de Llobregat, Barcelona, Spain.

We have recently set up an accurate and cost-effective strategy to screen for variations in the BRCA1 and BRCA2 genes. Our algorithm consists in a sequential cascade of complementary techniques using genomic DNA. First, we study copy number variations by using commercial MLPA kits (MRC-Holland). Samples showing positive MLPA results are always confirmed by a different approach. Samples with no copy number variations undergo SNPlex analysis, designed specifically to detect 38 Spanish common polymorphisms and 9 recurrent mutations. Direct sequencing is applied to confirm recurrent mutations. Negative samples for the previous steps are submitted to our chosen technique for mutational search for nucleotide changes, the CSCE approach (conformation sensitive capillary electrophoresis). CSCE analysis allows detecting altered electrophoresis patterns when DNA changes are present in heterozygosis in a given fragment. The screening of the whole coding region of both genes is performed by analysing 79 different fragments. Abnormal patterns are sequenced to determine the DNA change responsible for the observed mobility shift. When a DNA change is suspected to alter the correct splicing of the genes, mRNA studies are performed. We are applying this comprehensive approach since July 2007 in our routine setting and although numbers are still too low, results are promising and comparable to those reported in the literature. We detected about 2-3% copy number alterations, 3-5% recurrent mutations and 15-18% point mutations in a selected population of high-risk patients. Several mutations affecting the splicing have been also characterized at mRNA level.

P04.033

Rapid screening of BRCA1 and BRCA2 Spanish mutations by High Resolution Melting analysis

I. de Juan Jiménez, E. Esteban Cardeñosa, S. Palanca Suela, E. Barragan González, P. Bolufer Gilabert;

Molecular Biology Laboratory, Valencia, Spain.

Background: *BRCA1* and *BRCA2* are the major genes responsible for hereditary breast (BC) and/or ovarian cancer. Since *BRCA1/2* are large genes the majority of mutation detection procedures include screening methods which are time-consuming and expensive. High-resolution melting (HRM) is a recent promising screening method that combines the simplicity, cost-effectiveness and rapid identification of genetic variants. The aim of the study is to evaluate HRM in the screening of the reported Spanish mutations.

Methods: We studied 40 *BRCA1* and 47 *BRCA2* DNA samples containing different Spanish mutations. We also included a reference group of 20 unknown DNAs from patients with sporadic BC. The assay was carried out on LightCycler 480 (Roche) using LightCycler® 480 HRM Master and performing 21 and 25 independent PCR for the study of *BRCA1/2* gene mutations, respectively. The melting analysis was performed with LightCycler® 480 Gene Scanning Software v.1.0. All mutations and genetic variants detected were confirmed by sequencing the PCR products.

Results: The HRM could discriminate the 87 *BRCA1/2* Spanish mutations analyzed from wild-type DNA. Besides, 82 out of 87 mutations were clearly differentiated from each other. In the sporadic BC group we did not detect any deleterious mutations, however, we detected polymorphisms and unclassified variants in both genes.

Conclusions: HRM is a valuable method for rapid screening of *BRCA1/2* Spanish mutations. Besides, this procedure allows the genotyping of different mutations included and is capable of differentiating unknown genetic variants present in the PCR product.

P04.034

Novel deleterious BRCA1/2 mutations found in the population of Eastern Spain

E. Esteban Cardeñosa¹, S. Palanca Suela¹, I. de Juan Jiménez¹, E. Barragán González¹, I. Chirivella González², Á. Segura Huerta², C. Guillén Ponce², E. Martínez de Dueñas², P. Bolufer Gilabert¹;

¹Molecular Biology Laboratory, Valencia, Spain, ²Units of Genetic Counselling in Cancer of the Valencian Community, Valencia, Spain.

From the identification of *BRCA1* and *BRCA2* as major genes responsible of hereditary breast and/or ovarian cancer more than 1,800 pathogenic mutations have been reported in the Breast Cancer Information Core, many of them related with ethnic and/or geographic conditions (Neuhausen SL, 1999). The objective of the study is to describe the twenty novel deleterious mutations identified in the Valencian Community.

In the three first years of performance of the Program of Genetic Counselling in Cancer of the Valencian Community we studied the *BRCA1* and *BRCA2* mutations in 596 unrelated breast/ovarian cancer patients. The method followed consisted of multiplex PCR amplification of all exons of the genes, mutation screening by the study of homoduplex/heteroduplex and mutation identification by sequencing of the PCR products.

We found 52 different deleterious mutations (21 in *BRCA1* and 31 in *BRCA2*), among the 112 positive index patients. In *BRCA1* gene we found 12 frameshift, 3 nonsense, 3 missense and 3 splicing mutations. In *BRCA2* we found 24 frameshift, 5 nonsense and 2 splicing. Twenty of these mutations have not been reported previously, 5 in *BRCA1* (c.1689delG, c.3700delC, p.Y1429X, c.4424_4425delCT and c.5430_5452del23) and 15 in *BRCA2* (c.489_490delCT, c.1835insT, c.1874_1877delAGGA, c.2929delC, c.5025delT, c.5344_5347delAATA, c.5946_5947dupCT, c.6118delA, c.6722delT, c.7400insA, p.Y2621X, c.8270_8271delCA, c.8860+2T>G, c.9218delA and p.Q3156X).

From our data two main conclusions could be drawn: (a) the remarkable proportion of novel mutations (20/52; 38.4%) and (b) that the majority of these mutations (15/20; 75%) were found in *BRCA2* gene.

P04.035

BRCA1 and BRCA2 variability in breast/ovarian cancer families from the Basque Country

I. Zubillaga¹, M. Carrera², K. Mugica², C. Vidales¹;

¹Policlinica Gipuzkoa, San Sebastian, Spain, ²Instituto Oncologico, San Sebastian, Spain.

BRCA1 and *BRCA2* are tumor suppressor genes that are related with inherited susceptibility to breast/ovarian cancer. We are analyzing the polymorphic variants of *BRCA1* and *BRCA2* genes in families with clinical criteria of hereditary breast/ovarian cancer. After DNA isolation, the mutational analysis were performed by DNA sequencing of all *BRCA1* and *BRCA2* exons and flanking regions. Twentythree different types of *BRCA2* and twenty *BRCA1* polymorphic mutations were identified in twenty breast/ovarian cancer families. The patients selection was made after a genetic counseling procedure, according the diagnostic criteria recommended by de Spanish Society of Medical Oncology (SEOM) and also using the BRCAPRO informatic model.

P04.036

Novel and common BRCA1 mutations in familial breast/ovarian cancer patients from Lithuania

R. Janavicius^{1,2}, J. Kasnauskiene^{1,2}, V. Kucinskas^{1,2};

¹Vilnius University Hospital Santariskiu Clinics, Medical Genetics Center, Vilnius, Lithuania, ²Department of Human and Medical Genetics, Vilnius University, Vilnius, Lithuania.

Background: Mutations in the *BRCA1* gene are found in many families with multiple cases of breast and ovarian cancer. Twenty seven unrelated female patients diagnosed with breast cancer and/or ovarian cancer have attended cancer genetics clinic during period of 2006-2007 year.

Methods: *BRCA1* gene testing was initiated with direct sequencing for common founder mutations: 4153delA in exon 11, 5382insC in exon 20 and enzyme restriction digestion for 300T/G in exon 5. After the exclusion of common mutations, multiplex ligation-dependent probe amplification (MLPA) and prescreening by denaturing gradient gel electrophoresis (DGGE) with confirmation by direct sequencing were performed.

Results: Overall, pathogenic *BRCA1* gene mutations were prevalent in 8 (30%) unrelated proband patients: 3 (15%) with breast cancer (two 5382insC, one 4153delA), 2 (50%) with ovarian cancer (5382insC and 4153delA each) and 3 (100%) with breast and ovarian cancer (5382insC, 4153delA and novel previously not reported deletion 4635delG in exon 15). No 300T/G mutation and *BRCA1* rearrangements were detected.

For patients diagnosed with breast cancer ≤35 year, *BRCA1* mutation detection rate was 27% (3/11) and mutations were absent in breast cancer patients group diagnosed after 36 years (0/6).

Conclusions: Testing for two common *BRCA1* mutations should be considered in female cancer cases* when: (a) breast cancer diagnosed before the age of 36 year; (b) medullary breast carcinoma; (c) breast and ovarian cancer; (d) nonmucinous epithelial ovarian tumor regardless the age (*or first degree relative/second through male). Full *BRCA1* gene analysis is warranted in patients with strong family history of breast cancer.

P04.037

Occurrence of BRCA1 cryptic splice site mutation: IVS5-12A>G in hereditary breast cancer families in the Czech republic

E. Machackova¹, J. Hazova¹, S. Tavandzis², M. Lukesova¹, L. Foretova¹;

¹Masaryk Memorial Cancer Institute, Brno, Czech Republic, ²JG Mendel Cancer Centre, Novy Jicin, Czech Republic.

High Resolution Melting (HRM) analysis revealed presence of *BRCA1* cryptic splice site mutation IVS5-12A>G in high-risk breast/ovarian cancer patients. This change was described to form a cryptic splice site resulting in the addition of 11 nucleotides at the intron 5/exon 6 boundary. The *BRCA1* mutation IVS5-12A>G was not detectable by the previously used heteroduplex analysis (using MDE gel) at the MMCI. Therefore, the retrospective study of 480 high-risk familial breast/ovarian cancer patients without previously identified *BRCA1/2* mutation were analysed for exon 6 by HRM using LightScanner instrument. The *BRCA1* mutation IVS5-12A>G was found in 11 high-risk probands. Adjoining these new findings to our previous results, the IVS5-12A>G mutation in *BRCA1* gene represents 5,3% of all *BRCA1*

mutations detected in hereditary breast cancer families. All together, the mutation detection rate in BRCA1 or BRCA2 genes reached 39,8% in hereditary breast cancer families (309 families carrying BRCA mutation out of 778 analysed families with at least 2 diagnosed breast and/or ovarian cancer cases before the age of 50).

Any report about presence of BRCA1 mutation IVS5-12A>G in Slavic population is missing in the BIC database. Therefore other methods were tested for their capability to detect this mutation. We found that HRM as well as DHPLC can perfectly detect the IVS5-12A>G mutation, however detection with SSCP highly depends on running condition. By using SSCP or HA the BRCA1 mutation IVS5-12A>G might be easily overseen. *Supported by the Ministry of Health of the Czech Republic: Grant MZMOU2005*

P04.038

Expression of BRCA1 and TP 53 genes in different types of tumor

J. Ramic¹, L. Kapur¹, N. Lojo-Kadic¹, D. Macic¹, K. Radic¹, N. Bilalovic², K. Bajrovic¹;

¹Institute for genetic engineering and biotechnology, Sarajevo, Bosnia and Herzegovina, ²Department of pathology, University Clinical Center Sarajevo, Bosnia and Herzegovina, Sarajevo, Bosnia and Herzegovina.

The TP53 is one of the main suppressors in many types of tumor ailments. BRCA1 is another tumor suppressor gene involved in DNA repair and it is best known by its role in the development and proliferation of various types of breast and ovarian cancers. Previous studies indicate that mutations in these genes are related to pathogenesis and development of the disease.

Aim of our study was to determine if there is any relation between expressions of these two genes and also to determine level of expression of BRCA1 gene in colon cancer. Expression level of TP53 in different cancers was compared to the expression of BRCA1 and beta -actin that was used as a control gene. This study included samples from 76 subjects with breast, ovarian and colon cancer. Genetic material was extracted from bioptic specimens retrieved from Department of Pathology from University Clinical Center Sarajevo. Expression of the observed genes was measured by real time PCR on Applied Biosystems 7300 device using SYBR green method.

P04.039

Contralateral prophylactic mastectomy in BRCA1/2 mutation carriers with breast cancer

E. Dagan^{1,2}, R. Gershoni-Baruch^{1,3};

¹Rambam Health Care Campus, Institute of Human Genetics, Haifa, Israel, ²University of Haifa, Department of Nursing, Haifa, Israel, ³Technion-Institute of Technology, The Ruth and Bruce Rappaport Faculty of Medicine, Haifa, Israel.

The occurrence of bilateral breast cancer in BRCA1/2 mutation carriers varies subject to factors such as age at diagnosis of 1st tumor and family history for breast-ovarian cancer. BRCA1/2 mutation carriers are counseled to undergo prophylactic mastectomy (PM) and oophorectomy (PO). The incidence of contralateral prophylactic mastectomy was evaluated in BRCA1/2 mutation carriers diagnosed with unilateral breast cancer from one oncogenetic clinic in Northern Israel.

Socio-demographic and clinical profiles of 59 eligible BRCA1/2 mutation carriers were collected. Women who opted for contralateral PM were compared to those who choose medical surveillance.

Of the 59 women, three (5.1%) underwent contralateral PM and 33 (55.9%) underwent PO and five (8.5%) had both contralateral PM and PO. The three women who underwent contralateral PM were younger than 40 years of age at diagnosis. Mean age at diagnosis was not statistically different between those who opted for PM and those who preferred surveillance. However, women who chose contralateral PM were significantly younger than those who preferred follow-up (48.12±5.27 and 59.81±9.96, respectively, p=0.001). The only socio-demographic variable found to be associated with PM was graduate level of education; all eight women had academic education.

These findings suggest that most breast cancer patients diagnosed with BRCA1/2 mutation declined PM. It is yet to be clarified whether preferences of risk reduction management in Israel, are subject to woman's prevailing values or medical recommendations.

Chromosomal damage after *in vitro* treatment with radiation or mitomycin c in lymphocytes of BRCA1/BRCA2 mutation carriers

S. Gutiérrez-Enríquez^{1,2}, T. Ramón y Cajal³, C. Alonso³, A. Corral⁴, P. Carrasco⁵, J. Sanz², C. López², M. Ribas⁵, M. Baige⁶, O. Diez^{1,2};

¹Programa de Medicina Molecular i Genètica, Hospital de la Vall d'Hebron, Barcelona, Spain, ²Servei de Genètica, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain, ³Servei d'Oncologia Mèdica, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain, ⁴Grup de Mutagèsi, Universitat Autònoma de Barcelona, Barcelona, Spain, ⁵Servei de Radiofísica i Radioprotecció, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

INTRODUCTION AND OBJECTIVES: Mutations in *BRCA1* and *BRCA2* account for a fraction of inherited susceptibility to breast (BC) and ovarian cancer (OC). The *BRCA1/BRCA2* gene products help to maintain genomic integrity after DNA damage. To investigate this capacity in *BRCA1/2* heterozygous cells, we have evaluated their *in vitro* sensitivity to chromosomal damage induced by two mutagenic agents: ionising radiation and mitomycin C (MMC).

STUDY SUBJECTS AND METHODS: Lymphocyte cultures were established from 20 *BRCA1* mutation carriers (12 with cancer and 8 without), 21 *BRCA2* mutation carriers (11 with cancer and 10 without) and 11 non-carrier controls. The chromosomal damage (chromosome breakage and chromosome loss) induced *in vitro* was assessed quantifying bi-nucleated cells with micronuclei (MN). MN can be used as a measure of DNA repair capacity. Six cultures were set up for each subject (2 treated with 2Gy gamma irradiation from Co-60, 2 treated with 0,05 µg/ml of MMC and 2 without treatment).

RESULTS: The *BRCA1/BRCA2* heterozygous lymphocytes did not show a higher level of radiation-induced MN compared to the non-carrier controls lymphocytes. In contrast, the *BRCA2* lymphocytes, from both women with and without cancer, presented higher levels of MN after exposure to MMC than the lymphocytes of *BRCA1* carriers and women without mutation.

CONCLUSION: The haploinsufficiency of *BRCA1/BRCA2* in peripheral blood lymphocytes does not affect the repair of radioinduced DNA lesions. But the absent of one *BRCA2* functional allele is associated to a higher level of chromosomal damage induced by MMC probably due to an impaired DNA repair capacity.

P04.041

The prevalence of three mutations in BRCA genes in Romanian women with familial breast cancer

D. Cimponeriu¹, P. Apostol¹, M. Toma¹, M. Stavarachi¹, D. Usurelu¹, D. Letitia¹, I. Radu¹, T. Burcos², E. Popa², I. Popa², S. Stanilescu², L. Gavrilă¹;

¹Institute of Genetics, Bucharest, Romania, ²Coltea Clinical Hospital, Bucharest, Romania.

Background. BRCA1 and 2 mutations confer a substantial lifetime risk to breast and ovarian cancer. The spectrum of mutation in these genes has been not previously investigated in our country.

Aim. To evaluate the prevalence of BRCA1 and BRCA2 mutations in women with demonstrated history of breast cancers.

Material and methods. We started this study in 2007 and selected 30 Caucasian patients with breast cancer which was confirmed by clinical and paraclinical approach. All patients have at least one relative with early breast cancer onset. Signed informed consent for all participants was obtained before inclusion in study. We used blood samples to test the presence of BRCA1 185 AG, BRCA1 5382 insC, BRCA2 6174 delT mutations using commercial kit and classical PCR based methods. In addition we screened by indirect methods a region of BRCA1 (1000 bp) for other mutations.

Results. We identified the heterozygous BRCA1 5382 insC mutation in three patients, confirmed by both methods. The other two mutations have been not detected. Thus, we consider that both methods have similar efficiency in detection of these mutations. We also found no mutations in investigated regions using indirect methods. **Conclusion.** Our preliminary results showed that BRCA1 5382 insC could be the most common mutation in Romanian women with familial breast cancer.

P04.042

BRCA1/2 mutations: screening strategy for the analysis of Portuguese high-risk breast/ovarian cancer families

M. Santos¹, P. Machado¹, S. Frago¹, P. Rodrigues², S. André³, F. Vaz⁴;

¹Molecular Biology Department-Portuguese Institute of Oncology, Lisbon, Portugal, ²Breast Cancer Risk Evaluation Clinic-Portuguese Institute of Oncology, Lisbon, Portugal, ³Pathology Department-Portuguese Institute of Oncology, Lisbon, Portugal, ⁴Molecular Biology Department and Breast Cancer Risk Evaluation Clinic-Portuguese Institute of Oncology, Lisbon, Portugal.

Background: Five to ten percent of breast cancers are hereditary and 50-80% due to BRCA1/2 mutations. Because screening of BRCA1/2 mutations is complex and indeterminate results are frequent, only high-risk patients should be counselled for this diagnosis. The possibility of an informative result also depends on diagnostic methodologies performed. **Purpose:** elaboration of an algorithm for BRCA1/2 mutation screening in Portuguese high-risk breast cancer families. **Methods:** Integration of clinical and previous molecular data showing that c.156_157insAlu in the BRCA2 gene is a Portuguese founder mutation, BRCA1 immunohistochemistry helps in selection for screening as well as the prevalence of multiplex ligation dependent probe amplification (MLPA) detected rearrangements. **Results:** We suggest the following algorithm: 1-All samples are first screened for the founder mutation (6-8% positives); 2- if negative in 1 recurrent rearrangements (g.Ex13ins6kb and g.Ex11_15del) are screened by PCR; 3- negatives in 1 and 2 are screened by conformation sensitive gel electrophoresis. The first gene to analyze depends on tumor phenotype: BRCA1 first if BRCA1 immunohistochemistry is negative and/or is a triple negative tumor. BRCA2 first if a BRCA1 phenotype is excluded and/or history of male breast cancer or BRCA2 associated tumours (gastric, M. mieloma, pancreas); 4- if still negative MLPA is performed.

Conclusion: This algorithm might fit into a complete screening program and be superior to current practice in terms of providing more informative results.

P04.043

Correlation between BRCA1 mutations and BRCA1 expression level in breast cancer specimens

N. Lojo - Kadric¹, L. Kapur¹, J. Ramic¹, D. Macic¹, N. Bilalovic², K. Bajrovic¹;
¹Institute for genetic engineering and biotechnology, Sarajevo, Bosnia and Herzegovina, ²Institute of Patology, KCUS, Sarajevo, Bosnia and Herzegovina.

Tumor suppressor BRCA1 gene is associated with increased risk for developing breast and ovarian cancer. Approximately 80% of hereditary breast cancer cases have mutations in BRCA1 gene. This gene is expressed in several organs, including breast and ovary. BRCA1 encodes a 220 kDa protein which consist of 1863 amino acids. Expression of BRCA1 gene is decreased in the most early - detected sporadic breast cancer cases, and it decreases continuously with degree of malignancy.

The goal of this experiment was to investigate whether expression of BRCA1 is affected by mutations on BRCA1 gene. Tumor biptic specimens from patients fulfilling criteria to belong to high to medium risk group for breast cancer development have been consecutively collected at Sarajevo Clinical Center during the period of two years. DNA was isolated from tumor tissue samples using standard salting out procedure. Mutations in BRCA1 gene were identified by MLPA reaction. For expression level measurement, RNA from tumor specimens was isolated using guanidine isothiocyanate method, followed by reverse transcription. Measurement of expression levels of BRCA1 gene was performed in 7300 Real Time PCR system (Applied Biosystems) with SYBR green method. After collecting data, correlation calculations were performed. Results from MLPA analysis were correlated with expression levels of BRCA1 gene. Results are displayed in graphic figures.

P04.044

The 3-step PCR methodology is the correct option to screen the c.156_157insAlu BRCA2 Portuguese founder mutation

P. M. Machado¹, A. Hardouin², S. Santos¹, S. Frago¹, P. Rodrigues³, S. Bento³, S. Braga³, A. Luís⁴, A. Esteves³, F. Vaz⁶;

¹Molecular Biology Department-Portuguese Institute of Oncology, Lisbon, Portugal, ²Laboratoire de Biologie Clinique et Oncologique- Centre François Baclesse, Caen, France, ³Breast Cancer Risk Evaluation Clinic-Portuguese Institute of Oncology, Lisbon, Portugal, ⁴Breast Cancer Risk Evaluation Clinic

- Portuguese Institute of Oncology, Lisbon, Portugal, ⁵Molecular Biology Department and Breast Cancer Risk Evaluation Clinic-Portuguese Institute of Oncology, Lisbon, Portugal.

Introduction: The insertion of an Alu fragment in position c.156_157 of BRCA2, causing exon 3 skipping, was confirmed to be a Portuguese founder mutation and the most frequent BRCA2 rearrangement described. We also optimized a methodology for the screening of this mutation. **Patients and methods:** All new high-risk patients counselled for BRCA1/2 screening in our Centre are pre-screened for this mutation with a 3-step PCR method (Patent pending): 1) exon 3 PCR and sequencing, 2) nested PCR with primers 3AluF/3AluR and 3) RT-PCR and cDNA sequencing. Other Centres, in Portugal and abroad, are implementing this PCR-based method to screen for this mutation. Additional family inquiries are made due to the founder effect of this mutation. **Results:** Twenty-nine apparently nonrelated Portuguese c.156_157insAlu-positive families were diagnosed in our Centre and one BC/OC family of Portuguese ancestry was also diagnosed in Caen, France, using our method. Also, a first degree relative of one of our new probands had been studied in USA and diagnosed with an unknown variant (Q2731E). Exhaustive family inquiries allowed us to connect 3 of these new and apparently non-related families with families already identified. **Conclusion:** The correct option to screen the c.156_157insAlu BRCA2 Portuguese founder mutation is the 3-step PCR method we described. Our data suggests that other methodologies may miss this mutation, preventing these families from obtaining an informative result.

P04.045

Prevalence of large rearrangements in Portuguese hereditary breast/ovarian cancer families

S. Frago¹, J. Eugénio¹, P. Machado¹, S. Santos¹, P. Rodrigues², H. Vicente², S. Bento², A. Esteves², F. Vaz³;

¹Molecular Biology Department- Portuguese Institute of Oncology, Lisbon, Portugal, ²Breast Cancer Risk Evaluation Clinic- Portuguese Institute of Oncology, Lisbon, Portugal, ³Molecular Biology Department and Breast Cancer Risk Evaluation Clinic- Portuguese Institute of Oncology, Lisbon, Portugal.

Background: Hereditary breast/ ovarian (HBO) cancer is mainly related with BRCA1/2 mutations. Given the increasing number of rearrangements reported and the observation that the most frequent BRCA mutation in our country is a BRCA2 rearrangement (c.156_157insAlu), present in about 50% of our BRCA1/2 positive families, the contribution of other large genomic rearrangements to the Portuguese BRCA mutation spectrum must be analysed. **Aim:** to evaluate the frequency of large rearrangements in the BRCA1/2 genes in Portuguese HBO families. **Patients and methods:** Ninety high-risk families, previously negative for BRCA1/2 mutations by conformation sensitive gel electrophoresis, were screened for the g.Ex13ins6Kb BRCA1 by PCR using specific primers and multiplex ligation-dependent probe amplification (MLPA). **Results:** Two additional rearrangements, both in the BRCA1 gene, were observed: g.Ex13ins6Kb (1 family) and g.Ex11_15del (1 family), accounting for 22% (2/9) of the BRCA1 mutation spectrum in our families. With the MLPA BRCA2 kit, 1 patient was found to be positive for the 1100delC mutation in CHEK2 and 3 patients had copy number changes in this gene. No large BRCA2 rearrangements were observed. **Conclusion:** Besides the screening of the founder BRCA2 rearrangement in our population, index high-risk cases negative for BRCA1/2 point mutations should be analysed for other possible genomic BRCA rearrangements. Although infrequently, CHEK2*1100delC is present as a low penetrance allele in our population. Additional studies are necessary to clarify the relevance of copy number changes in CHEK2 gene.

Zoom-in Array-CGH in BRCA1, BRCA2, MLH1, MSH2 and APC genes : detection and characterization of five new germline large rearrangements

E. Rouleau¹, S. Tozlu¹, C. Andrieu¹, C. Lefol¹, V. Bourdon², T. Nogush², C. Nogues¹, S. Olschwang², H. Sobol², I. Bieche¹, R. Lidereau¹;

¹Centre Rene Huguenin, St Cloud, France, ²Institut Paoli-Calmettes, Marseille, France.

Genetic predisposition to breast, ovarian, colorectal cancers results mainly from alterations in BRCA1, BRCA2, MLH1, MSH2 and APC genes. Except for BRCA2, rearrangements represent 10 to 15% of

deleterious mutations. Many routine detection techniques are available, but none gives a panoramic view of the gene and characterizes breaking points.

We have developed a zoom-in array-CGH for detecting and characterizing rearrangements based on Agilent® high-resolution oligonucleotide array-CGH technology. The Centre René Huguenin designed three specific arrays for the *BRCA1* (1679 oligonucleotides) & *BRCA2* (1389), *MLH1* (1031) & *MSH2* (789) and *APC* (1573) genes.

Prior to use this approach in routine, we analyzed 18 DNA samples with a large deletion or duplication detected with QMPF, MLPA or qPCR: 10 *BRCA1/BRCA2*, and 3 *MLH1/MSH2* from Centre René Huguenin and 4 *APC* from Institut Paoli Calmettes.

All the large rearrangements from single small exon to the whole gene were detected (size estimated to within 1-2 kb). Five never-reported events were characterized (table). Except for the whole *APC* gene deletion, the event was characterized thanks to a simple PCR.

Zoom-in Array-CGH described here gives the opportunity to rapidly screen a group of genes involved in breast and colorectal cancer. Despite its cost, this method can assist with the development of simple PCR-based genetic test. Additional studies are needed to define its position in routine testing.

Five new germline large rearrangements characterized with zoom-in array-CGH and sequencing

Genes	Events	Size
<i>BRCA1</i>	deletion exon 3	11 452 bp
<i>BRCA2</i>	duplication exons 17-20	14 756 bp
<i>APC</i>	deletion exons 12-14	6 360bp with insertion 351bp
<i>MLH1</i>	duplication exon 4	1 664 bp
<i>MSH2</i>	deletion exons 8-10	26 349 bp

P04.047

Estrogen receptor- α (*ESR1*) gene polymorphisms in Iranian women with breast cancer: a case control study

S. Abbasi¹, P. Ismail², F. Othman², C. Azimi², R. Omranipoor⁴, Z. Ousati Ashtiani⁵, M. Mojarad⁶, S. Abdi-Oskouie⁵, F. Mahboubi Nejad⁶;

¹School of Allied Medical Sciences, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran, ²Department of Biomedical Science, Faculty of Medicine and Health Science, Universiti Putra, Serdang, Malaysia, ³Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran, ⁴Department of Surgery, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran, ⁵Department of Medical Genetics, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran.

Receptor-mediated estrogen activation participates in the development and progression of breast cancer. Evidence suggests that alterations in estrogen signaling pathways, including *ESR1* occur during breast cancer development. *ESR1* polymorphism has been found to be associated with breast cancer in Caucasians. Epidemiologic studies have revealed that age-incidence patterns of breast cancer in Middle East differ from those in Caucasians. Genomic data for *ESR1* in either population is therefore of value in the clinical setting for that ethnic group and we have investigated whether polymorphisms in the *ESR1* are associated with breast cancer risk.

A case-control study was conducted to establish a database of *ESR1* polymorphisms in Iranian population in order to compare Western and Iranian distributions and to evaluate *ESR1* polymorphism as an indicator of clinical outcome. The *ESR1* gene was scanned in Iranian patients newly diagnosed invasive breast tumors (150 patients) and in healthy individuals (147 healthy individuals). PCR single-strand conformation polymorphism technology and ³²P-cycle sequencing was performed.

The sets of silent single nucleotide polymorphisms were found, as reported previously in other studies, but at significantly different frequencies. Among these SNPs, the frequency of allele 1 in codon P325P (C1337G) was higher in breast cancer patients (10.3%) than in control individuals (8.8%; $P=0.538$), although the difference was not statistically significant. The allele 1 in codon H267L (A1162T) exhibited an association with the occurrence of family history of cancer among breast cancer (0.8%; $P=0.004$).

Our data suggest that *ESR1* polymorphisms are correlated with various aspects of breast cancer in Iranian *ESR1* genotype.

EMQN Best Practice Guidelines for Molecular Analysis in Hereditary Breast/Ovarian Cancer

N. E. Larsson¹, Å. Borg², O. Sinilnikova³, S. Hodgson⁴, C. Müller-Reible⁵, U. Kristoffersson¹;

¹Department of Genetics, Lund University Hospital, Lund, Sweden, ²Department of Oncology, Lund University Hospital, Lund, Sweden, ³Unité Mixte de Génétique Constitutionnelle des Cancers Fréquents, Hospices Civils de Lyon-Centre Léon Bérard, Lyon, France, ⁴Department of Cancer Genetics, St George's Hospital, University of London, London, United Kingdom, ⁵Department of Human Genetics, University of Würzburg, Würzburg, Germany.

Breast cancer is the most frequent form of cancer in women. Genetic predisposition underlies 5-10% of all breast cancer and up to 40% of cases in patients under the age of 35 years. The discovery of *BRCA1* and *BRCA2* in 1994 and 1995, respectively, was anticipated to greatly increase our knowledge of hereditary breast cancer. This was immediately followed by an increasing demand for genetic testing from health care to predict future cancer risks. Since then, breast cancer genetics has become a major part of the workload of clinical genetics clinics.

The identification of the *BRCA1/2* mutations and the communication of the genetic information are essential for women at high risk for breast cancer. As a result, guidelines for genetic counselling and laboratory quality assessment in cancer genetics have been developed at local and national levels both in Europe and in the USA. The European Molecular Genetics Quality Network (EMQN) drafted best practice guidelines on breast/ovarian cancer genetic testing as a first attempt towards European harmonisation in 1999. In 2007, OECD has issued general recommendations for molecular genetic testing. The best practice guidelines presented here are the results of discussions among European breast cancer geneticists at a workshop in Würzburg, Germany, October 24-25, 2007 with the aim of updating the 1999 EMQN guidelines.

P04.049

HFE and TFR polymorphisms in the risk of breast cancer in São Miguel population (Azores, Portugal)

P. R. Pacheco^{1,2}, M. J. Brilhante¹, C. Ballart¹, T. Eloi¹, C. C. Branco^{1,2}, R. Cabral^{1,2}, V. Santos¹, V. Carneiro¹, L. Mota-Vieira^{1,2};

¹Hospital Divino Espírito Santo de Ponta Delgada, EPE, Azores, Portugal, ²Instituto Gulbenkian de Ciência, Oeiras, Portugal.

Iron overload has been noticed as a feature of breast cancer (BC). *HFE* mutations, which lead to iron uptake increase, have been evaluated as risk factor. Some studies concluded that BC risk increase is also dependent on *HFE*-interacting genes, such as the transferrin receptor (*TFR*) and the combination between *HFE-TFR* genotypes.

To assess if *HFE* mutations, *TFR-S142G* polymorphism and *HFE-TFR* genotypes are related to BC risk, we compared C282Y, H63D and S142G frequencies in 86 BC women and in 183 gender/age matched healthy controls. Samples were obtained after written informed consent.

The C282Y allele frequency in the BC group was 4.07%, higher than in control group, 3.28%; while H63D mutation showed a similar frequency in BC, 21.51%, and controls, 21.04%. Although both groups were stratified according to menopausal status, odds ratio (OR) analysis for cancer risk associated with *HFE* mutations was not statistically significant. Regarding S142G polymorphism, the frequency of S142S, S142G and G142G genotypes were equivalent in both groups. In order to extend the search for a supposed BC susceptibility for *HFE-TFR* genotypes, we analysed BC and controls according to compound genotypes. Again, OR for all *HFE-TFR* genotype combinations revealed no increased risk for BC.

In conclusion, the results suggest that *HFE* mutations are not associated with an increased risk for BC. *TFR* polymorphism was not an independent risk factor and did not modify the disease risk. Furthermore, variants of the *HFE-TFR* have, apparently, no direct effect on the incidence of breast cancer in the Azorean female population.

P04.050**Chromosomal aberrations in Breast cancer patients in Tamilnadu Region**

R. Sangeetha, V. Balachandar, B. LakshmanKumar, K. Suresh, K. Sasikala; Human Genetics Laboratory, School of Life Sciences, Bharathiar University, Coimbatore, India.

Breast cancer is the most common cancer in women and accounts for between 18-25% of all female malignancies world-wide. In India, the incidence of breast cancer is increasing, with an estimated 80,000 new cases diagnosed annually. The frequency of chromosome instability in peripheral blood lymphocytes is relevant biomarker for cancer risk in humans. So, the present investigation aimed to find out the major chromosomal alteration in breast cancer patients in Tamilnadu region by using the conventional karyotyping method. In the present study 63 experimental subjects were selected on the basis of CA15.3 marker which is the most widely used serum biochemical tumor marker in breast cancer and equal number of controls were selected and confirmed by CA53 level. The work was carried out in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki. After signing a consent form, both cases (experimentals and controls) provided a blood sample (5 ml) to establish the 72hrs cell cultures.

In the present study deletion and translocation were frequently observed in chromosome 1, 11 and 17. (46, XX, del (1p); 46, XX, del (11q); 46, XX, del (17q). 46, XX, t (1q⁺16q⁻); 46, XX, t (11q⁺7p⁻); 46, XX, t (17q⁺4q⁻)).

In the near future, we can look forward to the identification of novel breast cancer predisposing genes due to rapid advancement of gene discovery technologies. The identification and functional characterization of such genes will have a significant impact on breast cancer research and early detection.

P04.051**Characterization of novel large genomic rearrangements in the BRCA1/2 genes of Spanish families with breast/ovarian cancer**

S. Palanca¹, E. Esteban¹, I. de Juan¹, E. Barragán¹, S. Oltra², I. Chirivella³, Á. Segura⁴, C. Guillén⁵, E. Martínez⁶, P. Bolufer¹;

¹Lab. Biología Molecular. Hospital U. La Fe, Valencia, Spain, ²Unidad de Genética. Hospital U. La Fe, Valencia, Spain, ³UCGC Hospital Clínico Universitario, Valencia, Spain, ⁴UCGC Hospital U. La Fe, Valencia, Spain, ⁵UCGC Hospital General de Elche, Alicante, Spain, ⁶UCGC Consorcio Hospital Provincial, Castellón, Spain.

Background: Mutations in *BRCA1/2* genes affecting a small number of nucleotides are the responsible for the majority (90%) of hereditary breast and/or ovarian cancers (HBOC). However, there is an increasing evidence of the contribution of large genomic rearrangements (LGRs) of *BRCA1/2* genes to HBOC.

The purpose of this study is to characterize the novel LGRs identified in *BRCA1/2* genes and determine its prevalence in families studied in Program of Genetic Counselling on Cancer of the Valencian Community (Spain).

Method: We used the multiplex ligation-dependent probe amplification (MLPA) to screen for LGRs in 255 unrelated index patients with familial breast and/or ovarian cancer negative for *BRCA1/2* mutations. Characterization of the LGRs was carried out by performing long-range PCR followed by sequencing.

Results: Nine different LGRs were identified in once index patients out of the 225 (4.3%), seven in *BRCA1* and two in *BRCA2*. Five *BRCA1* LGRs have been already reported (1A/1B and 2 deletion; 5 to 7 deletion; 8 to 13 deletion, exon 20 deletion and amplification of exon 20) and also four novel LGRs were found. Characterization of the novel mutations revealed the presence of deletions that encompass exons 3 to 5 of *BRCA1*, partial deletion of exon 21 of *BRCA1*, deletion of exons 22 to 24 of *BRCA2* and deletion of exon 2 of *BRCA2* gene.

Conclusions: These findings contribute to broaden the spectrum of LGRs described in the *BRCA1/2* genes. Additionally, our data emphasize the relevance of LGRs in the mutational study of *BRCA1/2* genes of high-risk families.

P04.052**UNC5 genes and breast cancer: a mutation screening and LOH analysis**

E. Bonora¹, C. Evangelisti¹, I. Kurelac¹, M. Vargiolu¹, D. Fusco¹, A. Berne², P. Mehlen³, G. Romeo¹;

¹Unit of Medical Genetics, Bologna, Italy, ²CNRS UMR 5238 Laboratoire Apoptose, Cancer et Développement, Centre Léon Bérard, Lyon, France, ³CNRS UMR 5238 Laboratoire Apoptose, Cancer et Développement, Centre Léon Bérard, Lyon, France.

Dependence Receptors (DR) display the common feature of inducing two completely opposite intracellular signals: in the presence of the ligand, they transduce a positive survival signal, whilst in its absence, they induce apoptosis. The three mammalian receptors named UNC5A, UNC5B, and UNC5C in human, belong to the family of the netrin-1 receptors, act as mediators of netrin-1 chemorepulsive effect during neural development, but also work as dependence receptors. Expression of human genes is down-regulated in multiple cancers including colorectal and breast cancers. In colorectal tumors, this down-regulation is associated with loss of heterozygosity (LOH). In order to verify the possible LOH in breast cancer, a panel of 57 breast tumors were analysed for these genes using intragenic microsatellite markers, but no LOH was detected. Since mutations impairing mRNA or protein levels would not have been detected by LOH analysis only, a mutation screening of PCR amplified exons is currently ongoing. In UNC5B a new variant was identified in exon 10, T1909C, which results in a silent substitution in the protein but by in silico analysis affects an exon splicing enhancer (ESE), which could modify mRNA processing. The change is now tested in a panel of 100 controls. Depending on the results obtained, the variant will be further investigated using a splicing assay with a synthetic minigene. The analysis is still ongoing and final results will be presented.

P04.053**Misbehaviour of XIST RNA in breast cancer cells**

S. M. Tabano¹, L. Monti¹, M. Recalcati², M. Gariboldi³, F. R. Grat⁴, P. Finelli^{5,6}, P. Radice^{3,6,6}, M. Miozzo¹, **S. M. Sirchia**¹;

Recently, a strong open debate has been dragging on about the role of the *BRCA1* in the XCI (X chromosome inactivation) process and about the meaning of the "Disappearing Barr Body" observed in breast and ovarian cancer. A definitive answer about the hypothetical function of *BRCA1* in the correct localization of *XIST* RNA on the inactive X chromosome (Xi) hasn't been found yet, while it's known that in breast cancer, especially with basal like phenotype, can be frequently observed X chromosome anomalies, mainly Xi loss associated to replication of the active X chromosome (Xa).

We investigated some aspects to further sound out the supposed link between *BRCA1* and *XIST* expression/localization. In addition, we tested the possibility of *XIST* RNA to associate with a different target than Xi, in presence of anomalous XCI status, a common feature of breast carcinomas. The study was performed on tumor cell lines and breast carcinomas by a combined genetics and epigenetics approach.

We drawn the following conclusions: i) high levels of *XIST* RNA were observed as a marker of *BRCA1*-associate BLC; ii) *BRCA1* was involved in regulation of *XIST* expression on the Xa, but we confirmed the absence of a link between *BRCA1* and *XIST* nuclear distribution; finally, we surprisingly surveyed in breast cancer cells the ability of *XIST* RNA to decorate an active X chromosome, demonstrating that the presence of focal *XIST* staining in the nucleus does not prove the existence of an inactive X chromosome.

P04.054**Genetic peculiarities of families with inherited bilateral breast cancer**

N. I. Pospekhova¹, L. N. Lubchenko², A. N. Loginova¹, E. V. Poddubskaya², R. F. Garkavtseva², A. V. Karpukhin¹;

¹Research Centre For Medical Genetics, Moscow, Russian Federation, ²Cancer

Research Centre, Moscow, Russian Federation.

Bilateral breast cancer (BiBC) is considered as phenotypic sign of inherited breast cancer risk. However it is unknown if there any peculiarities of familial breast cancer (BC) with cases of BiBC.

We investigated BRCA1/2 mutations among 38 patients with BiBC who had one or more relatives with BC or ovarian cancer (OC). The BRCA1/2 mutations were found among 19 patients (50%). The BRCA1 gene mutations were predominant (16 of 19, 84%) with prevailing 5382insC (9 of 16, 56%). Two BRCA1 gene mutations - 3411delCT and 3747insA and three BRCA2 mutations - P3039P, 9498delC, 886delGT were revealed in Russia for the first time. Among 10 BC/OC families there were 6 BRCA1 mutations that fully correspond to 60% defined earlier for the same families without BiBC. Among BiBC families with BC only 36% had BRCA1 mutations. For comparison, among 92 BC families unselected on BiBC there were 21% mutations. Another words, BRCA1 mutations in BiBC families more frequently predispose to BC only than in families without BiBC. Beside this, there were 10 cases of repeated BiBC in 8 families and all of them were BC only families. It may be proposed that in some families with BiBC there is genetic influence that modify risk of cancer localization. In part supported by grant RFBR N 07-04-01602.

P04.055

High frequency of BRCA1 gene mutations among patients with pregnancy associated breast cancer

A. N. Loginova¹, L. N. Lubchenko², A. A. Parokonnaya², A. A. Lushnykova², R. F. Garkavtseva², N. I. Pospekhova¹, A. V. Karpukhin¹;

¹Research Centre For Medical Genetics, Moscow, Russian Federation, ²Cancer Research Centre, Moscow, Russian Federation.

A relationship between a pregnancy and breast cancer risk is a subject of studying at last time. The reasons for breast cancer onset during a pregnancy are not clear at present time. A role of BRCA1/2 mutations in pregnancy associated breast cancer (PABC) onset is not well established. We studied the most frequent in Russia BRCA1 mutations 5382insC, C61G and 185delAG in a sample of 74 patients with PABC and in a control sample of 75 breast cancer patients. A control sample was adjusted on age of diagnosis among PABC patients (an average age 33 year). There were 12 of 74 PABC patients with BRCA1 mutations (16%). The patients with 5382insC mutation were predominant (11 of 12). For all but one of 12 PABC patients breast cancer was diagnosed during second or futher pregnancy. Among patients of control sample there were 6 with mutations (8%), all 5382insC. The high BRCA1 mutation frequency among PABC patients could connected with some peculiarities of this patient group. We found that the age of diagnose for BRCA1-associated breast cancer among PABC patients was in interval 26-35 years while among patients of control group - 33-46 years. Thus the high frequency of BRCA1 mutations and early breast cancer onset among PABC patients is suggestive on undetermined now genetics or phenotypic peculiarities that may increased breast cancer risk during a pregnancy.

P04.056

CLSPN gene in hereditary susceptibility to breast cancer

H. Erkkö^{1,2}, K. Pylkäs^{1,2}, S. Karppinen^{1,2}, R. Winqvist^{1,2};

¹Laboratory of Cancer Genetics, University of Oulu, Oulu, Finland, ²Biocenter Oulu, Oulu, Finland.

Approximately 5-10 % of breast cancer is thought to be due to an inherited disease predisposition. Mutations in currently known cancer susceptibility genes explain only 20-30% of the familial cases, which suggests the contribution of additional genes. Claspin, encoded by the *CLSPN* gene, is involved in monitoring of replication and sensing of DNA damage, during which it cooperates with CHK1, BRCA1 and ATR. As many previously identified susceptibility factors act in similar functional pathways as claspin, *CLSPN* is a plausible candidate gene for heritable breast cancer susceptibility. Here we have screened the entire coding region of the *CLSPN* gene for mutations in affected index cases from 125 Finnish families with breast and/or ovarian cancer using conformation sensitive gel electrophoresis (CSGE) and direct sequencing. Several sequence changes were observed, but none of them appeared to significantly associate with breast cancer susceptibility. To our knowledge, this is the first study reporting the mutation screening of the *CLSPN* gene in familial breast cancer cases.

P04.057

BRCA1-c.5272-1G>A and BRCA2-c.5374_5377delTATG are Founder Mutations in the East of Castilla-León (Spain)

M. Infante¹, M. Duran¹, L. Pérez-Cabornero¹, D. J. Sanz¹, E. Lastra², C. Miner¹, E. Velasco¹;

¹IBGM, Valladolid, Spain, ²Hospital General Yagüe, Burgos, Spain.

The incidence of germline mutations in BRCA1 and BRCA2 genes in high-risk families for hereditary breast and/or ovarian cancer varies among different populations; presenting a wide spectrum of unique mutations, whereas in other groups specific mutations show a high frequency due to a founder effect. The mutations c.5272-1G>A in BRCA1 and c.5374_5377delTATG in BRCA2 are the most prevalent in our region; they have been identified seven and nine times, respectively, in our population suggesting the existence of founder effects in our region.

Six highly polymorphic markers spanning BRCA1 (D17S800, D17S1185, D17S855, D17S1323, D17S1325 and D17S579) and four in BRCA2 (D13S171, D13S260, D13S1695 and D13S1698) were genotyped in 16 index cases and additional family members. The estimation of founder mutation age in generations was calculated using the equation $G = \log \delta / \log (1-\theta)^{-1}$.

All carriers of c.5272-1G>A shared the same alleles at the six markers of BRCA1. We could not estimate the age of the mutation because the lack of recombinant markers that are required for this purpose. A conserved haplotype was observed in c.5374_5377delTATG positive families between the two external markers (approximately 1 Mb interval). The mutation occurred approximately 36 generations (900 years assuming 25 years per generation). The corresponding haplotype of each mutation were absent in non-carriers and 75 healthy controls supporting the hypothesis of a common ancestry. Conclusively, mutations c.5272-1G>A for BRCA1 and c.5374_5377delTATG for BRCA2 are founder in our region.

P04.058

Tissue microarray analysis of 1q21.3 and 1q23.3 copy number changes in ovarian tumors with different clinicopathological parameters

I. Dimova¹, B. Orsetti², R. Dimitrov³, S. Raicheva⁴, N. Doganov³, C. Theille², D. Toncheva¹;

¹Department of medical genetics, Sofia, Bulgaria, ²INSERM U868, Montpellier, France, ³University Hospital of Obstetrics and Gynecology, Sofia, Bulgaria, ⁴Laboratory of Gynecopathology, Sofia, Bulgaria.

Many studies reported that aberrations like amplifications, deletions and translocations of 1q21-q23 have been found in ovarian tumors. These findings increase the scientific interest in analyzing this region by means of specific gene probes. The object of our study was to investigate the frequency of copy number changes of two specific BAC clones in 1q21.3 and 1q23.3 in large number ovarian tumors from different malignancy, histology, stage and grade, arranged in tissue microarrays, in order to analyze their correlation with tumor phenotype. Copy number changes of 1q21.3 were established in 9.64% of malignant, in 8.33% of LMP and in 13.13% of benign ovarian tumors. Copy number changes of 1q23.3 were found in 17.78% of malignant, in 16.67% of LMP and in 12.64% of benign ovarian tumors. We have found significantly more frequent gain of 1q23.3 in non-epithelial tumors (50%) compared to epithelial ones (14.73%) ($p < 0.03$). According to our results the gain of 1q21.3 prevailed in non-serous (especially mucinous) malignant and LMP ovarian tumors in comparison to serous tumors. In non-serous tumors both gains were associated with higher grade. The gain of 1q23.3 was 2.5 times more frequent than the gain of 1q21.3 in ovarian cancers.

P04.059

Complex BRCA1 and BRCA2 SNP combinations are associated with breast and ovarian cancer risk modification

T. Y. Smirnova¹, N. I. Pospekhova¹, A. N. Loginova¹, L. N. Lubchenko², R. F. Garkavtseva², E. K. Ginter¹, A. V. Karpukhin¹;

¹Research Centre For Medical Genetics, Moscow, Russian Federation, ²Cancer Research Centre, Moscow, Russian Federation.

There are growing evidence that a number of gene variant combinations have important value for cancer risk. We have studied a significance of all combinations of BRCA1 E1038G and BRCA2 N372H,

203G>A among patients with sporadic breast and ovarian cancer, patients with the same types of cancer with BRCA1 mutations and a control sample. It was shown that genotype E1038E-N372N-203AA was associated with ovarian cancer risk for both sporadic and BRCA1-associated ovarian cancer (OR=6,8; P=0,04). At the same time, genotypes E1038E-N372H-203GA and G1038G-N372N-203GA were associated with decreased ovarian cancer risk (OR=0,2; 0,1; P=0,04; 0,02, respectively). In the sample of sporadic breast cancer genotype E1038E-203GA was associated with decreased risk independently on N372H genotypes (OR=0,1; P=0,0001) and G1038G-N372N - independently on 203G>A (OR=0,2; P=0,01). The sporadic breast cancer risk was increased under E1038G-N372H (OR=2,1;P=0,04). There was no difference of any genotype frequencies and their combinations between BRCA1 mutation carriers with breast cancer and control sample. This may mean that no risk modifications are required for breast cancer localization under BRCA1 mutations. Thus the genotype combination increasing cancer risk is different for ovarian and sporadic breast cancer and those decreasing cancer risk are the same but degenerated on N372H under breast cancer. The results demonstrate that different genotype combination on the same SNPs may have influence on modifying cancer risk of definite localization. The risk genotypes on several SNPs may include both heterozygotes and homozygotes as on rare so on frequent alleles. It is necessary take into account under polygene influence analysis.

P04.060

Molecular cytogenetic analysis of malignant ovarian tumours

R. Mihalova¹, P. Lnenicka¹, N. Jancarkova², M. Vrbova¹, M. Janashia¹, M. Krkavcova¹, M. Kohoutova¹;

¹Institute of Biology and Medical Genetics of the 1st Faculty of Medicine and General Teaching Hospital, Charles University, Prague, Czech Republic, ²Department of Gynaecology and Obstetrics of the 1st Faculty of Medicine and General Teaching Hospital, Charles University, Prague, Czech Republic.

Ovarian cancer represents almost 30 % of the malignancies of the female genital tract with the highest mortality of all of the gynaecological cancers. Unfortunately, majority of patients is diagnosed at advance stage of the disease. The genetic changes involved in pathogenesis of ovarian cancer are still not completely understood. Currently there are no specific prognostic markers for prediction of the disease course, for earlier diagnostics or for individual therapeutic strategies. One of possible biological markers of great importance are chromosome changes. Chromosome aberrations in ovarian tumour cells are highly complex with hypodiploid or polyploid constitution. The aim of the study is to determine significant chromosome changes as reliable predictive markers.

We examined 30 ovarian cancer samples by comparative genomic hybridization. Chromosome imbalances were detected in 90 % of tumour samples. The most frequent recurrent changes were gains of 1q, 3q, 8q and 20q and losses of 4p, 4q, 18p, 18q, 19q and 22q. The results of molecular cytogenetic analysis were correlated with histological/morphological and clinical findings. Summarized data showed that significance of chromosome changes in our patients is relatively low. Despite of these results particular chromosome regions were assumed to be involved in ovarian cancerogenesis. These regions are worthy of further investigations considering the presence of candidate genes.

Supported by grant MSM 0021620808.

Aberrant promoter methylation of *GPR150*, *ITGA8* and *HOXD11* in ovarian cancers induced by *PRTFDC1* silencing

A. Kondo¹, L. Cai^{1,2}, M. Abe², Y. Morita¹, H. Yokoyama¹, S. Izumi¹, T. Ushijima²;

¹Tokai University, Isehara, Japan, ²National Cancer Center Research Institute, Tokyo, Japan.

It is known that methylated CpG island (CGIs) in promoter region could be seen in tumor-suppressor genes and disease markers. In this study, we performed a genome-wide screening for altered methylated DNA fragments with methylation-sensitive-representational difference analysis (MS-RDA) to show aberrant promoter methylation of CpG island in human ovarian cancers. We have obtained 185 DNA fragments specifically methylated in an ovarian cancer cell line (ES-2). We used a normal human ovarian epithelial cell line, HOSE6-3 as a control. In this control cell line, 33 DNA fragments were derived from putative promoter CGIs. Ten ovarian cancer cell lines were ana-

lyzed by methylation-specific PCR, and seven (*GPR150*, *LOC222171*, *PRTFDC1*, *LOC339210*, *ITGA8*, *C9orf64* and *HOXD11*) of the 33 CGIs were methylated in one or more of the cell lines. Expression of down stream genes of those methylated CGIs were analyzed by quantitative reverse-transcription-PCR and the result showed that those genes were not expressed in cell lines without unmethylated DNA. Demethylation of methylated cell lines with 5-aza-2'-deoxycytidine restored expression of two genes (*PRTFDC1* and *C9orf64*). In primary ovarian cancers, CGIs of *GPR150* (in 4 of 15 cancers), *ITGA8* (2/15), *PRTFDC1* (1/15), and *HOXD11* (1/15) were methylated. Silencing of *PRTFDC1* was revealed that aberrant methylation of *GPR150*, *ITGA8* and *HOXD11* could be candidate as tumor markers.

The study of P53 gene mutations in patients of breast cancer in Rafsanjan city

M. Mirzaei Abbasabadi, M. Hajizadeh, M. Mirzaei Abbasabadi, M. Mahmudi, G. Asadi karam, E. Rezazadeh, M. Asiabanan;

Medical University of Rafsanjan, Rafsanjan, Islamic Republic of Iran.

Background: P53 gene Mutation is the most common genetic change in human neoplasia. In breast Cancer, p53 mutation is associated with more aggressive disease and worse overall survival. The PCR-SSCP is the common test for mutation analysis of p53.

Materials and methods: DNA extraction from 48 paraffin Tissue samples of patients done by standard Phenol chloroform method, exons 5-8 amplified by PCR and PCR products underwent SSCP gel analysis for detection of probable mutations.

Results: Abnormal movement of PCR products band in SSCP gel that stained with silver nitrate reported as mutation. We found three mutations in exon 5, 2 in exon 6, one in exon 7 and 2 in exon8.

Discussion: Detection of P53 gene mutations can be helpful in pre diagnosis and prevention of breast cancer and so in treatment. These mutations occur in normal or benign breast tissue but resolutions of this role in the pathogenesis or breast cancer will require long-term follow-up studies.

p53, p63 and p73 isoforms in breast cancer

Z. Milicevic¹, V. Bajic², B. Potparevic-Spremo³, L. Zivkovic³;

¹"VINCA" Institute of Nuclear Sciences, Laboratory for Molecular Biology and Endocrinology, Belgrade, Serbia, ²Institute of Biomedical Research Galenika, Belgrade, Serbia, ³Faculty of Pharmacy, Institute of Physiology, Department of Biology and Human genetics, Belgrade, Serbia.

The spectrum of genetic alterations identified in cancer cells includes mutations in various genes leading to structural and functional dysfunctions in signal transmission as well as over- or under expression of positive or negative signal generating proteins. Recently, two family members of the suppressor gene p53 have been described, p63 and p73, which seem to be necessary for specific p53-induced stress-response pathways.

Furthermore, p63 and p73 appears to be crucial to determine the cellular sensitivity to anticancer drugs, particularly in tumors lacking functional p53.

For analysis we used invasive breast carcinoma of common types with a different differentiation and stages as well as a normal breast tissue from patients with benign and malignant tumors. Protein p53 expression was estimated by Western blot analysis using anti p53 Abs DO-7 and CM-1. Our data show that breast cancer cells express nine different isoforms of p53, p63 and p73. The changes in the interactions between p53, p63 and p73 isoforms are likely to be fundamental to our understanding in the transition between normal cell cycling and the onset of tumor formation.

Therefore, determination of p53 status in clinical studies is much more complex than hitherto appreciated. It suggests that it requires an integrated and complex analysis of p53 isoform expressions associated with p53 mutation analysis and immunohistochemistry. To date, no clinical studies have integrated all those p53 parameters to determine p53 status.

P04.064**Dissection of allelic molecular pathology of the *SEMA6B* gene frequently altered in breast cancer**

E. A. Pudova¹, E. B. Kuznetsova^{1,2}, L. E. Zavalishina³, G. A. Frank³, D. V. Zaitaev^{1,2}, V. V. Strelnikov^{1,2};

¹Research Centre for Medical Genetics, Moscow, Russian Federation, ²Sechenov Moscow Medical Academy, Moscow, Russian Federation, ³Moscow P.A. Gertsen Oncology Research Institute, Moscow, Russian Federation.

We have assessed promoter methylation, altered expression and allelic imbalance of the *SEMA6B* gene in sporadic breast cancer and report that at least one of these molecular alterations is found in 75% of tumors. Taken separately, allelic imbalance was demonstrated in a half of all tumor samples, reduced expression and abnormal promoter methylation in 40% each. At the same time, the features supposed to be in close relation to each other, such as allelic imbalance and expression and/or promoter methylation and expression were poorly correlated. Several samples demonstrated intact gene expression in the presence of methylation and/or allelic imbalance and vice versa, questioning functional interactions between these parameters. Similar observations were made for several other candidate tumor suppressor genes, including another member of the semaphorin family, *SEMA3B*. We suggest that this may be a result of a nonallelic approach, where each form of molecular pathology is analyzed in the sample as a whole, without allelic discrimination. We have developed assays to assess allelic alterations based on a minisequencing technique in its SnaPshot modification (Applied Biosystems, USA). Having elaborated a coding intragenic SNP rs2304213 with heterozygosity close to 50% we have evaluated allelic imbalance and patterns of allelic methylation and gene expression in 22 informative samples of breast cancer versus adjacent control tissues. Data obtained from each individual sample will be presented. *The study is supported by Friends for an Earlier Breast Cancer Test Foundation, USA.*

P04.065**Mutation screening of *BRCA1* using Non-Radioactive PCR-SSCP analysis at 17q21 in breast carcinomas from non-familial cases**

S. Ghorbanpoor¹, A. Bidmeshkipoor¹, M. H. Mirmomeni¹, S. khazaie²;

¹Razi university, Kermanshah, Islamic Republic of Iran, ²Imam Reza Hospital Molecular pathology, Kermanshah, Islamic Republic of Iran.

BRCA1 is a well-established breast cancer susceptibility gene. Correlation of breast cancer with *BRCA1* mutation was studied in sporadic breast cancers since this gene is implicated in the double strand DNA repair and mitotic checkpoint, and loss of its function is speculated to result in the accumulation of chromosomal instability. In the present study, breast tumors of sporadic cancer were investigated for allelic imbalance (AI) at the *BRCA1* locus. Furthermore, 30 breast carcinomas from patients with sporadic disease were examined to detect *BRCA1*-mutation(s), including exons 5, 11A, and 11B by using non-radioactive polymerase chain reaction-single-strand conformation polymorphism (PCR-SSCP) technique followed by direct sequencing. Designed primers were used to amplify three DNA fragments of 235, 300, and 296 bp for detection of these exons mutations, respectively. After the PCR products were denatured, we have used SSCP technique to detect *BRCA1* mutations. We investigated mutations in 6 cases (20%); 4 cases (13.3%) in exon 5, no case in exon 11A and 2 cases (6.7%) in exon 11B. Clinicopathological patients information was obtained from their files and pathologic reports. The relationship between these exons mutations and the clinicopathological variables was analyzed by the Fisher's exact test. Our results suggest that exon 5 and exon 11B gene mutations contribute to the development of sporadic breast cancer in kermanshah people.

P04.066**Investigation of chromosomal radiosensitivity in the peripheral blood of Iranian women with sporadic Breast cancer: A pilot study**

F. Mojtahedi^{1,2}, F. Seirati³, E. Keihani¹, M. Karimloo⁴, S. Akhlaghpour⁵, A. Sarem², I. Bagherizadeh¹, S. Ghasemi Firouzabadi¹, M. Fallah¹, J. Ansari¹, F. Behjati¹;

of social welfare and rehabilitation sciences, Tehran, Islamic Republic of Iran,

⁵Novin Radiation therapy Medical Center, Tehran, Islamic Republic of Iran.

Breast cancer is the most frequent malignancy and the main cause of death amongst women worldwide and in Iran. Links between cancer predisposition and cellular radiosensitivity are well established and arose from investigations into chromosomal instability syndromes such as ataxia-Telangiectasia.

It has been shown that sensitivity to ionizing radiation by induction of chromosome aberration is, on average, higher in lymphocytes of breast cancer patients compared to healthy controls. It is therefore important to show that elevated chromosomal radiosensitivity may be a marker for breast cancer predisposition. In addition to chromosomal instability syndromes, approximately 40% of patients with breast cancer, 30% with colorectal cancer and 30% with head and neck cancer appear to show evidence of cellular radiosensitivity compared to healthy controls using the chromosomal G2 assay. Approximately 5-14% of the normal population has been shown to be radiosensitive and the connection between predisposition to cancer and radiosensitivity has led to the suggestion that chromosomal radiosensitivity may be used as an indicator of cancer proneness in the normal population.

In this study, 32 patients with sporadic breast cancer and 30 normal women as controls were investigated for their Chromosome radiosensitivity using gamma irradiation for the cultured lymphocytes at G2 stage of the cell cycle. Our results showed significant increase in chromosome breakage in the patients compared to normal controls. There was also heterogeneity in chromosome breakage rate within the normal controls, which may suggest an increased risk for breast cancer in some normal women with increased chromosome breakage.

P04.067**X inactivation analysis in *BRCA1* carriers and in patients with hereditary breast cancer**

E. Beristain, C. Martínez-Bouzas, N. Puente-Unzueta, N. Viguera, M. I. Tejada; Hospital de Cruces, Barakaldo, Spain.

One of the two X chromosomes in female mammalian cells is inactivated in early embryonic life. The majority of females have a 50:50 distribution of the two cell types. A deviation from this distribution (skewed X inactivation) occur in female carriers of some X linked disorders. Furthermore, recently it has been reported that early onset breast cancer (BC) patients and *BRCA1* carriers have a significant higher frequency of skewed X inactivation than controls.

The aim of this work was to compare X inactivation in two groups of BC women: *BRCA1*-carriers and *BRCA1* negative cases with familial BC. We have studied 14 women carrying a *BRCA1* pathogenic mutation (median 40.6 years old); 48 women with non-*BRCA1/BRCA2* mutation (median 46.1 years) and a high familial history of BC (≥ 3 close relatives with BC). We also studied a control population of 56 women without BC and with no history of X-linked pathologies (median 41.9 years).

DNA was extracted from peripheral blood and X inactivation pattern was determined by PCR analysis of a polymorphic CAG repeat in the first exon of the androgen receptor gene (AR).

One hundred and three women were heterozygous for the CAG repeat (103/118=96%). Skewed X inactivation appeared only in 1 woman of the control population (1/50=2%) and in none of the BC women.

Data presented in this study does not support any association between *BRCA1* or breast cancer in inactive X heterochromatinisation, although this interpretation could be limited by the sample size.

P04.068**In Silico analysis of *BRCA1* and *BRCA2* sequence variants of unknown clinical significance: application to variants found in healthy women in Croatia**

P. Ozretic, M. Levacic Cvok, V. Musani, M. Cretnik, S. Levanat; Rudjer Boskovic Institute, Zagreb, Croatia.

BRCA1 and *BRCA2* are the major hereditary breast and/or ovarian cancer predisposing genes and their mutations increase the risk of developing cancer. At present, almost half of all *BRCA1* and *BRCA2* sequence variants found are unclassified variants (UVs) so their clinical significance is unknown or uncertain. That represents problem for risk assessment in genetic counselling. After revealing *BRCA1* and *BRCA2* sequence variants in healthy Croatian females, our aim was to find fast in silico method for assessing preliminary clinical significance

of UVs newly found in patients.

We used different publicly available programs and web-based tools to identify UVs that may have deleterious effects with respect to different biomolecular functional categories (splicing regulation, transcriptional regulation, nonsynonymous amino acid SNP effect...) so their clinical significance in cancer etiology could be assumed.

Using straightforward physical and comparative considerations, we have found that several sequence variants with nonsynonymous amino acid change could have possible impact on the structure and function of a BRCA1 and BRCA2 proteins. Synonymous amino acid changes (silent mutations) could have impact on splicing regulation by disrupting exonic splice enhancers. Intronic sequence variants showed no potential impact on splicing because nucleotide changes at that positions likely make no changes in consensus splice sites.

In Silico analysis of BRCA1 and BRCA2 presents fast, easy and cheap method for assessing preliminary clinical significance for UVs, especially in cases with low frequency and ethnic specific alleles, when it is difficult to make population based studies and when expensive experimental functional assays must be performed.

P04.069

Three years of real-time PCR-based gene dosage for BRCA1 large rearrangements in France : new perspective in combination with HRM curve analysis

C. Lefol, E. Rouleau, G. Christophe, F. Copigny, C. Andrieu, I. Bieche, R. Lidereau;

Centre Rene Huguenin, St Cloud, France.

BRCA1 germline mutations are responsible for susceptibility in breast-ovarian cancers. Some alterations are large rearrangements (15%). To detect them, our laboratory has proposed a real-time PCR-based gene dosage. Since 2004, samples from all of over France have been analyzed with this method to confirm large rearrangements detected with semi-quantitative multiplex PCR (MLPA or QMPSF). Recently, our qPCR experience have been transfer to LightCycler 480 combining High-Resolution Melting curve analysis.

For each genomic DNAs sent, suspected exons were scanned with a few others. Copy numbers of each exon were calculated with an algorithm based on delta Ct method. As reference of the diploidy, three genes (4q, 8q, 17q) were quantified.

148 samples have been analysed with ABI Prism 7900 and PowerSybr Mix. 49 rearrangements were confirmed (table). 99 samples have no rearrangement. Most of those BRCA1 large rearrangements were analysed and validated with LightCycler 480 and HRM Master Mix using the same qPCR primers. Furthermore, by applying the same algorithm and PCR conditions, selected HRM primers were also able to detect those rearrangements.

This large series confirms the abilities of qPCR to detect large rearrangements in a routine screening. HRM curve analysis combined with quantitative PCR can give in unique assay information for point mutations and large rearrangements. Therefore, this technique should be reconsidered as a first-line tool for BRCA1 screening.

Result of 148 suspected BRCA1 large rearrangements by real-time PCR-based gene dosage

	Number of samples	Number of confirmation	%
Deletion suspected	101	35	35%
Duplication suspected (5' region to exon 1-2)	16	4	25%
Duplication suspected (others exons)	31	10	30%

P04.070

Characterization of some acute lymphoblastic leukemia cases by cytogenetic technique

D. Usurelu¹, L. Gavrilă¹, D. Cimponeriu¹, P. Apostol¹, L. Dan¹, I. Radu¹, V. Teleanu², A. Moicean², A. Dumitrescu²;

¹Institute of Genetics, Bucharest, Romania, ²Fundeni Hospital, Bucharest, Romania.

Cytogenetical analyses are important for diagnostics, prognostic and monitoring of the treatment efficiency in leukemia.

Objective:

Cytogenetical characterization of some Romanian patients with acute lymphoblastic leukemia (ALL).

Material and methods:

Five patients with ALL from Fundeni hospital, Bucharest were analyzed.

Bone marrow cells were cultivated in specific medium for 96 hours. The slides were prepared according to the classical procedure and stained with Giemsa solution. 100 metaphases/patient were analyzed.

The cytogenetic analyses follow two directions:

- detection of chromosomal aberrations and identification of t(9;22)
- evaluation of a potential link between leukemic phenotype and the telomeres structure.

Results and conclusion:

An obvious genomic instability of the leukemic cells was noticed, expressed by different chromosomal rearrangements, as well as by genomic mutation i.e. aneuploidy (table).

Patients	Normal metaphases	Chromosomal rearrangements				
		PCD	Aneuploidy (>50chromosomes)	Telomere-to-telomere and telomere-to-centromere attractions	Fusions	ring chromosomes
1	43	10	1	8	12	0
2	55	15	3	2	7	1
3	29	11	0	1	5	0
4	48	13	8	3	3	2
5	35	20	5	7	7	0

The FISH analyses showed the t(9;22) was present in two patients. This translocation was present in 57% of the metaphases of the first patient and in 71% of the metaphases of the third one.

No correlation between the telomere length and the leukemic phenotype could be detected. The fluorescence signal was encountered in more than 97% of the chromosomes, that indicates almost intact telomeric repetition, without large terminal deletions.

The incidence of t(9;22) found in two out of five patients is comparable to other studies taking in account also that they didn't receive any treatment, being at the diagnostic stage.

P04.071

Chromosomes 3 and 7 rearrangements in complex chromosomal aberrations in patients with myelodysplastic syndromes and acute myeloid leukemia

J. Brezinova¹, Z. Zemanova², L. Babicka², S. Izakova¹, J. Cermak¹, M. Siskova³, K. Michalova^{1,2};

¹Institute of Hematology and Blood Transfusion, Prague, Czech Republic,

²Center of Oncocytogenetics Institute of Clinical Biochemistry and Laboratory Diagnostics General Faculty Hospital and 1st Faculty of Medicine of Charles University, Prague, Czech Republic, ³1st Medical Department General Faculty Hospital and 1st Faculty of Medicine of Charles University, Prague, Czech Republic.

Rearrangements of chromosomes 3 and 7 are frequent in myelodysplastic syndromes (MDS) and acute myeloid leukemia (AML) and are associated with poor outcome and resistance to treatment. Combinations of molecular cytogenetic techniques were used for identification of these rearrangements in bone marrow cells of patients with complex chromosomal aberrations (CCA). In cohort of 392 patients with AML and RAEBt (refractory anemia with excess blast in transformation) we proved CCA in 58 of them. Chromosome 3 was involved in complex aberrations in 26 patients, chromosome 7 in 23 patients, both chromosomes 3 and 7 in nine patients. The most frequent aberrations of chromosome 3 were non-reciprocal translocation combined with deletion of chromosome 3 (14 patients). Other abnormalities proved by FISH: non-reciprocal translocations without deletion (8 patients), reciprocal translocation (5 patients), partial trisomy (4 patients), inversion (1 patient) and insertion of a part of chromosome 3 into chromosome 2 (1 patient). Breakpoints 3p24.2 and 3q26 were the most frequent. Minimal deleted segment 3p25-3pter was ascertained in 12 patients. Similarly, large heterogeneity of the breakpoints and various extent of deletion were proved on chromosome 7 with the most frequent breakpoints 7q31 and 7p12. Partners in translocations were chromosomes 5, 3 and 12. Using combination of molecular cytogenetic techniques we found a wide variety of aberrations not detectable by conventional cytogenetic analysis. We presume contribution of more genes and participation of epigenetic factors in the origin and during the course of the disease.

Supported by grants IGA NR 9227-3, MZO 00023736, MSMT LC535.

P04.072**Acute promyelocytic leukemia relapsing as secondary acute myelogenous leukemia with t(3;21)(q26;q22): molecular characterization and clinical follow-up in a patient with *AME* fusion transcript and review of the literature**

T. Park¹, J. Song¹, K. Lee¹, Y. Min², S. Lee¹, Y. Park¹, J. Kim¹, O. Kwon³, R. Park⁴, S. Hwang⁵, E. Lee⁵, J. Choi¹;

¹Department of Laboratory Medicine, Yonsei University College of Medicine, Seoul, Republic of Korea, ²Department of Internal Medicine, Yonsei University College of Medicine, Seoul, Republic of Korea, ³Department of Laboratory Medicine, Yonsei University Wonju College of Medicine, Wonju, Republic of Korea, ⁴Department of Laboratory Medicine, Soonchunhyang University Hospital, Seoul, Republic of Korea, ⁵Department of Laboratory Medicine, Pusan National University School of Medicine, Busan, Republic of Korea.

Acute promyelocytic leukemia (APL) is a subtype of acute myelogenous leukemia (AML) that is characterized by peculiar clinical and biologic features such as severe hemorrhagic diathesis, specific chromosomal aberration with t(15;17)(q22;q12), and distinct morphologic features with predominant abnormal promyelocytes. In contrast to other subtypes of AML, APL has a particular sensitivity to treatment with all-trans-retinoic acid (ATRA) combined with chemotherapy; converting this once frequently fatal leukemia to a highly curable disease. However, therapy-related myelodysplastic syndrome/acute myelogenous leukemia (t-MDS/AML) has been rarely reported as a late complication of chemotherapy in APL. To our knowledge, 30 APL cases have been described as t-MDS/AML in the literature. Among these reports, only one case relapsed as an acute leukemia with t(3;21)(q26;q22). Here we describe a 48-year-old female who was diagnosed with APL relapsing as a secondary AML with t(3;21). In this study, chromosome analysis as well as fluorescent in situ hybridization (FISH), multi-color FISH (mFISH), and reverse transcriptase-polymerase chain reaction (RT-PCR) for *AML1/MDS1/EVI1* (*AME*) fusion transcript were performed. Although allogeneic peripheral blood stem cell transplantation (PBSCT) was done, bone marrow biopsy after PBSCT still revealed leukemic marrow in this patient.

P04.073**Array-CGH analysis of Turkish adult ALL patients**

S. Berker-Karazum¹, D. Yasar¹, I. Karadogan¹, G. Alanoglu², G. Luleci¹, J. J. Dermody³, G. A. Toruner²;

¹Akdeniz University, Faculty of Medicine, Antalya, Turkey, ²Suleyman Demirel University, Faculty of Medicine, Isparta, Turkey, ³UMDNJ-NJ Medical School, Newark, NJ, United States.

In basic cytogenetic analysis 40-50% of acute lymphoblastic leukemia (ALL) patients show a normal karyotype. ALL is a clinically heterogeneous group, but cryptic copy number alterations could explain some of the heterogeneity. Array based comparative genomic hybridization (array-CGH) allows genome-wide high-resolution analysis of copy number alterations that are not detectable by standard methods including fluorescence in situ hybridization (FISH) or comparative genomic hybridization (CGH). There are reports of array-CGH studies on leukemia patients, but to our knowledge no published array-CGH studies exist on adult ALL. In order to assess the diagnostic yield of array-CGH on adult ALL, we performed pilot experiments on 14 adult ALL cases using catalog Agilent 44K oligonucleotide arrays. Eleven (78%) ALL patients had cryptic chromosomal aberrations. Deletions including the loci at 9p22.2 (n=2), 11p14.1 (n=2), 7p22.3 (n=2), and amplifications including the loci at 16p13.12 (n=2), 19q13.32 (n=2) are observed in at least two different patients. Our preliminary results indicate that array CGH analysis provide additional information about cryptic genetic aberrations during cytogenetic studies of adult ALL patients.

P04.074**Der(7;10)(p10;q10) in acute myeloid leukemia**

H. Podgornik, A. Prijatelj, P. Cernelc;

Department of Hematology, Ljubljana, Slovenia.

We report a case of a female patient with der(7;10)(q10;q10) resulting in loss of long arm of chromosome 7 that has an established prognostic value in haematological malignancies. In acute myeloblastic leukemia (AML) most often deletion (7q) and monosomy 7 are observed. Both changes are classified as poor prognostic criteria. Whole-arm translocations of chromosome 7 are rarely described. Translocation with the long arm of chromosome 1 occurs nonrandomly in myelodysplastic

syndrome and AML. While there have been reports on significantly better clinical outcome than other -7/7q cases the same rearrangement was also recognized as very poor prognostic feature.

In April 2007 a 23-year old woman was admitted to the hospital. Diagnosis workup confirmed myelo-monocytic leukemia (AML M4/M5). Cytogenetic examination of bone marrow cells revealed that one normal chromosome 7 and 10 were lost and replaced by an abnormal chromosome consisting of the long arm of chromosome 10 and the short arm of chromosome 7. Additionally, a small marker chromosome was observed in all analyzed metaphases. The whole-arm exchange was confirmed by FISH using WCP and CEP probes as well as a locus specific probe (7q32). Combining the results of standard and molecular cytogenetics the karyotype was interpreted as: 46,XX,der(7;10)(p10;q10),+mar. The marker chromosome was found to consist of the chromosome 7 centromeric material. The patient is in cytogenetic remission now. Her condition will be further followed to clarify the significance of this chromosomal change. According to our best knowledge it was not described in hematological malignancies before.

P04.075**Gains of chromosome 2p in chronic lymphocytic leukemia**

M. Holzerova¹, H. Urbankova¹, R. Plachy¹, L. Kucerova², Z. Pikalova¹, T. Papajik¹, K. Indrak¹, M. Jarosova¹;

¹Department of Hemato-Oncology, University Hospital and Palacky University, Olomouc, Czech Republic, ²Department of Pathology, University Hospital and Palacky University, Olomouc, Czech Republic.

Chronic lymphocytic leukemia (CLL) is the most common adult leukemia. The progress in molecular genetic characterization of CLL confirmed the prognostic role of IgV_H mutational status, expression of CD38, as well as chromosomal abnormalities defined by molecular cytogenetic methods. However, besides chromosomal changes with known prognostic impact, such as deletions of 6q, 11q (ATM), 13q, 17p (p53) detected routinely, the other additional abnormalities can be found. It is presently not clear whether other aberrations that are not detected by the standard FISH panel have any impact on prognosis and disease progression. Therefore, we performed clinical and laboratory analysis of 7 CLL patients (males) with detected gains of chromosome 2p. The aim of the genetic study was supported by the fact, that gains of genetic material can lead to oncogenic activation of protooncogenes located within the gained regions. Since 2p23-p11 harbors many protooncogenes already known to be involved in human tumorigenesis, we decided to check a few selected genes: ALK, N-MYC, REL, BCL11a and their protein levels.

Comparative genomic hybridization (CGH) or 1 Mb arrayCGH revealed gain of 2p23-p11 region. For detailed mapping of gained region we used iFISH with commercial available and BAC-derived probes. In all cases IgV_H mutational pattern was established and immunohistochemical analysis of selected proteins was performed.

Our study will summarize molecular cytogenetic, molecular genetic and clinical findings with respect to the 2p abnormalities in 7 CLL patients.

This work is supported by grant MSM 6198959205 and NR 9484-3.

P04.076**Cytogenetic study of variant acute promyelocytic leukemia**

B. B. Ganguly;

MGM Centre for Genetic Research & Diagnosis, MGM's New Bombay Hospital, New Bombay, India.

Hematologic malignancies are heterogeneous group of clonal hematopoietic stem cell disorders resulting from wide spectrum of nonrandom chromosome abnormalities ranging from balanced translocations to unbalanced karyotypes with numerical and/or structural gains or losses and to complex rearrangements involving three or more chromosome abnormalities. In >95% acute promyelocytic leukemia (APL), t(15;17) is the hallmark of pathogenesis while remaining cases have cryptic insertion or more complex rearrangements where *RARA* is constantly involved. The fusion of *PML-RARA* disrupts the normal interaction of retinoic acid and *RARA*, and converts *RARA* into a transcription activator. All-trans retinoic acid receptor (ATRA) is able to interact with this mechanism and prevent life-threatening thromboembolic/bleeding complications. We have investigated 30 APL patients by conventional G-banding and detected two (7%) cases with t(11;17)(q23;q22), which leads to fusion of *PLZF* (promyelocytic leukemia zinc finger) and *RARA*

genes. One of them had two additional unbalanced translocations, t(12;14)(p;q11) and t(12;16)(p;p) with complex karyotype such as 45,XY,-14,t(11;17)(q23;q21),der(12)t(12;14)(p11;q11),der(16)t(?12;16)(p11;q13) in 96% cells. It has been reported that such variant cases are resistant to ATRA and exhibit no therapeutic response, though resemble *PML-RARA* morphologically. Therefore, these two patients are presumed to experience poor prognosis. Investigation of all these cases by FISH for *PML-RARA* would have given normal result to these two patients and could have led to progression of the disease condition. Therefore, it's understood that conventional cytogenetics still plays an important role in diagnosis, classification, prognostication and monitoring of hematologic malignancies in the era of microarray technology and cannot be replaced by any other molecular technique.

P04.077

Cytogenetic study of chronic myeloid leukemia (CML)

R. Joshi, B. B. Ganguly;

MGM Centre for Genetic Research & Diagnosis, New Bombay, India.

To explore the clinical cytogenetic feature & prognosis of chronic myeloid leukemia patient, evaluation of 8 CML cases (6 men and 2 women) from the Indian population with ages ranging from 25 to 55 years were studied in the present dissertation project. Bone marrow samples were processed following direct method &/or 24hrs culture without mitogen for chromosome preparation and karyotype analysis of G-banded metaphases. 25 metaphases were studied for each case using karyotyping software (Metasystems, Germany). All 8 cases showed Philadelphia chromosome i.e. t(9;22)(q34;q11) in 100% cells. Two (25%) cases showed extra Philadelphia chromosome in 8% & 38% cells respectively. One case had missing of Y chromosome in addition to Philadelphia chromosome. It has been established that the major secondary chromosomal aberration in adult is double Philadelphia chromosome & minor one is -Y chromosome. The i(17)q is not very common in adult. Since chromosome 17 was normal in all the above cases the prognosis of these patients will be comparatively better. However, the prognosis of patient in which abnormal metaphase with +ph chromosome was 38% expected to be poor compared to the patient with 8.6% abnormal metaphases. Due to the additional chromosomal abnormality, patient may acquire resistance to Imatinib - the tyrosine kinase inhibitor. Therefore, it is understood that cytogenetic study is important in diagnosis & prognostication of CML patient.

P04.078

Another case with der(8)t(8;17)(p11;q11) in Sézary's syndrome

A. Valera^{1,1}, A. Carrió¹, D. Costa¹, A. Arias¹, M. Rozman¹, M. Aymerich¹, D. Colomer¹, P. Abrisqueta², F. Bosch², T. Estrach³, E. Campo¹;

¹Unitat d'Hematopatologia. Hospital Clínic de Barcelona., Barcelona, Spain,

²Servei d'Hematologia.Hospital Clínic de Barcelona, Barcelona, Spain, ³Servei de Dermatologia.Hospital Clínic de Barcelona, Barcelona, Spain.

Sézary's syndrome (SS) is a peripheral T-cell neoplasm characterized by a pruritic exfoliative or infiltrated erythroderma, lymphadenopathies, and atypical T lymphocytes in the peripheral blood. Chromosome abnormalities, mostly complex karyotypes, are seen in about 50% of patients with SS, and there have only been a few instances of recurrent rearrangements.

We report a 60 year-old female referred to Hematology Service due to 20 months history of lymphocytosis. The patient showed a cutaneous hyperpigmentation and bilateral axillary and inguinal lymphadenopathies. The peripheral blood smear presented 40% of Sézary cells. The diagnosis was Mycosis Fungoides with leukemic involvement.

The karyotype in peripheral blood was performed. We used G-banded technique in conventional cytogenetics. Molecular cytogenetics (FISH analysis) permitted discovering the rearrangements involved. The whole chromosome paints (WCPs) for chromosomes 1, 5, 9, 10, 11, 15, 17 and 19 were used. Finally the karyotype was: 44-45, XX, t(1;5)(p33;q31)[4], der(8)t(8;17)(p11;q11)[4], -9[2], inv(9)(p21;q34)[2], -10[4], del(11)(q21)[4], der(14)t(10;14)(?q?;p11)[4], del(15)(q22)[4], der(15)t(9;15)(q21;q26)[2], -17[4], +mar1[4] [cp4] / 45, X, -X[6] / 46,XX[10].

Cytogenetic alterations were concordant with other abnormalities described before in SS, like: breakpoints at 1p32-36 and 10q23-26, and other alterations involving chromosomes 8, 9, 11 and 17. But the most important event was the presence of der(8)t(8;17)(p11;q11), because to our knowledge, this is the fourth case with the same alteration re-

ported in SS. First of all was Thangavelu M, et al. Blood (1997) with two cases with der(8)t(8;17)(p11;q11) and a psu dic(17;8)(p11.2;p11.2) was observed by Batista D, et al. Genes, Chromosomes and Cancer (2006).

P04.079

Der(1;16)(q10;p10) in Acute Myeloid Leukemia: the first female case described

N. Kokalj Vokac¹, A. Zagorac¹, A. Erjavec Skerget¹, Z. Roskar¹, H. Podgornik², P. Cernelc²;

¹University Medical Centre Maribor, 2000 Maribor, Slovenia, ²University Medical Centre Ljubljana, 1000 Ljubljana, Slovenia.

Whole-arm translocation of chromosome 1 and 16 is recurrently observed in non-hematologic neoplasias such as breast carcinomas and Ewings sarcoma but rarely in hematologic neoplasias, mostly in multiple myelomas. To our knowledge, only 7 cases were described in MDS/AML, interesting all were males.

Here we describe the first female patient with AML M4/M5 with der(1;16)(q10;p10) as the sole chromosome rearrangement found.

Cytogenetic examination of bone marrow cells revealed that the normal chromosome 16 was lost and replaced by an abnormal chromosome consisting of the long arm of chromosome 1 and the short arm of chromosome 16, resulting in trisomy of the long arm of chromosome 1 and monosomy of the long arm of chromosome 16. The karyotype was confirmed by FISH: 46,XX,+1,der.ish (1;16)(q10;p10)(wcp1+,wcp16+,cep16+).

Due to a small number of metaphases available and bad resolution of chromosomes, CGH was also performed. Only the amplification of the long arm of chromosome 1 and deletion of the long arm of chromosome 16 was confirmed.

Unfavorable outcome, including no response to chemotherapy, and short survival were characteristic of our patient. Despite very short survival of our patient, prognostic significance remains to be determined. It is possible that some other unidentified molecular mechanism could play a role in bad prognosis or simply the fact that this is the only female patient described until now. From this point of view, the pathogenesis of der(1;16) still remains unresolved.

P04.080

Detection of gene expression profile for BAALC and WT1 genes by real time RT-PCR in patients with acute myeloid leukemia

L. A. Tamas, E. Seclaman, A. Mihala, A. Neghina, C. Samoila, I. M. Ciuca;

University of Medicine and Pharmacy, Timisoara, Romania.

Acute myeloid leukemia (AML) is a heterogeneous group of diseases characterized by uncontrolled proliferation of clonal neoplastic hematopoietic precursor cells and impaired production of normal hematopoiesis leading to neutropenia, anemia, and thrombocytopenia.

High mRNA expression of BAALC and WT1 have been shown to be an adverse risk factor in newly diagnosed AML patients with normal cytogenetics.

Independent confirmation is required to validate the initial results so that BAALC and WT1 expression may be exploited for risk-adapted treatment stratification of AML patients with normal cytogenetics.

We analyzed patients selected from newly diagnosed cases of AML and a control group of healthy individuals.

Total RNA from leukocytes was extracted from blood samples treated with RNA-later (QIAGEN) following the manufacturer's directions (RiboPure - blood kit, Ambion). For semiquantitative RT-PCR we used One-step RT-PCR kit (QIAGEN), with gene-specific, intron spanning primers for BAALC, WT1 and GPDH as housekeeping gene. Comparative real-time RT-PCR assays were performed for each sample in triplicate.

The results showed a significantly increased level of expression for BAALC and WT1 genes in de novo acute myeloid leukemia patients with normal cytogenetics comparative with healthy individuals from the control group.

In conclusion, the analyse of BAALC and WT1 genes expression in AML patients is a molecular marker which can be used for the evaluation of disease aggressiveness and prognosis for patients with normal cytogenetics.

P04.081**Discordance between morphological and cytogenetical remission in a patient with AML and t(2;11)(p21;q23)**W. G. Kroes¹, E. den Ouden¹, M. Baasten¹, J. Kerkhoffs², R. Willemze¹;¹Leiden University Medical Center, Leiden, The Netherlands, ²Haga Hospital, the Hague, The Netherlands.

We report here on a 58 year old male presenting with biphenotypical acute myeloblastic leukemia. Conventional cytogenetic techniques on bone marrow at initial diagnosis, before treatment, showed the following karyotype:

46,XY,t(2;11)(p21;q23),del(5)(q21),add(12)(p12)[9]/46,XY,t(2;11)(p21;q23)[5]/46,XY[1].

FISH analysis with a DNA probe for the MLL-gene demonstrated that the breakpoint at 11q23 was telomeric to the MLL gene. T(2;11)(p21;q23) is a rare but recurrent translocation observed in MDS and AML. This translocation is specifically associated with a deletion of the long arm of chromosome 5. After induction treatment the patient was in complete morphological remission. However, cytogenetic studies revealed the t(2;11) in all metaphases, without the del(5q) and the add(12p). Evaluation after the second therapy cycle showed again a complete morphological remission but persistence of t(2;11) in all analyzed metaphases. To investigate the possibility of a constitutional chromosome aberration chromosomal analysis was performed on skin-fibroblasts and peripheral blood. The skin-fibroblasts revealed a normal karyotype in all 100 analyzed metaphases. PHA stimulated blood showed a mosaic karyotype: 46,XY,t(2;11)(p21;q23)[11]/46,XY[21]. This suggests that the t(2;11) is an acquired aberration that persists in spite of morphological remission.

The patient underwent a bone marrow transplantation and is still in complete morphological remission after 10 months.

To our knowledge this is the first description of an AML case with a t(2;11) showing discordant morphological and cytogenetical remission.

P04.082**A pediatric case with atypical CML with ETV6/PDGFRB fusion gene**A. V. Divane¹, M. Baka², D. Bouhoutsou², A. Pourtsidis², M. Varvouts², D. Doganis², K. Koronioti¹, H. Kosmidis²;¹Department of Cytogenetics, Locus Medicus, Diagnostic Centre, Athens, Greece, ²Department of Oncology, Aglaia Kyriakou Children Hospital, Athens, Greece.

Atypical chronic myelogenous leukemia (aCML) is a leukemic disorder that exhibits both myelodysplastic and myeloproliferative features at the time of diagnosis. The median age of this rare disorder has been reported to be in the seventh or eighth decade of life. Herein we report a rare pediatric case of a 14 months old boy who was presented with leukocytosis and frequent infections since the age of 6 months. Bone marrow showed marked myeloid hyperplasia with elements of dysplasia, particularly in eosinophil series. Conventional and molecular cytogenetic analysis of BM were performed. FISH analysis for chromosome abnormalities, commonly observed, in MDS/MPD were performed using the appropriate probes, such as LSI BCR/ABL, CEP 8, LSI CBFβ, LSI D205108 and LSI D7S486/CEP7 (Vysis). FISH results revealed normal hybridization pattern for all the chromosomes analysed. Conventional cytogenetic analysis revealed a clone of 46,XY,t(5;12)(q33;p13). RT-PCR analysis for the detection of the fusion gene ETV6/PDGFRB was positive. In addition, FISH analysis using the ETV6 (12p13) split probe (Vysis), confirmed the translocation t(5;12)(q33;p13). With the above findings patient was diagnosed as aCML with Philadelphia chromosome negative and BCR/ABL fusion gene negative. The patient was treated with Gleevec (imatinib) for 8 months, achieved complete hematological and cytogenetic remission (MRD of 0,4% in the latest sample) and underwent MUD bone marrow transplantation.

P04.083**BCR/ABL negative myeloproliferative neoplasms- cytogenetic and molecular study**G. Cardos^{1,2}, A. Arghir¹, C. Diaconu³, M. Chivu³, L. Dragomir³, A. R. Lupu⁴, M. Closca Gheorghiu⁵, D. Mut-Popescu⁴, M. E. Hinescu^{1,4}, A. Lungeanu¹;¹"Victor Babes" National Institute, Bucharest, Romania, ²Institute of Human Biology, University of Hamburg, Hamburg, Germany, ³"Stefan Nicolau" Institute

of Virology, Bucharest, Romania, ⁴"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania, ⁵Coltea Clinical Hospital, Bucharest, Romania. Myeloproliferative neoplasms (MPNs) originate in hematopoietic stem cell compartment and exhibit a consistent phenotypic diversity. Only a small fraction of patients harbour cytogenetic abnormalities (+8, +9, 20q-, 13q-, 12p-). The recent identification of JAK2 V617F mutation as a key genetic event in a majority of cases has greatly advanced the understanding of pathogenetic mechanisms in BCR/ABL negative MPNs.

Our study has been focused on cytogenetic and molecular characterization of BCR/ABL negative MPNs, with emphasis on correlation between cytogenetic changes and JAK2 mutation status.

Chromosome analysis, FISH and RT-PCR (Revers-Transcription PCR) have been used to investigate the BCR/ABL fusion and MPN-associated genomic recurrent abnormalities in 28 patients by date, diagnosed with MPNs. Chromosome analysis was performed on cultured bone marrow cells (GTG banding). To detect cryptic chromosomal changes (13q14, 17p13.1, 20q12-13 deletions) interphase and metaphase FISH with various LSI probes (Vysis) and Microsatellite PCR (D20S206 and D20S119 Markers) were performed. Allele-specific PCR have been used to detect the JAK2 V617F mutation.

All 28 patients displayed BCR/ABL negative status. The JAK2 V617F mutation has been detected in 16 patients. The cytogenetic analysis revealed chromosomal anomalies in 4 patients (trisomy 8, complex cytogenetic changes). No losses at investigated loci were found (13q14, 17p13.1). All patients were heterozygous for at least one of the two DNA markers.

Further investigations will be performed in order to reveal other genetic abnormalities, thus, we hope to contribute both in more precise diagnosis and novel, patient-tailored therapeutic strategies.

P04.084**Microhomologies and interspersed repeat elements at genomic breakpoints in Chronic Myeloid Leukemia**E. Mattarucchi¹, V. Guerini², A. Rambaldi¹, L. Campiotti³, A. Venco³, F. Lo Curto¹, F. Pasquali¹, G. Porta¹;¹Department of Experimental and Clinical Biomedical Sciences, Università dell'Insubria, Varese, Italy, ²Hematology Unit, Ospedali Riuniti, Bergamo, Italy, ³Department of Clinical Medicine, Università dell'Insubria, Varese, Italy.

Reciprocal translocation t(9;22) is central to the pathogenesis of chronic myeloid leukemia. Some authors have suggested that *Alu* repeats facilitate this process, but supporting analyses have been sparse and often anecdotal. The purpose of this study is to analyze the local structure of t(9;22) translocations, and assess the relevance of interspersed repeat elements at breakpoints. Collected data have been further compared to the current models of DNA recombination, in particular the Single-Strand Annealing (SSA) and the Non-Homologous End Joining (NHEJ) processes. We proposed a protocol for the rapid characterization of patient-specific genomic junctions, and we considered a total of 27 patients diagnosed with chronic myeloid leukemia. Sequences analysis reveals microhomologies at the junctions of 21 patients of 27, while interspersed repeats were of relevance (p<0.05) in at least 16 patients of 27. These findings are more frequent than expected and give indication that the main mechanisms involved in the t(9;22) translocation are the SSA and NHEJ pathways, both playing a role. More in detail, our report is consistent with microhomologies facilitating the joining of DNA ends in the translocation process, and with both *Alu*, and a variety of other repeat sequences pairing non-homologous chromosomes during the SSA pathway

P04.085**The four and a half LIM domain protein 2 (FHL2) interacts with CALM and is highly expressed in AML with complex aberrant karyotypes**

Z. Pasalic, P. Greif, M. Mulaw, B. Tizazu, L. Fröhlich-Archangelo, S. Bohlander, Helmholtz Zentrum, Munich, Germany.

The CALM/AF10 translocation t(10;11)(p13;q14) is found in acute myeloid leukemia (AML), T-cell acute lymphoblastic leukemia (T-ALL) and malignant lymphoma. The CALM/AF10 fusion gene has been shown to cause biphenotypic leukemia in a murine bone marrow transplant model. The CALM (Clathrin Assembly Lymphoid Myeloid leukemia

gene) protein is a clathrin assembly protein which plays a role in clathrin-mediated endocytosis and trans Golgi network trafficking. AF10 is a putative transcription factor likely involved in processes related to chromatin organization.

To learn about the function of CALM/AF10 fusion protein, we searched for protein interaction partners of CALM using a yeast-two-hybrid assay and identified FHL2 as a putative CALM interacting partner. The CALM-FHL2 interaction was confirmed by GST pull-down and CoIP experiments. In co-localization studies a translocation from cytoplasm to the nucleus is seen.

Expression analysis (Affymetrix based) in CML and different AML subtypes showed a significantly higher expression of FHL2 in CML and AML with complex aberrant karyotypes compared to AML with normal karyotypes or balanced chromosomal translocations like the t(8;21), inv(16) or t(15;17).

Reporter gene assays using a GAL4-DNA binding domain FHL2 fusion protein and a GAL4 responsive luciferase reporter were able to demonstrate a transcriptional activation function of FHL2 that got inhibited when adding CALM but not CALM/AF10. Previous findings show that high expression of FHL2 in breast cancer associate with an adverse prognosis.

It is thus conceivable that CALM/AF10 may play a role in a pathway that enforces progression of malignancy when not downregulating the FHL2 expression.

P04.086

Polymorphisms and haplotypes of the NBS1 gene in childhood acute leukemia

M. Mosor¹, I. Ziolkowska¹, D. Januszkiwicz-Lewandowska^{1,2}, J. Nowak¹;

¹Polish Academy of Sciences, Poznań, Poland, ²University of Medical Science, Poznań, Poland.

DNA repair gene polymorphisms and mutations may influence cancer risk. The product of NBS1 gene, nibrin, is functionally involved in double strand DNA break repair system. Heterozygous, germline mutations of the NBS1 gene are associated with increased risk of tumors including familial/sporadic breast and prostate cancer, larynx cancer and childhood acute lymphoblastic leukemia. So far reports on NBS1 polymorphisms in lymphoproliferative diseases are scarce. The aim of the present study was to answer the question whether polymorphisms of NBS1 gene may influence susceptibility to the development of childhood acute leukemia. We genotyped c.102G>A, c.553G>C, c.1124+18C>T, c.1197T>C c.2016A>G c.2071-30A>T polymorphisms of the NBS1 gene in 157 cases of childhood acute leukemia and 275 control subjects. The distribution of allele, genotype and haplotype of the polymorphisms were compared between cases and controls using PCR-SSCP and Chi-square test. The TT genotype of c.2071-30A>T polymorphism was increased in leukemia patients than in healthy controls ($p=0.04$, OR=1.828 (1.005 to 3.325)). No significant differences in allele and genotypes frequencies at the other five polymorphisms sites were observed in a comparison of leukemia cases and controls. Genotyping data from six polymorphisms loci in NBS1 in leukemia cases and controls, were used to impute haplotypes. Three main haplotypes made up the majority of cases and controls (GGC-TAA (41%), ACTCGT (20%), GGCCAA (11%)). Two of them GGCTAA and ACTCGT were associated with significantly increased leukemia risk, $p=0.0038$ and $p<0.0001$, respectively. Our results suggested that some specific haplotypes of the NBS1 gene may be associated with childhood leukemia cases.

P04.087

Chronic lymphocytic leukemia: optimization of cytogenetic method for detection of chromosomal alterations

R. Pinto Leite¹, M. Souto¹, S. Rebelo², M. Cunha¹, M. Guerra¹, E. Ribeiro¹;

¹Centro Hospitalar de Tras-os-Montes e Alto Douro, Vila Real, Portugal, ²Universidade de Aveiro, Aveiro, Portugal.

B-cell chronic lymphocytic leukemia (CLL) is the most frequent type of leukemia in adults in the Western world and is generally considered to be a disease of the older population. The role of cytogenetics in diagnosis and follow-up studies of CLL is now widely recognized. According to the literature, clonal chromosomal aberrations are detected in approximately 40-50% of tumors. However, conventional cytogenetic analysis is not currently applied to CLL's study, due to the low mitotic activity of the tumor cells *in vitro*.

The aim of this study was describe a reliable cytogenetic technique for the detection of chromosomal alterations in CLL. We have tested several protocols described in the literature and optimized them in order to obtain metaphases in all samples.

We describe the methodology and discuss the results according to the different protocols applied.

P04.088

Residual disease monitoring in chronic myelogenous leukaemia (CML) using tricolour dual fusion fluorescence *in situ* hybridisation (FISH) probe system

L. L. P. Siu¹, V. W. K. Fung¹, J. S. L. Chung¹, W. S. Wong¹, E. S. K. Ma², K. F. Wong¹;

¹Department of Pathology, Queen Elizabeth Hospital, Kowloon, Hong Kong,

²Division of Molecular Pathology, Department of Pathology, Hong Kong Sanatorium Hospital, Kowloon, Hong Kong.

Objectives: We investigate the application of the *BCR-ABL* + 9q34 tricolour dual fusion translocation probe system (Vysis) for the monitoring of residual disease in chronic myelogenous leukaemia (CML) with der(9) deletion through analysis of both interphase and metaphase FISH signal patterns.

Methods: *BCR-ABL* dual colour dual fusion FISH (D-FISH) was performed on the diagnostic samples of 22 CML patients. The tri-colour system was tested on cases that showed aberrant signal patterns other than the classical 1G1O2F. Using the aqua band-pass filter, random signal overlap would be indicated by the presence of an aqua signal (ASS) in the "fusion" signal, while genuine fusion was represented by the absence of the ASS signal.

Results: Using the D-FISH system, the signal patterns could be categorized into 4 groups: group 1 (n = 17) showed the classical 1G1O2F; group 2 (n = 2) showed 2G1O1F indicating *ABL* deletion; group 3 (n = 1) showed 1G2O1F indicating *BCR* deletion; group 4 (n = 2) with 1G1O1F indicating reciprocal *ABL-BCR* deletion. The tri-colour dual fusion system showed excellent correlation with D-FISH for cases with der(9) deletion. In particular, the added aqua ASS probe allowed the discrimination of random signal overlap from genuine *BCR/ABL* fusion in the interphase cells (group 4).

Conclusion: Although the D-FISH probe remains valuable in establishing the different patterns of aberrant signals and monitoring patients with the classic 2-fusion signals in CML, the tri-colour dual fusion translocation probe should be used for patients with der(9) deletion to monitor response to treatment.

Clonal evolution and genomic instability in chronic myeloid leukemia during imatinib mesylate therapy

A. Arghir¹, G. Cardos¹, N. Berbec², O. Ciocar², S. Chiriac¹, A. Lungeanu¹;

¹"Victor Babes" National Institute, Bucharest, Romania, ²"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania.

Chronic myeloid leukemia is characterized by the Philadelphia chromosome which originates in most cases from the translocation t(9;22)(q34;q11), and leads to the formation of *BCR/ABL* oncogene. Ph positive clonal evolution, including amplification/duplication of the *BCR-ABL* gene, has been found to contribute to disease progression and imatinib mesylate resistance.

We report the results of a study monitoring the dynamics of chromosomal anomalies in Philadelphia positive hematopoiesis during imatinib therapy.

Cultured bone marrow cells were used for chromosomal studies. FISH studies with *BCR/ABL* dual fusion probe and locus specific probes for various chromosomal loci were performed. The follow-up interval ranges from 6 to 60 months.

Imatinib therapy was monitored in 80 Ph positive CML patients. Seventy eight patients showed standard translocation t(9;22) and two, a variant Philadelphia translocation. Four patients demonstrated additional chromosomal abnormalities, at diagnosis. Duplication of the *BCR-ABL* gene as free additional der(22) or isochromosome ider(22)t(9;22) was observed in 4 out of 6 cases with clonal evolution. Three cases showed unusual additional changes (translocations, additions). An unexpected sequence of events leading to accumulation of multiple aberrations [ider(22)t(9;22);i(17)(q10);+8] was observed in one case.

Clonal cytogenetic aberrations of Ph positive hematopoiesis is considered to herald disease progression and to reflect the genomic instability.

ity of the malignant clone in CML. We appreciate that all new cases might bring new insights, with a special emphasis on prognostic impact of additional chromosomal changes in imatinib therapy era. Financial support: CNCSIS (Project 60GR/2007), CEEX (Project 111/2006).

Acknowledgments: The authors thank Mrs. Marioara Cristea for technical assistance.

P04.090

Complex karyotype and cryptic t(9;22) translocation at the onset of chronic myeloid leukemia - case report

A. Lungeanu¹, A. Arghir¹, G. Cardos¹, S. Chiriac¹, M. Ciochinaru²;

¹"Victor Babes" National Institute, Bucharest, Romania, ²"Dr. Carol Davila" Clinical Hospital, Bucharest, Romania.

Among patients with chronic myeloid leukemia (CML) positive for Philadelphia chromosome, 5-8% show variant translocations in which at least a third chromosome in addition to 9q34 and 22q11 is involved.

We report an apparently Ph negative CML patient with unusual complex karyotype showing a typical fusion transcript detected by reverse transcription PCR (RT-PCR) and BCR/ABL fusion gene localized in a complex rearranged chromosome identified by FISH.

Cell cultures from bone marrow and peripheral blood, and GTG banding were performed for karyotype investigation. Dual fusion BCR/ABL probe, chromosome painting (WCP 9 and WCP 22) and locus specific BAC (1p36.33 and 17p11.2) probes for metaphase FISH analysis were used. RT-PCR for BCR/ABL fusion transcripts detection was applied. Bone marrow cytogenetic analysis showed a complex rearrangement consisting of chromosome 1 deletion, 17p addition, telomere-to-telomere fusion of chromosomes 21 and 22, but no standard Philadelphia translocation. Constitutional aberrations were ruled out by peripheral blood karyotyping. RT-PCR detected BCR/ABL fusion transcript. FISH analysis showed two fusion signals for hybrid gene, and confirmed the complexity of rearrangements involving chromosomes 1, 9, 17, 21 and 22.

The FISH techniques allowed us the identification of chromosome rearrangements that could not otherwise be detected by conventional banding procedures.

The frequency, formation mechanisms and clinical significance of such rare type of clonal rearrangements need to be investigated.

Financial support: CNCSIS (Project 60GR/2007), CEEX (Project 111/2006).

Acknowledgments: The authors thank Prof. Dr. Jean-Michel Dupont and Mrs. Dominique Blancho for kindly providing BAC probes and Mrs. Marioara Cristea for technical assistance.

P04.091

Major causes of imatinib resistance in chronic myelogenous leukemia: BCR-ABL kinase domain mutations and clonal evolution

N. Meggyesi¹, A. Bors¹, A. Szilvási¹, S. Lueff², Á. Bata², E. Ádám², A. Kozma², G. Haln², S. Nahajevszky², B. Kapás², Z. Csukly², N. Lovas², P. Reményi², T. Massz², A. Tordai², H. Andrikovics¹;

¹Hungarian National Blood Transfusion Service, Budapest, Hungary, ²Dept. of Hematology and Stem Cell Transplantation, St. Istvan and St. Laszlo Hospital, Budapest, Hungary.

Imatinib mesylate, a targeted BCR-ABL tyrosine kinase inhibitor (TKI) has become the standard drug for the treatment of chronic myelogenous leukemia (CML). Mutations in the kinase domain (KD) of BCR-ABL and nonrandom, karyotypic abnormalities (referred to as clonal evolution) contribute to imatinib-resistance. Imatinib-resistance may be defined as primary or secondary, hematologic or cytogenetic and it occurs in 10-15% of patients with CML. The aim of our study was to screen for BCR-ABL KD mutations and additional chromosomal abnormalities (ACA) in 35 Hungarian patients (33 CML and 2 Philadelphia chromosome positive ALL) with imatinib-resistance. Point mutations in the entire tyrosine kinase domain (aa 230-490) were detected by Sanger-sequencing after two separate, two step semi-nested PCR. The presence of T315I, M244V, Y253H, M351T, F359V, L384M mutations were confirmed by PCR-RFLP. Clonal alterations were assessed by standard cytogenetic techniques. Overall, twelve different mutations (aa. exchange M244V, G250E, Y253H, E255V, E279K, D276G, T315I, M351T, F359I/V, V379E, L384M, E460K) were identified in 21 patients. M244V was the most frequent mutation (4 patients). T315I occurred in

2 ALL and one CML patients. In three cases, double mutations, and in 8 patients, extra Philadelphia chromosome were detected. ACA was present overall in 13 patients. KD mutations were found in 75% (9/12) in hematologic, and 43% (9/21) in cytogenetic TKI resistance. In summary, BCR-ABL KD mutations and clonal evolution are common in imatinib-resistant CML patients. Early detection of emerging mutant clones may guide therapeutic decisions, because the degree of imatinib-resistance varies among different mutants.

P04.092

Mutation profile of BCR-ABL kinase domain in imatinib primary and secondary resistant chronic myeloid leukemia cases

S. Kutsev, M. Velchenko, S. Mordanov;

Rostov State Medical University, Rostov-on-Don, Russian Federation.

Chronic myeloid leukemia (CML) is hematopoietic stem cell disorder characterized by balanced translocation t(9;22). Fusion gene *BCR-ABL* appeared in the result of t(9;22) gives rise to Abl tyrosine kinase activation with followed leukomogenic effects. Bcr-Abl selective tyrosine kinase inhibitor imatinib mesylate revolutionized CML therapy and allow achieve complete cytogenetic remission (CCR) in most cases of chronic phase of CML. Nevertheless refractoriness (primary resistance) or relapse of initial response (secondary resistance) are observed in over 30% cases of CML. More than 40 different point mutations of *BCR-ABL* decrease sensitivity to imatinib. To study *BCR-ABL* mutations profile in imatinib resistant cases of CML we have studied *BCR-ABL* kinase domain mutations in 27 patients (middle age 43 y.o. from 21 to 60) with chronic phase of Ph+ CML that did not achieve any cytogenetic response (95-100% Ph+ BM cells) after 1 year imatinib therapy 400 mg daily (n=22) or loose cytogenetic response (n=5). Mutation status was studied by direct sequencing of *BCR-ABL* cDNA samples. *BCR-ABL* kinase domain mutations were founded in 7 patients (25,9%). The mutational spectrum included five missense mutations: M244V, L248V, Y253N, M351T, T315I. Five primary resistant cases were characterized by L248V mutation (3 cases), T315I (1) and M244V+M351T (1). Two patients with secondary resistance shown L248M (1) and Y253N (1) mutations. In conclusion, mutation analysis of primary refractoriness or relapse of initial response CML patients is very useful tool for changing of CML strategy therapy include imatinib dose escalation, new generation of BCR-ABL inhibitors, combination therapy and BMT.

P04.093

Differential expression pattern of *ITPA* gene in CML patients

Genetic material in nucleus or mitochondria is the most significant intracellular target of damages that cells exposure every day. One of the most important of these damages is oxidative deamination of DNA and free nucleotides in the cell pool. Incorporation of deaminated nucleotides such as inosine triphosphate (ITP, dITP) into DNA or RNA can increase the frequency of base substitution mutation. It has been suggested that presence and accumulation of these rough nucleotides can lead to genetic and chromosomal instability which is the prerequisite of different types of diseases or cancer. The evidences demonstrate the role of inosine triphosphate pyrophosphates (ITPase) encoded by *ITPA* gene, in protecting the cells by omitting the rough deaminated purines nucleotides of the cell pool. Chronic myelogenous leukemia (CML) is a type of cancer which is mainly characterized by the presence of Philadelphia chromosome. There are some reports about existence of several structural and numerical chromosome abnormalities in addition to Philadelphia chromosome in these patients. The objective of this study is to compare *ITPA* gene expression in CML patients versus normal samples to examine the possible dysfunction of *ITPA* gene activity as an important predisposing factor for genetic instability. Our results revealed different expression pattern of *ITPA* gene expression between two groups.

P04.094**Grafting outcome prediction by optimizing the protocol for molecular monitoring of leukaemia patients**

A. M. Constantinescu¹, C. M. Constantinescu¹, G. Girbea¹, D. Iancu¹, B. Iancu¹, E. Neagu¹, A. Tanase², S. Varady³, L. Barbarii¹;

¹National Institute of Legal Medicine, Bucharest, Romania, ²Bone Transplant Unit-Clinic of Fundeni Hospital, Bucharest, Romania, ³Bone Marrow Transplant Unit-Clinic of Fundeni Hospital, Bucharest, Romania.

Introduction. Disease relapse represents the major cause of treatment failure after allogeneic hematopoietic stem cell transplantation (allo-HSCT). The aim of our study was to optimise the testing protocol for establishing the chimeric status of patients performing allo-HSCT. We compared the efficacy of two different multiplex STR-PCR kits, focusing on their sensitivity and sensibility.

Method. DNA samples, provided by 17 patients and their haploidentical donors were tested at various intervals in order to determine the chimeric status. The samples were analysed using two different commercial kits, each of them containing a set of 16 STRs (AmpFISTR Identifier, Applied Biosystems; PowerPlex 16 System, Promega). For each case, the most informative markers were selected and analysed in dynamics. Artificial mixtures prepared from recipients and their donors samples were analysed to set up reconstruction curves.

Results. Complete chimerism was detected for 15 patients, while 2 patients exhibited mixed profiles. Both commercial kits gave similar results concerning the chimeric status. The reconstruction curves showed a slightly higher sensitivity for the Identifier kit, which quantified more accurately the low concentrations of minor DNA component.

Conclusions. Our data indicate that both commercial STR-PCR kits were able to establish an accurate chimeric status. A kit selection should be performed in an objective manner, after analyzing its performances regarding the typing sensitivity and sensibility for artificial mixtures. Thus, precise monitoring of post-transplant hematopoietic chimeric status becomes of outmost interest for the clinical follow-up of leukaemia patients.

P04.095**Tracking the natural history of leukaemic clone in MLL-driven childhood acute leukaemias**

J. Zuna¹, T. Burjanivova¹, E. Mejstrikova¹, E. Fronkova¹, Z. Zemanova², K. Muzikova¹, C. Meyer³, S. W. Horsley⁴, L. Kearney⁴, H. Ptoszkova⁵, D. Mendelova⁶, R. Marschalek³, O. Hrusak¹, J. Stary¹, M. Greaves⁴, J. Trka¹;

¹CLIP, Charles University Prague, 2nd Medical School, Prague 5, Czech Republic, ²Center of Oncocytogenetics, Institute of Clinical Biochemistry and Laboratory Diagnostics, General University Hospital and 1st Medical School, Charles University, Prague, Czech Republic, ³Institute of Pharmaceutical Biology/DCAL, JWG University of Frankfurt, Frankfurt/Main, Germany, ⁴Institute of Cancer Research, Sutton, Surrey, United Kingdom, ⁵University Hospital Ostrava, Ostrava, Czech Republic, ⁶University Hospital Brno, Brno, Czech Republic.

We and others have previously documented prenatal origin of paediatric acute lymphoblastic leukaemias (ALL) by demonstrating identical clonal changes in monozygotic twins/triplets and/or backtracking of the (pre)leukaemic clone to neonatal blood spots or cord blood of patients. We have also detected the cells of preleukaemic clone in the cord blood of healthy newborns never developing leukaemia. However, the evolution of definitive leukaemic clone remains largely unclear. Secondary ALL developing during leukaemia treatment represents a unique chance to follow this process. We analysed two cases of treatment-related ALL involving notorious oncogenic transcription factor MLL. In both patients, cells bearing MLL fusion (MLL/FOXO3A, MLL/MAML2) appeared in bone marrow long before the definitive leukaemic clone was identified: 20 and 24 months, respectively. Moreover, in both cases, FISH and/or qRT-PCR showed this fusion in a substantial proportion (10%-90%) of marrow cells with morphologically intact differentiation during the preleukaemic phase. In the MLL/FOXO3A case we were able to document its presence in lymphoid as well as myeloid lineage, thus indicating the fusion arose in a multipotent progenitor. In both cases, definitive lymphoblastic leukaemic clones arose only shortly before relapse. Comparison by SNP-array revealed a 10Mb region of amplification on 19q13.32 in one of the leukaemic samples, absent in the preleukaemic phase. Taken together, we document a striking sequence of events including covert protracted preleukaemic phase characterised by dominant MLL-fusion with intact differentiation and subsequent acquisition of secondary genetic abnormality (proven

in one case). These data provide unique insight into the MLL-driven leukaemogenesis.

P04.096**Amplification of hTERT and hTERT genes in leukemic cells detected by fluorescent in situ hybridisation (FISH)**

A. Erjavec-Skerget, A. Zagorac, N. Kokalj Vokac;
University Clinical Centre, Maribor, Slovenia.

The high level of genomic amplification of the human telomerase genes hTERT and hTERT, which maps to chromosome bands 3q26 and 5p15, was determined in different human cancer cells. We represent the results of the fluorescent in situ hybridisation (FISH) analysis with both locus specific probes on cell cultures from bone marrow of 35 patients with acute malignant blood disease. Among them 32 patients were with non-lymphoid and 3 with lymphoid type of malignancy. Bone marrow cells were first karyotyped by standard cytogenetic analysis. FISH revealed a low grade amplifications of hTERT gene at 4/35 patients and a low grade of the hTERT amplifications at 5/35 patients.

The comparison of the karyotypes and the FISH results by each patient reveals low grade amplification of hTERT gene only at one patient with previously determined complex karyotype. We didn't confirm any amplification of hTERT gene. Our results, based on comparison of the results derived by FISH and karyotyping, show that the hTERT and the hTERT amplification are not so common in patients with malignant blood disease as in other types of cancers.

P04.097**MRP1 polymorphisms (T2684C, C2007T, C2012T, and C2665T) are not associated with multidrug resistance in Leukemic patients**

F. Mahjoubi, S. Akbari, F. Moshyree;
NIGEB, Tehran, Islamic Republic of Iran.

One of the major problems in treating cancer patients is that cancer cells can evolve in drug resistance. Because this form is resistant to multiple anticancer drugs, so called multidrug resistance (MDR), the mode of resistance must be nonspecific, involving drug-efflux transporters. One of the most extensively studied genes involved in MDR is multidrug resistance protein 1 (MRP1). We have investigated the possible association between the expression level of MRP1 and occurrence of MDR in 111 patients with acute leukemia (which included 52 patients with acute myelogenous leukemia and 59 patients with acute lymphoblastic leukemia). mRNA level of *MRP1* had been determined by quantitative real time RT-PCR and compared to the type of response to chemotherapy. We found that high expression of *MRP1* was associated with poor clinical outcome in both AML and ALL patients. In our previous studied we had shown that the increase in *MRP1* gene dosage was not responsible for the upregulation of *MRP1* expression in leukemic patients.

Therefore, we aimed to investigate the effect of *MRP1* polymorphisms on the expression level of it. The T2684C, C2007T, C2012T, and C2665T polymorphisms were genotyped in all the patients and control group. There was no effect of a particular genotype on the expression level of the *MRP1* gene. This could show the lack of dependency of any of these genotypes on the chemosensitivity in this group of patients.

P04.098**Study of the effect of MRP1 gene polymorphisms on its mRNA expression in patients with acute leukemia**

S. Rezvani^{1,2}, F. Mahjoubi¹, K. Alimoghaddam³;

¹NIGEB, Tehran, Islamic Republic of Iran, ²Azad University, Tehran, Islamic Republic of Iran, ³Hematology, Oncology and BMT Research Center, Shary-attae Hospital, Tehran, Iran, Tehran, Islamic Republic of Iran.

Principle: One of the major problems in treating cancer patients is that cancer cells can evolve in drug resistance. Because this form is resistant to multiple anticancer drugs, so called multidrug resistance (MDR), the mode of resistance must be nonspecific, involving drug-efflux transporters. One of the most extensively studied genes involved in MDR is multidrug resistance protein 1 (MRP1).

We aimed to investigate the possible association expression level of *MRP1* and occurrence of MDR in leukemic patients wished to test the hypothesis that *MRP1* polymorphisms would be predictive of MDR in patients with acute leukemia.

Method: mRNA level of MRP1 was determined in 111 patients with acute leukemia including 52 patients with AML and 59 patients with ALL by RT-PCR and compared to the type of response to chemotherapy.

We found that overexpression of MRP1 is indeed and associated with MDR phenotype in leukemic patients.

Furthermore, the 128G>C, 816G>A, 825T>C, 1299G>C and -260G>C, -275

A>C were genotyped in all the patients and control group.

P04.099

PHLPP gene is mutated in pediatric acute myeloid leukemia patients and might act as a tumor suppressor gene

T. A. Tekiner^{1,2}, F. Atalar¹, A. Karabay-Korkmaz², S. Anak³, U. Ozbek¹;

¹Istanbul University, Institute of Experimental Medical Research (DETAE), Genetics Department, Istanbul, Turkey, ²Istanbul Technical University, Molecular Biology and Genetics Department, Istanbul, Turkey, ³Istanbul University, Istanbul School of Medicine, Department of Pediatric Hematology and Oncology, Istanbul, Turkey.

The overactivated PI3K/Akt pathway represents potential therapeutic targets for AML. The protein phosphatase PHLPP has been shown recently to specifically dephosphorylate S473 of Akt which regulates the balance between cell survival and apoptosis. Human PHLPP contains an amino-terminal PH domain, a leucine-rich repeat region (LRR), a PP2C-like catalytic core and a PDZ binding motif. So far, there are no described mutations in PHLPP gene. In this study, we aimed to understand the architecture of PHLPP gene variations in pediatric AML patients. We report here the molecular screening results of 11 exons covering the four domains of PHLPP gene in 38 pediatric AML patients. The screening for the presence of a mutation was performed by dHPLC analysis. Mutation detection was accomplished by direct sequencing.

We found the following sequence variations, **exon2** and **3**; 59insA(5.2%), 60C>T(2.8%), 77C>A(2.8%), 109A>T, 289C>A(7.8%), 352C>A(7.8%), 343insA(2.8%), **exon5, 6** and **7**; 599insA(47%), **exon14,15,16,17** and **18**; 1980T>C(5.2%), 1992T>C(5.2%), **exon19**; 3280C>A(13.1%), 3302insA(13.1%), 3303T>C(13.1), 3407insA(5.2%) and 3611insC(7.8%). The expression analysis of the exons covering the four domains were performed by QRT-PCR. Interestingly, in all patients, we could not detect any expression in LRR domain. We are currently investigating the effect of 599insA (S200R), which might result structural and functional changes at protein level due to the change of the amino acid charges. This is the first study evaluating sequence variations together with the expression of PHLPP gene. We propose that PHLPP gene might act as a tumor suppressor in AML leukomogenesis and this can provide an important guidepost for the development of diagnostic tools for acute leukemia.

P04.100

Beta Catenin gene expression and mutation analysis in T-ALL patients and cell line

Y. Erbilgin, M. Aydin Sayitoglu, O. Hatimaz, U. Ozbek;

Institute of Experimental Medical Research, Istanbul, Turkey.

The molecular mechanisms regulating the development and differentiation of the haematopoietic system are not clearly understood. Recent studies showed that Wnt signaling proteins play significant roles in both normal lymphocyte development and leukemia pathogenesis. Wnt proteins activate a complex signaling cascade, leading stabilization of β -catenin, which is a key component of the Wnt signaling pathway. β -catenin levels are regulated post-translationally by the canonical Wnt signaling pathway. In this study, we investigate the Wnt/ β -catenin pathway activation in T-cell acute lymphoblastic leukaemia (T-ALL) patients and cell lines.

We analyze β -catenin mRNA expression using quantitative real time PCR (QRT-PCR). We measured protein levels by western blot and search for mutations in exon 2-3 of the β -catenin gene in 73 T-ALL patients that were applied to our department for molecular diagnostic purposes and 29 T-ALL cell lines. Wnt signals are transduced by active β -catenin. We showed that T-ALL patients and cell lines have abnormal nuclear accumulation of β -catenin. We also found a β -catenin gene (exon3) mutation in one T-ALL patient. To the best of our knowledge, this is the first study that shows β -catenin gene mutation in T-ALL patients. No mutation was found in any of the cell lines. Our find-

ings reconfirm that Wnt signaling is deregulated in T-ALL by abnormal β -catenin expression. We discuss that β -catenin may play a significant role in promoting leukemic cell proliferation, adhesion, and survival via increased transcription of Wnt target genes.

P04.101

Deregulation of IRS4 as a result of juxtaposition to T-cell receptor beta in a pediatric t(X;7)(q22;q34)-positive T-cell acute lymphoblastic leukemia

K. Karman¹, C. Lassen¹, E. Kjeldsen², T. Fioretos¹, B. Johansson¹;

¹Department of Clinical Genetics, Lund, Sweden, ²Cancer Cytogenetic Laboratory, Aarhus, Denmark.

OBJECTIVES: A t(X;7)(q22;q34), an abnormality not previously described in hematologic malignancies, has been molecularly characterized in a pediatric T-cell acute lymphoblastic leukemia (T-ALL). PATIENTS AND METHODS: The t(X;7), initially detected by G-banding analysis, was further investigated with fluorescence in situ hybridization (FISH), real-time polymerase chain reaction (PCR) and Western blot analysis. RESULTS: FISH disclosed a breakpoint in the T-cell receptor beta locus (7q34) and a breakpoint between RP11-815E21 and RP11-105F23 mapping at Xq22.3. The two genes located closest to this region, i.e. insulin receptor substrate 4 (IRS4) and collagen, type IV, alpha 5 (COL4A5), were analyzed using real-time PCR. COL4A5 was not differentially expressed in the t(X;7)-positive sample compared to five T-ALL controls. However, a marked overexpression of IRS4 was identified in the (X;7)-positive case in relation to the controls. Although the Western blot analysis was suboptimal due to protein degradation, a band representing IRS4 was found in the t(X;7)-positive T-ALL; this band was not seen in the control samples. CONCLUSION: We report the first T-cell neoplasm with a translocation resulting in deregulation of IRS4. In fact, this is so far the only reported neoplasia in which a member of the IRS family has been implicated.

P04.102

Clinical significance and prevalence of T315I mutation in Indian CML patients treated with Imatinib mesylate

R. Mir, S. Sazawal, R. Chobey, S. Bharti, A. Chopra, P. Mishra, B. Bohra, R. Saxena;

Department of Haematology, All India Institute of Medical Sciences, New Dehli, India.

Background: The early detection of T315I mutations may allow timely treatment intervention to prevent or overcome resistance.

Lacunae: Prevalence of T315I mutation in Indian CML patients.

Aims: To detect T315I mutation in CML patients by ASO-PCR. To study prevalence of T315I mutation in Indian CML patients.

Methodology: CML patients were diagnosed by RT-PCR. ASO-PCR was done for all 160 patients for BCR-ABL mutations especially for T315I. The patients were evaluated for hematologic and molecular responses, time to progression, survival and toxicity.

Results : The study included 160 CML patients. The mutation was detected in 30% of patients (30/160). The median time of Gleevec treatment 25 months. The onset of T315I mutation in 30 patients developed poor prognostic factors in these patients. 25/30 lost hematological & molecular responses. 20/25 progressed to advanced stage. T315I mutations had proven to be fatal & is soul cause of Imatinib resistance in our patients. Survival and time-to-progression curves were obtained from Kaplan-Meier method.

Discussion : India is a developing country, the patients cannot effort expensive tests like sequencing for T315I mutation. So we had standardized ASO-PCR for routine screening of T315I mutations in our patients.

Conclusion: ASO-PCR proved to be very economical, sensitive and rapid technique for detection of known T315I mutations and is even sensitive than mutation detection by sequencing. The early detection by ASO-PCR assay proved to be helpful in clinical management of therapeutic decisions in CML patients.

P04.103**Integrated CGH and MicroRNA analysis in Mantle Cell Lymphoma reveals miRNA signatures associated with specific cytogenetic changes**

C. Gomez-Abad¹, L. Di Liso¹, N. Martinez², B. Ferreira², E. Rodriguez¹, M. Sanchez-Beato¹, J. Cruz Cigudosa², M. A. Piris¹;

¹Lymphomas Group, Molecular Pathology Program, CNIO, Madrid, Spain, ²Cytogenetics Group, Human Cancer Genetic Program, CNIO, Madrid, Spain. Mantle Cell Lymphoma (MCL) is characterized by a t(11;14) translocation, which leads to Cyclin D1 overexpression. Although CGH and Expression profiling data in MCL has been investigated, until now no equivalent studies have been performed for miRNA. Here we explored the relation between miRNA expression profiling and CGH microarray data from a series of 20 MCL cases and 5 reactive tonsils. MCL presents a unique miRNA signature revealing overexpression of 15 miRNAs and downregulation of 50 miRNAs in at least 50% of the cases, when compared with the average expression level of the controls. Some of these miRNAs have already been described in other tumor types, such as miR-143 and miR-145 downregulated in B-cell malignancies.

CGH analysis in this series identifies a series of changes, roughly coinciding with those described. We have investigated whether chromosomal gains and losses could explain the miRNA MCL signature. A microRNA profile has been identified as associated to the most frequently chromosomal aberration described in MCL. Thus losses of 9p21-pter, 1p, 13q, 11q21; and gains of 15q and 3q were associated with distinctive miRNA changes. Taken together, MCL seems to combine a disease-specific miRNA signature that correlates with specific chromosomal changes.

P04.104**A rare karyotype including t(2;17) in a patient with myelodysplastic syndrome-derived acute myeloblastic leukemia**

F. Hazan, H. Akin, A. Vahabi, A. Alpman, F. F. Ozkinay, C. Ozkinay;

Ege University Medical Faculty Medical Genetics Department, Izmir, Turkey.

Myelodysplastic syndrome (MDS) is a clonal disorder characterized by dyshematopoiesis and high susceptibility to acute myeloid leukemia (AML). Complex chromosomal aberrations are present in $\leq 30\%$ of patients with primary myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML) and are associated with a poor prognosis. We report a 45 year-old patient with MDS-AML. The Wright-Giemsa stained peripheral blood smears showed blast cells (WBC: 3180/mm³, Hb: 9.69g/dl, Plt: 21100/mm³). An abnormal karyotype 44,XX, t(2;17),-16,-18 was obtained on G-banded metaphases from unstimulated bone marrow aspirate cell culture. Cytogenetic studies of AML showed that isolated -16 and -18 were significantly more common. To our knowledge, isolated t(2;17) is not described in AML to date. This is the first report of a patient presenting with a AML with t(2;17),-16,-18. We evaluated the outcome of the treatment and the prognosis of the patient. As in our patient, this rare karyotype may be associated with poor prognosis.

P04.105**Increased incidence of monoclonal B-cell infiltrate in chronic Myeloproliferative disorders. Report of four cases**

S. N. Kokkinou, K. Tzanidakis, A. Lindou, H. Alafaki, G. Floropoulou, R. Hatzi-kyriakou, G. Drosos;

Cytogenetic Unit, Sismanoglion General Hospital, Halandri, Greece.

INTRODUCTION: The coexistence of chronic myeloproliferative disorder (CMPD) and B-cell chronic lymphocytic leukemia (CLL) in the same patient is rare.

AIM OF THE STUDY: We report 4 cases of CMPD/CLL simultaneously occurred.

PATIENTS

1st patient: An Albanian man 57y with polycythemia Vera (PV).

2nd patient: A woman 73y with essential thrombocytosis (ET)

3rd patient: A man 83y with ET

4th patient: A man 78y with ET

In paraffin sections of the bone marrow samples was found 15-18% of monoclonal lymphocytic infiltrate CD5+, CD23+, CD10-, CD3-, ZAP-70-, CD79+ simultaneously with the findings of CMPD.

The patients were untreated and the trephine biopsies derived from the primary diagnostic procedure. In the Albanian patient a cervical lymph node (LN) was biopsied and the cell population was of Borigin

METHODS: Bone marrow specimens (BM) and PB lymphocytes were cultured using standard techniques. Thirty GTG banded metaphases were analyzed (ISCN2005).

RESULTS: The karyotypes looked normal. For FISH we used the LSI IGH dual color, break apart rearrangement probe, LSI BCR/ABL ES dual color translocation probe and WCP CEP-8 (VYSIS).

Two hundred interphase nuclei were counted. Up to 25% of the cells carried the BCR/ABL translocation, and the IGH rearrangement.

There was also monosomy of #8 in more than 10% of the cells.

CONCLUSIONS: Although the coexistence of CMPD and CLL is rare, we established that these two conditions in the PB, in the BM and in one LN is more frequent than expected. That implies that there is a predisposition for the development of monoclonal B-cell population. With FISH technique we demonstrated the coexistence of two diseases. Since we studied simultaneously PB, BM and a LN, we believe that CMPD and CLL support the hypothesis of multi step cancerogenesis.

P04.106**Molecular cytogenetic study of 69 patients with myelodysplastic syndromes and complex chromosomal aberrations**

Z. Zemanova¹, J. Brezinova², L. Babicka¹, S. Izakova², M. Siskova³, J. Cermak², K. Michalova^{1,2};

¹Center of Oncocytogenetics, General University Hospital and First Faculty of Medicine, Charles University, Prague, Czech Republic, ²Institute of Hematology and Blood Transfusion, Prague, Czech Republic, ³1st Medical Department, General University Hospital and First Faculty of Medicine, Charles University, Prague, Czech Republic.

Complex chromosomal aberrations (CCA) are detected in 10-20% patients with myelodysplastic syndromes (MDS), and are associated with drug resistance and poor outcome. Precise identifications of chromosomal regions involved in CCA could help in detection of cryptic, recurrent, prognostically significant aberrations and in identification of candidate genes involved in leukemogenesis.

During the last 6 years 590 patients with MDS were examined at diagnosis and in 69 of them CCA were ascertained. Chromosomal aberrations were verified by FISH with locus specific probes (Abbott-Vysis, Des Plaines, Illinois, USA), and by mFISH/mBAND with the "XCyte" probe kits (MetaSystems, Altlußheim, Germany).

The most frequently involved in complex rearrangements was chromosome 5 (58x) followed by chromosomes 3 (27x), 17 (25x), 12 (23x), 11 (20x) and 7 (20x). Parts of deleted chromosome 5 were in many cases translocated into other chromosomes. The most recurrent partners of chromosome 5 in translocation were chromosomes 17 (6x), 12 (6x), 3 (3x) and 7 (3x). Pure monosomy of chromosome 5 was proved in one case only showing that monosomy 5 in this cohort was not an isolated entity. The most frequent breakpoints were 5q31 (25x), 5q13.3 (24x), 5q12 (5x) and 5q14 (5x). Presence of CCA at diagnosis was connected with poor response to therapy and short survival (mean 5 months).

Finding of new chromosomal rearrangements and breakpoints might lead to discovery of genes, involved not only at the origin but also into pathways leading to progress of malignancy.

Supported by NR/9227-3, NR/9481-3, MZO 000064165, MSM 0021620808 and MSMT LC535.

P04.107**Trisomy 9: A rare chromosomal abnormality in MDS**

D. Pathak¹, R. Chaubey², R. Kumar¹, S. Sazawa¹, R. Saxena², R. Dada¹;

¹Lab for Molecular Reproduction and Genetics, Dept of Anatomy, All India Institute of Medical Sciences, New Delhi, India, ²Dept of Hematology, All India Institute of Medical Sciences, New Delhi, India.

Myelodysplastic Syndrome (MDS) is a clonal disorder of haematopoietic stem cells and result in progressive cytopenia and defects in erythroid, myeloid and megakaryocytic maturation. Clonal chromosomal abnormalities have been reported in 30 to 60% cases of MDS. As a result conventional cytogenetics plays a prominent and well established role in determining the contemporary diagnosis, prognosis and grading of this disorder. The chromosomal abnormalities are predominantly characterized by partial/ total chromosomal losses or chromosomal gains. The chromosomal abnormalities include mainly -5/del (5q), -7/del (7q), del (11q), del (12p) (12q), -y and +8. In an attempt to assess the frequency and type of cytogenetic abnormalities, cytogenetic analyses of 20 cases of MDS was done. Chromosomes

preparations were obtained by GTG banding of blood and bone marrow cells. On presentation 30% of cases revealed 46, XX and 46, XY normal karyotypes and 70% of cases revealed abnormal karyotypes del(5q),-7,del(6q),del(11q). Out of 20 cases 1 case revealed an addition of chromosome 9, 47,XX+9(90%) and 46,XX(10%) metaphase. Trisomy 9 is a rare chromosomal aberration found in MDS, to the best of our knowledge this is the first published report of trisomy 9 as a sole chromosomal aberration in MDS. The presence of trisomy 9 in such cases carries a poor prognosis and thus cytogenetic studies help to correlate the genotype with the phenotype.

P04.108

Complex cytogenetic findings in bone marrow of an elderly patient with chronic idiopathic myelofibrosis

T. Bulakbasi¹, M. K. Yuksef², Z. Yilmaz¹, F. I. Sahin¹;

¹Baskent University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey, ²Dr. Abdurrahman Yurtarslan Oncology Training and Research Hospital, Ankara, Turkey.

Chronic idiopathic myelofibrosis is a chronic myeloproliferative disorder characterized by splenomegaly, myeloid metaplasia and reactive bone marrow fibrosis. Clonal cytogenetic abnormalities are observed in 30 to 75% of the patients. Among these, trisomy 1q, 20q-, 13q- and +8 are the most common aberrations. Here we report a 70-year-old male patient with massive splenomegaly. His leukocyte count was 2300/mm³, hemoglobin 6,5 mg/dl and thrombocyte count 700 000/mm³ on admission. Bone marrow biopsy revealed signs of chronic myeloproliferative changes and dysmegakaryopoiesis and no specific diagnosis was established. During disease classification studies, he received hydroxyurea treatment, splenic radiotherapy and multiple blood transfusions. The clinical course worsened in the following months and the second bone marrow biopsy revealed myelofibrosis. Cytogenetic analysis of the bone marrow sample revealed a karyotype reported as 46,XY,del(9)(q22q34),t(8;17;21)(q22;q21;q22)[23]/46,XY[2], with a previously undefined three-way translocation and a deletion in chromosome 9. The patient died shortly thereafter. Karyotype analysis of the bone marrow is an integral part of diagnosis in myeloproliferative disorders, especially as a discriminative tool in ruling out reactive conditions.

P04.109

Inducible expression of the oncogenic transcription factor *EV11* in human myeloid cells leads to phenotypes characteristic of myelodysplastic syndromes (MDS)

T. Konrad, R. Wieser;

Medical University of Vienna, Vienna, Austria.

The *EV11* gene, which codes for a zinc finger transcription factor, is overexpressed in subsets of patients with acute myeloid leukemia (AML), chronic myeloid leukemia (CML), and myelodysplastic syndromes (MDS). Its overexpression in AML has been studied intensively because it is associated with particularly aggressive disease. However, recent bone marrow transplantation studies in mice have shown that *EV11* overexpression by itself causes MDS, while AML arises only in the presence of additional, cooperating genetic events.

To gain a better understanding of the biological properties of *EV11*, an HA-tagged version of the human *EV11* cDNA was expressed in human U937 myelomonocytic cells in a tetracycline regulable manner. Induction of *EV11* in this system strongly inhibited cellular multiplication, an effect that was in part due to cell cycle arrest, and in part to increased rates of apoptosis. Exposure of *EV11* expressing cells to differentiation stimuli caused cells to die rather than to differentiate. The *c-myc* gene, which is implicated in the control of cellular proliferation, was downregulated rapidly after the induction of *EV11*, suggesting that it may be a direct target of this transcription factor, and may play a role in its phenotypic effects.

The phenotypes observed after induction of *EV11* correspond well to what would be expected for a gene involved in the pathogenesis of MDS, and have also been observed with other MDS-associated oncogenes. We have therefore established a suitable model system to explore the role of *EV11* in the pathogenesis of this fatal disease.

P04.110

Familial myelodysplastic syndromes

A. Carrió^{1,2}, A. Valera¹, D. Costa¹, I. Madriga², C. Gómez¹, J. L. Aguilar¹, M. Aymerich¹, D. Colomer¹, B. Nomdedéu³, E. Montserrat^{2,3}, E. Campo^{1,2};

¹Hematopatología Unit Hospital Clínic, Barcelona, Spain, ²IDIBAPS, Hospital Clínic, Barcelona, Spain, ³Hematology Department Hospital Clínic, Barcelona, Spain.

The myelodysplastic syndromes (MDS) are a heterogeneous group of clonal disorders of hematopoietic stem cells, whose manifestation is cytopenia, hypercellular and dysplastic bone marrow, often with increased amount of blasts. The pathogenesis of the majority of MDS remains unexplained. It is regarded that genetic predisposition and exposure to toxic environmental agents contribute to genetic mutations in MDS.

We report an adult MDS family with 6 siblings, of which two presented myelodysplastic syndrome (MDS), namely refractory cytopenia with multilineage dysplasia (RCMD), at the ages of 37 and 49, respectively. Conventional cytogenetics showed complex karyotypes, at diagnoses, in both:

44,XX,del(5)(q13q33),-7,-9,der(15;21)(q10;q10),-21,+mar[9]/46,XX[10] in the propositus, and 46,XY,-3,del(5)(q13q35),+8,der(12)t(3;12)(q13;p13) [20] in the second one. The propositus developed acute leukaemia and underwent an allogenic transplantation of peripheral blood progenitor cells. She relapsed and eventually died of sepsis eight months post-transplantation. In order to know the status of the 4 other siblings, we performed morphological and cytogenetics bone marrow analyses. Since del(5)(q31q33) was the only chromosomal abnormality common to both complex karyotypes, we decided to investigate all the samples by FISH with the specific probe for 5q31. Surprisingly, we found that in the propositus the deleted chromosome was an i(5)(p10;p10), and one of the healthy brothers showed 12% of deletion 5q.

We postulate that in this family an inherited mutator effect is present and that it causes a karyotype instability, which leads to MDS/AML, with an unstable 5 chromosome.

P04.111

HFE C282Y mutation as a genetic modifier influencing disease susceptibility for chronic myeloproliferative disease

H. Andrikovics¹, N. Meggyesi¹, A. Szilvasi¹, J. Tamaska², G. Halm², S. Lueff², S. Nahajevszky², M. Egyed², J. Varkonyi⁴, G. Mikal², A. Sipos², L. Kalasz¹, T. Masszi², A. Tordai¹;

¹Hungarian National Blood Transfusion Service, Budapest, Hungary, ²St. Istvan and St. Laszlo Hospital, Budapest, Hungary, ³Kaposi Mor Hospital, Kaposvar, Hungary, ⁴Semmelweis University, Budapest, Hungary.

The Janus kinase 2 (JAK2) V617F point mutation is a common clonal alteration in chronic myeloproliferative disorders (CMPD). Genetic variations influencing susceptibility of CMPD have not been recognized previously. The aim of our study was (i) to establish V617F mutation status in CMPD patients (ii) to confirm associations with distinct clinical characteristics, and (iii) to examine the potential associations of CMPD development with genetic modifiers of iron metabolism (HFE C282Y, H63D and TFR S142G). HFE C282Y was genotyped in 328 CMPD-patients and 996 blood donors, HFE H63D and TFR S142G in CMPD patients and 171 first time blood donors. JAK2 V617F mutation was tested in CMPD patients and 122 repeated blood donors. The frequency of JAK2 V617F was 75.9% (249/328) in the CMPD group. At presentation, significantly elevated hemoglobin levels were found in V617F-positive patients compared to V617F-negative counterparts ($p < 0.000$). Vascular complications were more common in V617F-positive patients ($p = 0.039$, 26.6% vs. 15.2%). Decreased HFE C282Y allele frequency (AF±95%CI) was found in the CMPD-group (1.8±/1.0%) compared to controls (3.4±/0.8%; $p = 0.048$). TFR S142G AF was significantly reduced among V617F-negative CMPD-patients (34.8±/7.6%) compared to controls (47.8±/5.4%, $p = 0.02$). The age of CMPD onset and the rate of different complications were not different according to HFE or TFR genotypes. We found that HFE C282Y variant may be associated with a protective role against CMPD especially among V617F-positive cases. Since chronic iron deficiency or latent anemia may trigger disease susceptibility for CMPD, HFE C282Y positivity may be a genetic factor influencing this effect.

P04.112**NBS1 657del5 mutation in patients with myelodysplastic syndromes (MDS)**

B. Jekić¹, L. Luković¹, B. Popović², I. Novaković¹, J. Milasir², T. Damjanović¹, N. Maksimović¹, A. Bogdanović³, V. Bunjevacki¹;

¹Institute of Human Genetics, School of Medicine, University of Belgrade, Belgrade, Serbia, ²Institute of Biology and Human Genetics, School of Dentistry, University of Belgrade, Belgrade, Serbia, ³Institute of Hematology, Clinical Center of Serbia, Belgrade, Serbia.

Myelodysplastic syndromes (MDS) are the most common group of hematological disorders in persons older than 60-year age. MDS are characterized by elevated apoptosis in bone marrow and peripheral blood cytopenias. Since more than one third of all MDS patients develop acute leukemia MDS are considered preleukemic states.

NBS1 gene encodes for the nibrin (p95 protein). p95 acts in a double-strand DNA break repair as the part of MRE11/RAD50 double-strand break (DSB) repair complex. Nibrin is involved in cell cycle checkpoint, meiotic recombinations and telomere maintenance.

NBS1 gene mutations are recognized as a main molecular event in development of Nijmegen breakage syndrome (NBS). NBS is chromosome instability syndrome resulting in microcephaly, growth retardation, immunodeficiency and predisposition to different types of cancer. NBS patients have a particularly high predisposition to lymphoid malignancy.

Independently from Nijmegen breakage syndrome, alterations of *NBS1* gene sequence (mostly nucleotide substitutions and deletions) and expression are found in number of malignancies. Deletion of 5bp in exon 7(657del5) is the most often *NBS1* gene mutation found in Slavic population (so-called Slavic mutation).

In this study we have analyzed *NBS1* 657del5 mutation in a cohort of 71 MDS patients. Patients DNA were obtained from bone marrow microscope slides splices. To detect mutation we have compared PCR products of MDS patients DNA with control DNA containing *NBS1* 657del5 mutation. Only one patient harbored mutation. According to this study, *NBS1* 657del5 mutation may not be important event in evolution of MDS.

P04.113**A pediatric MDS patient with 5q31 deletion**

H. Acar¹, U. Caliskan², T. Cora¹, Ö. Balasar¹, C. Ucar²;

¹Dept. of Medical Genetics, Meram Medical School, Selcuk University, Konya, Turkey, ²Dept. of Pediatric-Hematology, Meram Medical School, Selcuk University, Konya, Turkey.

Myelodysplastic syndrome (MDS) includes the ineffective proliferation or production of cells in bone marrow (BM) leading to peripheral blood cytopenia and a preleukemic state. The pathogenesis of MDS involve a multistep process involving two or more genetic alterations that lead to alteration in cellular function that cause clonal proliferation of an abnormal stem cell. In the present study, we report on a childhood patient with MDS. The patient had 5q31 deletion by conventional cytogenetics and fuorescence in situ hybridization (FISH) analysis with a specific FISH probe at the diagnosis. We present the clinical features, genetics and immunologic analysis at the diagnosis and also followed-up results.

P04.114**FISH studies in multiple myeloma patients**

O. O. Yuregir¹, F. I. Sahin¹, Z. Yilmaz¹, E. Kizilkilic², S. Karakus², H. Ozdogru²;

¹Baskent University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey, ²Baskent University Faculty of Medicine Department of Adult Hematology, Ankara, Turkey.

Multiple Myeloma (MM) is a heterogeneous disease regarding its clinical and genetic properties. Cytogenetic studies are valuable diagnostic tools in MM patients both at the time of diagnosis and during clinical follow up. Although conventional karyotyping is the first choice, fluorescent in situ hybridization (FISH) is also important in detecting abnormalities that cannot be detected by karyotype analysis. Conventional cytogenetic analysis and FISH results of bone marrow samples of 36 MM patients at the time of diagnosis have been evaluated in the current study. Three probes for chromosome 13q (RB1, D13S319, D13S25), one for 14q32 (IgH) and one for 17p13 (p53) have been used for hybridization with fixed cells. Conventional cytogenetic results revealed that 20 patients (55.5%) had normal karyotypes, whereas 8

(22.2%) had numerical or structural chromosomal abnormalities. We did not find appropriate metaphases for chromosome analysis in 8 (22.2%) patients. FISH analyses revealed at least one or more abnormal results in 25 (69.5%) cases, whereas 11(30.5%) cases had no abnormal findings. 14q32 rearrangement was the most common finding in FISH analyses and has been detected in 21 cases (58.3%). 13q deletion and 17p deletion have been detected in 11 (30.5%) and 5 (13.9%) cases, respectively. In evaluating MM patients, FISH studies including 14q32 and 17p13 chromosome regions may yield quite significant results during clinical follow up of the disease which has a multistep pathogenesis.

P04.115**Cytogenetic studies among patients with myelodysplastic/myeloproliferative diseases**

M. Khaleghian, C. Azimi;

Department of Genetics, Cancer Institute, Imam Khomeini Medical Center, School of Medicine, Medical Sciences / University of Tehran, Tehran, Islamic Republic of Iran.

The myelodysplastic/myeloproliferative diseases (MDS/MPD) are clonal myeloid disorders that possess both dysplastic and proliferative features. Clinical symptoms are caused by complications resulting from cytopenia, dysplastic cells with abnormal function, leukemic infiltration of various organ systems, fever and malaise.

We are reporting the chromosome studies among 34 patients which referred to us with diagnosis of MDS/MPD by Hematologists/Oncologists during the last 12 months. Chromosome preparations were obtained from lymphocyte cultures and analyzed after GTG-banding and HR-banding.

30 patients (88.24%) showed normal karyotype. 4 patients (11.76%) had chromosome abnormalities.

Only one 67-year-old man patient who were diagnosed by MDS, showed abnormal karyotype of : mos 46, XY, add (20)(q) / 46, XY.

Three patients with diagnosis of MPD also showed chromosome aberrations as follows : First patient was a 32-year-old woman and her karyotype was : mos 46, XX, t (2, 11) (q33, q23) / 46, XX, del 2 q33 +7+9 -11+18 -X / 46,XX. Second one was a 56-year-old man with karyotype:

mos 47, XY, +22 / 45, XY, -7 / 46, XY.

Third case was a 57-year-old man and had a karyotype of: mos 92, XYYY / 46, XY.

All the patients did not have a Philadelphia chromosome.

P04.116**Cytogenetic study of 25 myelodysplastic syndrome**

M. D. Souto, R. Pinto Leite, M. Cunha, M. Guerra, E. Ribeiro;

Centro Hospitalar de Tras-os-Montes e Alto Douro, Vila Real, Portugal.

The myelodysplastic syndromes (MDS) are a heterogeneous group of clonal hematopoietic stem cell disorders. Cytogenetic analyses in bone marrow samples of MDS patients have both pathophysiologic significance and prognostic implications. Chromosomal abnormalities are found in 40 - 70 % of the patients with MDS, and the characteristic chromosomal abnormalities are del(5q), -5, del(7q), -7, +8, del(11q), del(12p), del(13q), del(17p), del(20q), +21.

We analyzed cytogenetically twenty five samples of MDS patients. There were 12 female and 13 male patients with an age-range of 51 to 87 (median 69). Cytogenetic abnormalities were observed in 40% of patients. The most common abnormalities were monosomy of chromosome 7 and trisomy of chromosome 8. Complex karyotypes were found in 3% of the cases.

Despite the small number of cases studied the results obtained corroborate those described in the literature and the importance of the cytogenetic study in the prognosis of MDS.

P04.117**Role of JAK2 V617F mutation in myeloproliferative disorders**

B. Kumar, V. Sharma, S. K Hasan, S. Sazawal, B. Sharma, R. Kumar, R. Saxena;

All India Institute of Medical Sciences, New Delhi, India.

Chronic Myeloproliferative disorders (MPD) polycythaemia vera(PV), essential thrombocythaemia(ET), and idiopathic myelofibrosis(IMF) form a range of clonal haematological malignant diseases characterized by proliferation of one or more lineages of the myelo-erythroid se-

ries. The identification of the JAK2-V617F mutation is an exciting new discovery in the field of MPDs. This acquired mutation is characterized by G→T nucleotide substitution at 1849 position leading to valine to phenylalanine substitution at amino acid position 617 (V617F) of the JAK2 tyrosine kinase protein which results in constitutive JAK2 activation that promotes proliferation. **Objective:-** To study the role and frequency of the JAK2 mutation in myeloproliferative disorder patients. **Materials & Methods:-** 60 MPD patients (30PV, 16IMF, 14ET diagnosed by bone marrow biopsy), 90 AML and 70 age & sex matched controls were studied. DNA was extracted from peripheral blood mononuclear cells and Allele Specific PCR was performed for V617F mutation. **Results:-** Majority of PV patients (28/30; 93.4%) had V617F mutation whereas the frequency of the mutation was lower in IMF and ET patients (7/16; 43.7% and 7/14; 50% respectively). The mutated patients had significantly higher mean haemoglobin and platelet count compared to JAK2 wild type patients and controls ($p=0.01$). Higher hematocrit and splenomegaly was observed in V617F patients. Only one AML patient and none of the 70 controls had V617F mutation. **Conclusion:-** Thus presence of the mutation confers a proliferative and survival advantage. Identification of the Val617Phe JAK2 mutation lays the foundation for new approaches to the diagnosis specially PV and classification. JAK2 can be new gene for the targeted therapy in myeloproliferative disorders.

P04.118 Importance of using JAK2 mutation in the diagnosis of myeloproliferative diseases

P. Riedlová¹, M. Brejcha¹, L. Sokol^{1,2}, J. Gumulec^{3,1}, M. Kučerová¹, M. Radina¹; ¹JG Mendel Cancer Centre, Nový Jičín, Czech Republic, ²The University Hospital L Pasteur, Košice, Slovakia, ³The Faculty Hospital, Ostrava, Czech Republic.

Chronic myeloproliferative disorders (CMPDs) are a group of various clonal haematological malignant diseases including chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET) and chronic idiopathic myelofibrosis (CIMF). Except for CML with a genetic abnormality the t(9,22), the molecular mechanisms underlying the CMPDs have not been identified. Recently, several research groups shown that a significant proportion of patients with non-CML CMPDs have a missense somatic mutation in JAK2 gene that substitutes phenylalanine for valine at residue 617 (JAK2 V617F). JAK2 is a nonreceptor tyrosine kinase (TK). Pseudokinase domain of JAK2 in haematopoietic cells is responsible for the constitutive activation of molecular signalling pathway and takes control of cell proliferation in CMPDs.

DNA from 306 samples was isolated from peripheral blood granulocytes in patients with CMPDs and genotyped for the JAK2 V617F (G>T) mutation. To identify the mutation we used a real-time polymerase chain reaction assay using fluorescent hybridization probes and melting curve analysis. In a few cases that are JAK2 V617F negative and have the non-CML CMPDs phenotype we detected novel mutations in JAK2 exon 12 by direct sequencing. The detection of the JAK2 mutations could be useful in the diagnostics of myeloproliferative disease patients.

P04.119 Association between antral nodularity, severe gastritis, positive serology, age, gender, ABO blood group and Helicobacter pylori in children

T. Sabbi;
Pediatric Unit Belcolle Hospital, Viterbo, Italy.

Hp causes one of the most widespread infections worldwide. It is well known that blood group antigens are related to the development of peptic ulcer and gastric carcinoma.

Association between virulence factors of Hp, severe gastritis, age, gender and ABO blood group.

25 patients underwent to esophagogastroduodenoscopy with antral biopsy for a suspicious upper gastrointestinal disease. In all of them serum sample were assayed for IgG antibodies to CagA and ABO blood groups were determined.

19 children (76%) were Hp positive by histopathology and urease rapid test. 15 of these 19 (79%) Hp positive patients were positive for CagA serology. At endoscopic examination of the 19 infected children, hyperemia of the gastric antrum was observed in 7 (37%) patients and antral

nodularity in 12 (63%) children. The histologic examination of all infected patients showed an active and chronic gastritis. The children CagA positive presented more intense hyperemia of gastric antrum, important lymphoplasmacellular infiltrate and a degenerative and vacuolar lesions of gastric epithelium. The 6 (24%) non infected patients, also negative for CagA serology, had a normal gastric finding. As expected from previous studies, we found that seropositivity for Hp increased with age and the rate of Hp infection was not significantly different in boys and girls. Similarly, Hp serological status was not significantly different between subjects of different ABO blood groups. Despite epidemiological evidence of increased peptic ulcer disease in ABO blood group O subjects, we found no association between Hp infection and ABO blood groups.

P04.120 Low Expression of ARHI Contributes to Glial Tumor Development

S. Yakut¹, R. Tuncer², M. Berker³, E. Goksu², I. Gurer⁴, G. Luleci¹, S. B. Karazum¹;

¹Akdeniz University, Faculty of Medicine, Department of Medical Biology and Genetics, Antalya, Turkey, ²Akdeniz University, Faculty of Medicine, Department of Neurosurgery, Antalya, Turkey, ³Hacettepe University, Faculty of Medicine, Department of Neurosurgery, Ankara, Turkey, ⁴Akdeniz University, Faculty of Medicine, Department of Pathology, Antalya, Turkey.

Although the ARHI gene shows 60% sequence homology to the Ras proto-oncogene, it is the first maternally imprinted tumor suppressor gene identified in the Ras family. ARHI gene is constitutively expressed from the paternal allele of normal breast, ovarian, heart, liver, pancreas, thyroid, brain tissues and its expression is lost or markedly downregulated primarily in breast, ovarian, pancreas and thyroid tumor tissues. In this study, we investigated the mRNA expression, LOH (loss of heterozygosity) and methylation analysis of ARHI gene in tumor and peripheral blood samples of 21 cases with glial tumor, and 7 normal brain tissue samples. Evaluation of the ARHI gene expression levels by RT-PCR revealed reduction in 7 of 21 glial tumor samples (33.3%). Analysis of LOH was performed by fragment analysis using 5 labeled polymorphic markers specific for 1p31 region. LOH was detected in 2 of 21 cases (9.5%). Methylation status of CpG island II of 5 cases was evaluated using COBRA (combined bisulfite restriction analysis) and RFLP. Results indicated complete lack of hypermethylation in the CpG island region II. Our results suggest that silencing of ARHI tumor suppressor gene may play a role in the glial brain tumor development.

P04.121 Analysis of ATM case-control mutation screening data

D. T. Babikyan^{1,2}, F. Lesueur², C. Voegelé², M. Hashibe², J. Hall³, G. B. Byrnes⁴, S. V. Tavtigian²;

¹Center of Medical Genetics and Primary Health Care, Yerevan, Armenia, ²International Agency for Research on Cancer, Lyon, France, ³Institut Curie, Orsay, France, ⁴Centre for MEGA Epidemiology; University of Melbourne, Carlton, Australia.

The susceptibility gene for Ataxia telangiectasia, ATM, recently has been established as an intermediate-risk breast cancer (BC) susceptibility gene. However, the answer to the question "what sort of sequence variation in ATM confers increased risk of BC" has been controversial. To address this question, we have pooled available ATM mutation screening data and carried out a combined analysis of truncating variants, splice junction variants, and rare missense substitutions (carrier freq $\geq 1\%$). The analysis of rare missense substitutions was accomplished by constructing a sufficiently informative protein multiple sequence alignment of ATM from full-length sequences of seven species and using a missense analysis program Align-GVGD with developed new classifiers. Systematic case-control analysis of the missense substitutions independently provided evidence that ATM is a BC susceptibility gene. We found that a combined analysis of truncating mutations, splice junction mutations, and rare missense substitutions provides stronger evidence that ATM is a BC susceptibility gene than simple consideration of truncating plus splice junction variants alone. We also found significant evidence of risk both in truncating plus splice junction variants and in the in silico predicted highest-risk class of missense substitutions. Taken together, these results led us to two conclusions: (1) Careful analysis of missense substitutions by measuring risk attributable to rare missense substitutions in a known or candidate suscep-

tibility gene will have real utility in case-control mutation screening. (2) The attributable fraction of rare missense substitutions in ATM for risk of BC is approximately equivalent to that of truncating and splice junction variants.

P04.122

Alterations in genes encoding sarcoplasmic-endoplasmic reticulum Ca²⁺ pumps in association with head and neck squamous cell carcinoma

M. Ravnik-Glavac, B. Korosec, M. Volavsek, D. Glavac;

University of Ljubljana, Faculty of Medicine, Ljubljana, Slovenia.

Recent studies have suggested that perturbation of intracellular Ca²⁺ homeostasis or signalling could contribute to cancer development. The purpose of this study was to evaluate whether germline variants of the ATP2A2 and ATP2A3 genes might act as susceptibility alleles in head and neck squamous cell carcinoma. In both genes, we identified eight different alterations in 11 patients with head and neck squamous cell carcinoma (11/79; $P = 0.0002$, odds ratio = 0.054, 95% confidence interval = 0.0069-0.4236). We also detected low expression level of both genes in connection with some of alterations, but could not correlate low expression level with methylation in the promoter region of either gene. The results suggest that Ca²⁺ pumps of sarcoplasmic-endoplasmic reticulum are involved in an increased susceptibility to develop head and neck squamous cell carcinoma in humans.

P04.123

Neuroendocrine carcinoma in Birt-Hogg-Dubé syndrome - do FLCN mutations contribute to malignancy?

M. A. Van Steensel¹, S. Weppeler¹, T. Claessens¹, B. G. Wouters²;

¹University of Maastricht, Maastricht, The Netherlands, ²University of Toronto, Toronto, ON, Canada.

Birt-Hogg-Dubé syndrome (BHD) is a dominantly inherited disorder characterized by an increased risk of developing kidney cancer, pneumothorax as a consequence of lung cysts and benign hair follicle tumors called fibrofolliculomas. It is caused by mutations in the gene coding for folliculin, a protein involved in mTOR signaling. As the relative risk of developing renal malignancies is around 5, BHD syndrome is generally considered to be a relatively benign condition for which annual follow-up suffices. However, the possibility that the pre-existing gene defect might act to modify the behavior of other cancers that arise in patients with BHD syndrome has so far not been considered. We describe a patient with BHD syndrome who succumbed to an extremely malignant neuro-endocrine tumor of prostatic or bladder origin within 6 weeks of its discovery. Tumor tissue showed elevated staining of phosphorylated mTOR and phosphorylated p70S6K, as did foci in clinically normal skin and kidney, confirming that folliculin is a negative regulator of mTOR signaling. We propose that the behavior of this cancer might have been modulated by the germline FLCN mutation and propose that patients with BHD syndrome be more closely monitored than is currently the case.

The prediction of tumour recurrence in patients with superficial bladder tumours presents several challenges in clinical management. For the improvement of recurrence prognosis in these patients we investigated gene expression and identified differences between superficial bladder tumours without recurrence during period of two years (10 patients) and with early recurrence (12 patients), which might explain differences in the biology and clinical outcomes High-density oligonucleotide microarrays (29,019 genes, AB) were used to analyze the transcript profiles of 22 superficial bladder tumours: 19 pTa and 3 pT1, grading 5 G1 and 17 G2. Statistical analyses were applied to investigate the ability of the genes to identify patients without recurrence during period of two years and with early recurrence. Initial screening using the GeneSpring and Bioconductor software tools revealed a putative set

of about 120 genes associating with the recurrence class. Significant differences were observed by HOXA10, GPNMB, TCN1, INA, H19, AURKC, FABP3 and PLOD2 genes. Besides, we integrated the microarray dataset with additional background knowledge, in order to algorithmically mine for differential-expression patterns in terms of the Gene Ontology functions and processes as well as known regulatory pathway memberships. Our results indicate that it may be possible to identify patients with a high risk of disease recurrence at an early stage using a molecular profile present already in the superficial tumours. Research is supported by MSM 0021620808 and IGA NR 8934-3.

Military Medical Academy, Department of Public Health, Ankara, Turkey.

Bladder cancer is the fourth most common cancer in men and the eighth in women in the western world. The aim of this study was to investigate the relationship between bladder tumor and variants of the cytochrome p450 (CYP), family 1, subfamily A, polipeptide 2 (CYP1A2) C734A, CYP2D6 G1934A, the glutathione S-transferase (GST), family M, subfamily 1 (GSTM1 null), GSTT1 null and GSTP1 I105V which play important roles in xenobiotic metabolism. In this study, we investigated the distribution of these polymorphisms in 135 bladder cancer patients and 128 age-matched healthy individuals as controls. The polymorphisms were analyzed using polymerase chain reaction (PCR) - restriction fragment length polymorphism (RFLP) assay and multiplex PCR method. Genotype and allele frequencies were calculated, and their associations with bladder cancer risk are calculated, and their association with bladder cancer risk or demographic factors, smoking status, and tumor stage was investigated. The prevalence of GSTT1 null genotype in cases was 23%, compared with 7% in the control group (OR, 0.254, %95 CI, 0.115-0.558, $p=0.001$). No association was observed between CYP1A2, CYP2D6, GSTM1, and GSTP1 genes polymorphisms and bladder cancer. There was association between smoking status and bladder cancer (OR, 1.914, %95 CI, 1.055-3.472, $p=0.033$), but there was no statistically significant association between demographic factors, tumor stage, tumor grade and bladder cancer. These data seem to indicate that GSTT1 gene polymorphism may be associated with bladder cancer in this Turkish population.

P04.127

FGFR3 mutations and 3p, 9p, 9q & p53 deletions in noninvasive bladder cancer

A. Y. Babayan¹, O. A. Kuznetsova¹, S. V. Bashkatov², O. B. Karyakin², D. V. Zaletaev^{1,3}, M. V. Nemtsova^{1,4};

³Research Centre for Medical Genetics, RAMS, Moscow, Russian Federation,

⁴Research Centre for Medical Genetics, RAMS, Moscow, Russian Federation.

The bladder cancer is one of the most severe oncological diseases. Importance of the development of new diagnostic clinical markers is dictated by its high incidence and aggressive tumor growth. Cancer development is a complex, multistage process involving various genetic and epigenetic alterations. In our study we have tried to establish associations between several genetics alterations (loss of heterozygosity (LOH) at 3p, 9p, 9q and p53 loci and S249C activating mutation in *FGFR3*) and tumor clinical phenotype (tumor differentiation, type of growth and a non-recurrent period). During the last year and the half we have studied 40 matched samples (blood and tissue) from patients with primary bladder cancer and 35 samples from patients with recurrent bladder cancer, of which 17 patients demonstrated recurrence within one year. All samples were divided into groups by differentiation rate: 53 samples classified as G1+G2 and 22 as G3. By growth type 53 samples were unifocal and 39 multifocal. LOH at 3p, 9p, 9q and p53 loci were detected by microsatellite analysis, and SSCP and direct sequencing sought for identification of *FGFR3* activating mutations. Statistical analysis of the results included comparison of the patients' clinical groups by Fisher's exact test, calculation of odds ratios and corresponding 95% confidence intervals, with GraphPad InStat v.3.5 software. Our results demonstrate that 9p deletions are significantly more frequent in tumors with high recurrence rate (within one year). *FGFR3* mutations are prevalent in G1+G1 group of tumors. No significant differences were found between tumors with various growth types.

Evidences for cancer cells showing stem features from human bladder Transitional Cell Carcinoma

A. Bentivegna¹, D. Conconi¹, E. Panzeri¹, E. Sala², G. Bovo², M. Casu², P. Viganò², G. Strada², L. Dalprà^{1,2};

¹Università degli Studi di Milano-Bicocca, Monza, MI, Italy, ²S. Gerardo Hospital, Monza, MI, Italy.

Transitional cell carcinoma (TCC) is the most common type of bladder cancer accounting for more than 90-95% and it often recur (75% after 5 years).

Emerging evidence has suggested that the capability of a tumor to grow, propagate and recur is dependent on a small subset of cells within it, termed cancer stem cells (CSCs). Current failure of cancer therapies may be due to their lower effect on CSCs that are resistant and retain their full capacity to divide and restore the tumor cell mass. Although data have been provided to support this theory in human blood, brain, and breast cancers, the identity of bladder cancer stem cells has not been determined. Here, we report the initial findings towards the isolation and preliminary characterization of a putative CSCs population from human bladder TCCs. These cells, isolated from fresh surgical specimens, were induced to proliferate *in vitro* in serum-free medium containing the mitogenic growth factors EGF and bFGF. The proliferating cells generated within 48 h detached spheres that showed clonal origin. Cells also resulted positive by immunofluorescence for the stem cells' markers CD133, Oct-4, Nestin and Cytokeratins. We also conducted a cytogenetic study on fresh chromosome spreads and, when possible, on chromosome spreads after different time of culture and a parallel molecular cytogenetic study by FISH on paraffin embedded tissue sections and on fresh and after culture nuclei. We found important karyotype changes by culture selection, losing the complexity present in fresh tumors and a marked molecular heterogeneity between the tumors.

P04.129

Reliable Methylation Analysis for Epigenetic Research - Novel Technologies offering a complete and standardized workflow

G. Schock, T. Träger, C. Korfhage, R. Peist, N. Rudinger, N. Fang, D. Jansen, D. Löffert;

QIAGEN GmbH, Hilden, Germany.

The analysis of changes in DNA methylation is challenging due to the lack of standardized methods for providing reproducible data. Here we present a complete and standardized workflow for methylation analysis.

Bisulfite Conversion: QIAGEN's EpiTect Bisulfite technology represents a unique system for DNA protection against DNA degradation which guarantees the highest conversion efficiency of $\geq 99\%$ and highest DNA quality.

Whole bisulfiteome amplification: Since the quantity of converted DNA is often limited, we here present a novel technology for the reliable and representative amplification of the entire bisulfite converted genomic DNA _ the bisulfiteome _ to overcome limitations in methylation analysis derived by limited DNA amounts.

Dedicated PCR technology for methylation analysis: Methylation Specific PCR (MSP) reactions often require extensive optimization. We present a mutant Taq DNA Polymerase that has been genetically engineered to increase primer extension specificity through better discrimination of 3' single base mismatches of the primer.

For highly sensitive TaqMan probe based real-time PCR, we have developed a novel reagent that yields accurate methylation analysis in real-time. A selection of pre-developed MethyLight assays for a first set of genes will also be made available.

Assay control reagents: Assay design and the success of methylation analysis by PCR can be facilitated and assessed by the use of standardized human control DNAs.

With its newly introduced EpiTect solutions, QIAGEN makes available standardized, pre-analytical and analytical solutions from DNA sample collection, stabilization and purification, to bisulfite conversion and real-time or endpoint PCR methylation analysis or sequencing.

P04.130

Karyotype alterations of CD133(+) stem-like cells of glioblastoma multiforme

W. Yang¹, D. Yang¹, C. C. Lin², L. Hsieh², D. Cho³, C. Hung¹, T. Li¹;

¹Cell/Gene Therapy Research Lab., China Medical Univ Hospital, Taichung, Taiwan,

²Dept of Medical Research China Medical Univ Hospital, Taichung, Taiwan,

³Dept of Neurosurgery, China Medical Univ Hospital, Taichung, Taiwan.

Recent studies have demonstrated the existence of cancer stem-like cells with CD133 surface marker in glioblastoma multiforme (GBM). It is believed that these minor CD133(+) tumor cells possess more efficient DNA-repair function than the majority CD133(-) progeny cells and thus can survive the radiation therapy and/or chemotherapy and rapidly give rise to fatal tumor recurrence. To isolate CD133(+) GBM cells, we administered ionizing radiation to short-term tumor cell cultures from 8 new GBM patients (participants in a clinical trial of immunotherapy). In one particular case, the GBM cells that survived irradiation contained 50- 60% highly clonogenic and neurosphere-forming CD133(+) cells. We also used FACS to isolate the CD133(+) cells from un-irradiated original GBM cell population of this patient. Karyotype analysis showed that the majority CD133(-) cells of initial culture were 46, XY, +7, +der(7;9)(p10;p10), -10, -18, der(19)(q13), with little change in near diploid karyotype within 10 passages *in vitro*. In contrast, majority of FACS-isolated un-irradiated CD133(+) cells showed a hypo-tetraploid with variation of chromosome number among them. The radiation-survived CD133(+) cells of this patient showed similar hypo-tetraploid patterns with slightly higher variation in chromosome number than the un-irradiated CD133(+) cells. Individual cell clones of the two CD133(+) categories were consistently hypotetraploid but still with variation of chromosome number, suggesting chromosomal instability during cell proliferation. Using these hypotetraploid CD133(+) GBM cells, we have obtained preliminary results that certain therapeutic agents that down-regulated CD133(+) expression also could shift the hypotetraploid to the near diploid karyotypes of CD133(-) GBM cells.

P04.131**Familial Cancer Database (FaCD) online**

R. H. Sijmons;

University Medical Center Groningen, Groningen, The Netherlands.

Cancer is associated with a wide range of hereditary disorders. Recognising these disorders in cancer patients is important for the medical management of both patients and their relatives. The Familial Cancer Database (FaCD) - online is a web-based application aimed at healthcare professionals with at least basic knowledge of clinical cancer genetics. It has been developed to support the clinical genetic differential diagnosis in cancer patients and families. FaCD tries to match the tumour and non-tumour features observed in a particular patient and family with those of the disorders included in its database and provides a clinical synopsis with literature references for each of these disorders. In addition to reported familial clustering of cancer (e.g. familial cases of cervical cancer) and known cancer-associated hereditary disorders (e.g. Lynch syndrome), the database includes patterns of multiple primary tumours and data on the tumours associated with common multifactorial disorders (e.g. diabetes) or exogenic risk factors (e.g. use of OAC). In total, FaCD contains files on more than 400 different disorders. Users can choose from over 900 clinical tumour and non-tumour features to compose a search profile. Links are provided to corresponding OMIM entries, PubMed abstracts and websites of research and support groups. The database can be found at www.facd.info and access is granted free of charge.

P04.132**Quantification of CEA mRNA for micrometastases detection in peripheral blood and bone marrow specimens of gastric cancer patients by Real-Time PCR**L. Dardaei Alghalandis^{1,2}, R. Shahsavan², S. H. Ghaffari², E. Aslankoochi², K. Alimoghaddam², A. Ghavamzadeh²;¹Tarbiar Modares University, Tehran, Islamic Republic of Iran,²Hematology, Oncology & BMT research center, Shariati Hospital, Tehran, Islamic Republic of Iran, ³Khatam University, Tehran, Islamic Republic of Iran.

Introduction: Gastric adenocarcinoma is the first leading fatal malignancy in Iran. Despite advances in therapeutics approaches for gastric cancer (GC), tumor dissemination to distant organs is still the major cause of death. CEA that is a tumor antigen is abundantly expressed by malignant cells. The aim of our research was to use CEA for detection of micrometastases in peripheral blood (PB) and bone marrow (BM) specimens of patients with GC.

Materials and Methods: we used CEA as a tumor marker and GAPDH as an internal control to detect and quantify disseminated tumor cells in PB and BM specimens of affected individuals. Total RNA was extracted from AGS cell line and CEA and GAPDH fragments were generated by reverse transcription. The amplified fragments were cloned into T/A vector. Double cloning of these fragments has been done into T/A vector. Serial dilutions of this plasmid are used as standard curve, each containing a known amount of input copy number. Total RNA was extracted from PB and BM specimens of about 30 patients. cDNA of these specimens were synthesized by reverse transcription.

Results: We set up quantitative Real-Time PCR for CEA and GAPDH. The assay determined the copy number of disseminated tumor cells in the PB and BM specimens of patients.

Conclusion: The quantitative real-time PCR for the CEA can be a useful technique for detection of micrometastases in the PB and BM specimens of GC patients

P04.133**DNA methylation of human telomerase reverse transcriptase (hTERT) gene in premalignant cervical lesions**P. Oikonomou¹, A. Tsezou^{1,2};¹University of Thessaly, Larissa, Greece, ²Institute of Biomedical Research and Technology, Larissa, Greece.

Human Telomerase Reverse Transcriptase (hTERT) mRNA expression seems to play an important role in cervical carcinogenesis. Analysis of the hTERT promoter region revealed the presence of a CpG island and a high overall GC content, suggesting a possible role for methylation in the regulation of hTERT gene expression. In the present study we evaluated the role of hTERT promoter methylation in hTERT regulation in premalignant cervical specimens. The methylation status of hTERT promoter gene, hTERT mRNA quantification and telomerase activity

were investigated in 26 normal and 64 specimens of abnormal cytology using the Methylight technique, the Telo TAGGG hTERT Quantification kit and LightCycler technology as well as Telomeric Repeat Amplification Protocol (TRAP). E6/E7 HPV-16 mRNA expression was also evaluated. No significant correlations were observed between hTERT mRNA expression and hTERT promoter methylation, as well as between telomerase activity and hTERT promoter methylation in normal and in premalignant cervical specimens. E6/E7 HPV-16 mRNA expression was observed in 72% of HPV-16 infected samples and was correlated with hTERT mRNA expression and telomerase activity ($p < 0.05$). This is the first study investigating the role of hTERT promoter methylation in hTERT mRNA expression and telomerase activity in premalignant lesions. The observed lack of correlation suggests that other mechanisms might be involved in the regulation of hTERT expression. The correlation between hTERT mRNA and E6/E7 mRNA expression confirms the role of HPV infection in hTERT regulation.

P04.134**Identification of new splicing isoforms of the β -chimaerin gene by transcript analysis in human cancer tissues and cell lines**L. Barrio-Real^{1,2}, M. Caloca², R. González-Sarmiento^{1,2};¹Unidad de Medicina Molecular. Universidad de Salamanca, Salamanca, Spain,²Centro de investigación del cáncer, Salamanca, Spain.

Chimaerins are a family of GTPase-activating proteins (GAPs) that selectively inactivate the Rac GTPase. The four members of this family (α 1- α 2- β - and β 2- chimaerins) are generated by alternative start of transcription of two different genes, the α and β -chimaerin genes. Chimaerin proteins have a catalytic GAP domain, a C1 domain that binds DAG and phorbol esters, and a SH2 domain that is only present in α 2 and β 2-chimaerin isoforms.

The β -chimaerin gene is located in the 7p15 locus and consists of 13 exons. In addition to the initial start site in exon 1, it poses an alternative start of transcription in intron 6 that is used to render the β 1-chimaerin isoform. This alternative transcript has only been reported in rat testis.

Since recent work demonstrates a role for the β 2-chimaerin protein in cancer progression, we decided to perform a transcript analysis of the β -chimaerin gene in human cancer tissues and cell lines, to search for tumor-related alterations.

We report for the first time a differential pattern of expression of β 2- and β 1-chimaerin in several glioblastomas and tumor cell lines. In addition we have identified and characterized additional new isoforms generated by alternative splicing: 8 isoforms of β 2-chimaerin and 9 of β 1-chimaerin. Some of these isoforms maintain some functional domains, but most of them would render non-functional proteins which could behave as dominant negative mutants.

Functional studies of these new isoforms will help us to understand the mechanism of action of these proteins and their role in tumor development.

P04.135**Chimerism monitoring: bone marrow vs. peripheral blood**A. D. Krstic¹, O. Stojkovic², M. Guc-Sccecic¹, D. Vujic¹, D. Jevtic¹, T. Vartljen²;¹Mother and Child Health Care Institute Vukan Cupic, Belgrade, Serbia and Montenegro, ²Institute of Forensic Medicine, School of Medicine, Belgrade,

Serbia and Montenegro.

The goal of post-transplantation monitoring in hematopoietic stem cell transplantation (HSCT) is to predict disease relapse, graft rejection and graft-versus-host disease. The main principal in chimerism detection is to determine genetic markers which differ between donor and recipient and monitor them after transplantation with highest accuracy and sensitivity.

First it is important to determine whether engraftment took place and second whether the recipient cells, if present, are normal or malignant. Sensitivity of chimerism monitoring using STR-PCR analysis is 1-5%, and on the other hand the sensitivity of RT-PCR for minimal residual disease (MRD) monitoring is at least 1000 times higher.

We present three cases with detected genetic aberrations before HSCT: one patient had AML with complex karyotype 48,XX, t(11;17)(q23;q21), +6,+mar and two patients had ALL with 46,XX, t(9;22)(q21;q12) and bcr-abl (p190) rearrangement detected on molecular level. These patients were followed by cytogenetics and molecular genetics using BCR-ABL probes for MRD and STR markers for chimerism monitoring.

Our experience show that it is useful to follow up MRD in the patients bone marrow cells in cases where genetic aberrations were detected before HSCT, in order to be ready for appropriate intervention. In this work we discuss different chimerism status registered in the bone marrow and peripheral blood at the same time point, in cases with complications after HSCT.

P04.136

Cisplatin inhibits in vivo mouse telomerase activity in melanoma squamous cells

B. G. Bumbacila¹, C. Dragaescu², R. O. Dumache³, C. A. Dehelean⁴, D. Ionescu⁴, A. D. Kaycsa³;

¹West University, Faculty of Chemistry-Biology-Geography, Chemistry Department, Timisoara, Romania, ²Public Health Institute, Timisoara, Romania, ³"Victor Babes" University of Medicine and Pharmacy, Faculty of Medicine, Biochemistry Department, Timisoara, Romania, ⁴"Victor Babes" University of Medicine and Pharmacy, Faculty of Pharmacy, Toxicology Department, Timisoara, Romania.

Cis-diamminodichloridoplatinum is a platinum (II) complex with chemotherapeutic use in treating neck and head cancers, small cell lung cancer, ovarian and testicular cancers. It is accepted that its mechanism of action relies on the fact that it binds to one DNA chain, by two guanosine residues, modifying DNA's double-chain structure and capacity to repair. The cell dies from apoptosis. Telomerase is a reverse transcriptase that adds TTAGGG repeating sequences to the 3' end of DNA strands in the telomere regions, which are found at the ends of the eukaryotic chromosomes. This way, it protects the genetic information in the DNA molecule by wasting with each replication cycle. Telomerase carries its own RNA molecule, used as a template for elongating telomeres. Cancer cells are expressing telomerase activity, while the most of the somatic normal cells do not.

We induced skin cancer in mice, by injecting them with dexamethasone and irradiating them with an UVB lamp. The mice were divided in two groups. One group was not treated. The other group was treated with cisplatin. Telomere lengths were analyzed in squamous cells from the carcinomic tissue of these mice by using the PCR / STELA technique. We found that the cisplatin treatment gradually reduces the telomere lengths in mice treated with this compound vs mice untreated, by decreasing telomerase's activity. We conclude that our findings support the idea that platinum compounds may have other ways of action in the cell nucleus, beside the classical one accepted.

P04.137

Quantification of CK20 mRNA for micrometastases detection in peripheral blood and bone marrow specimens of colorectal cancer patients by Real-Time PCR

E. Aslankoohi^{1,2}, S. H. Ghaffari², L. Dardaei Alghalandis^{4,3}, K. Alimoghadam², A. Ghavamzadeh³;

¹Khatam university, Tehran, Islamic Republic of Iran, ²Hematology, Oncology & BMT Research center, Tehran, Islamic Republic of Iran, ³Hematology, Oncology & BMT research center, Tehran, Islamic Republic of Iran, ⁴Tarbiat Modares university, Tehran, Islamic Republic of Iran.

Introduction: Colorectal carcinoma is the third cause of cancer related deaths in the world. Despite advances in therapeutic approaches for colorectal cancer, tumor cells dissemination to distant organs is still the major cause of death.

Cytokeratins, are abundantly expressed by epithelial cells. The presence of epithelial cells in peripheral blood (PB) or bone marrow (BM) indicates the malignant nature of them. The aim of our research was to use CK20 for detection of micrometastases in PB and BM specimens of patients with colorectal cancer.

Materials and Methods: We used CK20 as a marker and GAPDH as an internal control. Total RNA was extracted from Caco2 cell line. CK20 and GAPDH cDNA were synthesized. Double cloning of these fragments has been done into T/A vector. Serial dilutions of this plasmid will be used as standard curve. Total RNA was extracted from PB and BM specimens of 30 patients, and cDNA were synthesized. We are quantifying CK20 mRNA levels and CK20/GAPDH mRNA ratios using a TaqMan real-time PCR system in the specimens.

Results: We set up quantitative PCR for CK20 and GAPDH using Real-Time PCR. The assay determined the copy number of disseminated tumor cells in the specimens of patients.

Conclusion: The quantitative real-time PCR for the CK20 can be a use-

ful technique for detection of micrometastases in colorectal cancer.

P04.138

Screening of CYP1B1 alleles shows a less frequency of hyperactive variants Leu432Val and Asn453Ser in Mexican Population

L. M. Gonzalez-Huerta¹, O. M. Messina-Baas¹, C. Chima², S. Kofman-Alfaro¹, R. Rivera-Vega¹, S. A. Cuevas-Covarrubias³;

¹Hospital General de Mexico, Mexico D.F., Mexico, ²Hospital 20 de Noviembre, ISSSTE, Mexico D.F., Mexico, ³Hospital General de Mexico, Fac Medicina, UNAM, Mexico D.F., Mexico.

Human cytochrome P4501B1 is an important enzyme in the activation of diverse procarcinogens. CYP1B1 gene is polymorphic and hyperactive variants can lead to a higher susceptibility to estrogen-related cancers. Several single nucleotide polymorphisms have previously been reported in the human CYP1B1 gene. Previous studies have revealed a relation between Ala119Ser allele and breast cancer and between Leu432Val and prostate cancer, two polymorphisms that result in a higher catalytic activity of the enzyme. Mexican population shows a lower incidence of this type of cancers in comparison with other western countries. In the present study we analyzed the frequency of five CYP1B1 polymorphic sites to initially explore the possible relation between the lower incidence of estrogen-related cancer and the presence of these alleles in Mexican population. The genetic distribution of CYP1B1 variants was evaluated in 100 Mexican healthy subjects through genomic DNA sequencing analysis. The frequency of homozygous hyperactive variant Ala119Ser (23%) was higher than those reported in other populations. The frequencies of polymorphic variants 4326C>G (Leu432Val) and 4390A>G (Asn453Ser) (3% and 0%, respectively) were significantly lower than those observed in other populations except for Japanese population. The homozygous variant 4390A>G was not identified in our population. Our data demonstrates that the CYP1B1 alleles encoding hyperactive variants, and the silent polymorphism 1347C>T, are significantly less frequent in Mexican population than those observed in western countries. Further studies should focus on the potential interaction of the occurrence of these polymorphisms and the incidence of estrogen-related cancers in Mexican population.

P04.139

Molecular characterization of patient-derived melanoma cell lines employed in therapeutic vaccine preparation

Z. Ogbah¹, F. Simonetta¹, J. Puig-Butillé¹, C. Badenas^{1,2}, J. Malveyh^{1,2}, D. Benitez², R. Vilella³, S. Puig^{1,2};

¹Melanoma Unit, Department of Dermatology and Genetics Service, Hospital Clínic de Barcelona, IDIBAPS, Barcelona, Spain, ²Centre of Biomedical Research on Rare diseases (CIBERER), ISCIII, Barcelona, Spain, ³Melanoma Unit, Department of Immunology, Hospital Clínic de Barcelona, Barcelona, Spain.

We studied eleven human cutaneous melanoma cell lines with the aim to detect the presence of genetic aberrations currently considered to have a role in the pathogenesis of melanoma. By multiplex ligation dependent probe amplification assay (MLPA), mapping the region 9p21, we identified homozygous deletion of CDKN2B region in seven cell lines and homozygous deletion in CDKN2A region in eight cell lines. Sequencing analysis of the three cell lines that presented either loss of heterozygosity or no deletion for all loci tested in the 9p21 region showed deleterious mutations in two of them. NRAS and BRAF sequencing revealed a mutation in NRAS gene in one cell line and V600E change in BRAF in six cell lines. Four of the BRAF mutated cell lines presented one or more changes in MC1R. NRAS and BRAF mutations were mutually exclusive. No mutation affects CDK4 gene. We also have studied gains in several oncogenes by MLPA. NRAS (1p13) was amplified in the cell line carried NRAS mutation; CDK6 (7q21) was amplified in other seven cell lines. Amplifications of the chromosomal region 12p13 (CCND2) and 20q13 (STK15) were the more frequently detected (45% and 45% of cases, respectively). The region 11q13 (CCND1) was amplified in two cell lines. Finally, punctual amplifications of some oncogenes were identified (p.e. BIRC5). We detect two profiles: CDKN2A alterations with and without NRAS/BRAF/MC1R changes. Both patterns were associated to oncogenic amplifications. In conclusion, our results constitute a comprehensive molecular characterization of melanoma cell lines, offering important

information for melanoma research.

P04.140

A semi-automated unbiased differential methylation screening assay for applications in cancer epigenetic research

V. V. Shkarupo^{1,2}, A. S. Tanas³, E. B. Kuznetsova^{1,4}, L. E. Zavalishina⁵, G. A. Frank⁶, D. V. Zaletaev^{1,4}, V. V. Strelnikov^{1,4};

¹Research Centre for Medical Genetics, Moscow, Russian Federation, ²Russian State Medical University, Moscow, Russian Federation, ³Sitronics Telecom Solutions, Moscow, Russian Federation, ⁴I.M.Sechenov Moscow Medical Academy, Moscow, Russian Federation, ⁵Moscow P.A.Gertsen Oncology Research Institute, Moscow, Russian Federation.

Screening for differential methylation in tumor and control samples is one of the powerful approaches towards the identification of novel cancer related genes. Still there is no universal technique to screen for differential methylation, although the spectrum of methylation detection methods is vast. We have developed a synthetic highly effective, unambiguous, unbiased, semi-automated screening technique to serve as a possible basis for cancer epigenome research. Our differential methylation screening approach is based on a fluorescent methylation sensitive PCR with primers complementary to the adaptors ligated to the DNA digestion fragments. These AIMS (amplification of intermethylated sites) products are analyzed on automatic genetic analyzers with single-nucleotide resolution using GeneScan software. Specific software for automatic identification of differentially methylated fragments have been developed as well as the software capable of identifying the AIMS fragments *in silico* by comparison with available genome databases. Additional computer service is available to assist in experimentation design respective to specific applications. With technical variations this approach may be elaborated to identify novel targets of DNA methylation/demethylation as well as to roughly characterize epigenomic status as a whole. We suggest that the assay is universal and can be applied for screening differential methylation in any disease where epigenetic component may be suspected. *The study is supported by Friends for an Earlier Breast Cancer Test Foundation, USA.*

P04.141

The investigation of tumor suppressor gene (P53) LOCUS-17 P13 in late stage Endometriosis patients by fluorescent in Situ Hybridisation (FISH) technique

F. A. Teksen¹, & Keleş², H. Şatıroğlu³;

¹Faculty of Health Sciences, Ankara, Turkey, ²Düzen Laboratory, Ankara, Turkey, ³Ankara University Faculty Medicine, Obstetrics and Gynecology Department and Biotechnology Institute, Ankara, Turkey.

In the study, the incidence of genetic alterations in p53 gene locus in late stage endometriosis cases were investigated in comparison with the endometrium and peripheral blood samples of the same patients and the same tissues of normal healthy women.

The study group was composed of six endometriosis samples (n:6). Control group included; normal endometrium samples (n:6, control I) and peripheral blood lymphocytes (n:6, control II) of the same patients with normal endometrium samples (n:5, control III) and peripheral blood lymphocytes (n:5, control IV) of the healthy women.

Frequency of monosomic, disomic and trisomic cells in controls and endometriotic tissue specimens were determined by using Multicolor Fluorescence in situ hybridization (FISH) technique and statistically analysed by Khi squared test.

In endometriosis samples the frequency of monosomy and trisomy were 16.4 % and 2.1 % respectively for chromosome 17 p13 (p53) locus. In endometrium samples (n:6) the frequency of trisomy was 3.2 %. In peripheral blood lymphocytes (n:6) the frequency of trisomy was 0.3 % for the same locus.

Finally, chromosome 17p13 (p53) locus genetic alterations were found to be significantly greater ($p < 0.0001$) in the endometriosis specimens than in normal endometrial cells and peripheral blood lymphocytes of the same patients and healthy control group.

These findings support a multistep pathway involving somatic genetic alterations in the development and/or progression of endometriosis and give evidence for the need of more detailed, further studies on the subject.

P04.142

Evaluation of mtDNA common deletion ($\Delta 4977$) in patients affected by esophageal SCC

S. Morovvati¹, S. Shari², M. Jeihounian³, S. Ghaffari⁴, Z. Ahmadi⁵;

¹Research Center of Molecular Biology, Baqiyatallah Medical Sciences University, Tehran, Islamic Republic of Iran, ²Faculty of Sciences, Tabriz University, Tabriz, Islamic Republic of Iran, ³Pathology Department, Baqiyatallah Hospital, Tehran, Islamic Republic of Iran, ⁴Medical Genetic Department, Tehran University, Tehran, Islamic Republic of Iran.

Background: Mitochondrial defects have long been suspected to play an important role in the development and progression of cancer. One of the most common mutations of mtDNA is a 4977 bp deletion that is called common deletion or $\Delta 4977$. The studies show that there is an association between this deletion and some cancer, aging and environmental factor such as alcohol and smoking. The aim of this study was to determine the frequency of $\Delta 4977$ in mtDNA of tumor tissue in patients affected by esophageal squamous cell carcinoma.

Methods: The presence of $\Delta 4977$ was investigated in mtDNA of 41 tumor tissues obtained from patients affected by esophageal squamous cell carcinoma, 10 adjacent normal tissues obtained from same patients and 10 blood sample of healthy individuals, using nested PCR standard protocol.

Result: $\Delta 4977$ were detected in 33 out of 41 (80.5%) of tumor tissue, 9 out of 10 (90%) of adjacent normal tissues of same patients and none of the blood sample of healthy persons.

Conclusion: Our results demonstrate that $\Delta 4977$ is prevalent in the esophageal squamous cell carcinoma and there is an association between this deletion and esophageal SCC ($p < 0.01$). This deletion may play an important role in the development and progression of esophageal.

P04.143

SDHD and SDHB: The clinical presentation, Phenotype and Care Pathway

C. A. Giblin, F. Laloo;

Regional Genetic Service and Medical Genetics Research Group, Manchester, United Kingdom.

Familial Paraganglioma are rare tumours of the head and neck; they are often bilateral and are known to be more aggressive than spontaneous forms. The parasympathetic paraganglia lie along the whole of the parasympathetic nerves, paraganglioma are usually found at the intersection of large vessels. It has been shown that early detection of paragangliomas (PGs) has reduced morbidity following surgical intervention.

Clinical genetics have worked closely with endocrinologists in the 3 teaching hospitals in Manchester over the past 5 years with families with hereditary endocrine conditions including MEN type 1 and 2 and also Familial Paraganglioma syndrome (FPS). Due to the increased recognition of the syndrome and the advent of molecular testing the referral for assessment of paraganglioma / pheochromocytoma has increased exponentially.

To date 19 families with proven FPS have attended the Manchester Regional Genetics service.

We will describe the clinical presentation of families with SDHB and SDHD mutations, in particular the difference in the phenotype, the impact on the families and the care pathways for individuals both affected and at risk.

P04.144

Recent studies into the FA/BRCA pathway

K. Neveling¹, R. Kalb¹, O. Levrar², S. D. Batish², S. Reid³, A. E. Sims⁴, T. T. Huang⁴, N. Rahman³, A. D. Auerbach², H. Hanenberg⁵, D. Schindler¹;

¹Department of Human Genetics, Wuerzburg, Germany, ²Laboratory for Human Genetics and Hematology, New York, NY, United States, ³Institute of Cancer Research, Surrey, United Kingdom, ⁴Department of Biochemistry, New York, NY, United States, ⁵Department of Pediatric Hematology and Oncology, Dueseldorf, Germany.

Fanconi anemia (FA) is a rare recessive disease with patients suffering from various congenital malformations, progressive bone marrow failure and high cancer susceptibility. Underlying FA are defects in any one of currently 13 known genes. Their products interact in the FA/BRCA pathway to mediate ICL repair involving NER, translesion synthesis and homologous recombination. This signalling path-

way consists of three major components: the nuclear core complex composed of at least eight FA proteins (group 1), which activates the "group 2" proteins FANCD2 and FANCI (ID complex). The ID complex is then targeted to chromatin and co-localizes with "effector" proteins such as BRCA2 or RAD51 (group 3). Recent progress in understanding the FA/BRCA network was achieved by the discoveries of the three FA genes *FANCI*, *FANCI* and *FANCN*. Besides FANCD2, FANCI is the second monoubiquitinated member of the FA/BRCA pathway. We show the biallelic mutations of four FA-I patients. The 5'-3' helicase BRIP1 and the BRCA2-binding protein PALB2 both act downstream of the monoubiquitination step and belong to the "group 3" proteins. We identified biallelic truncating *BRIP1* mutations in eleven FA patients. In an additional seven FA patients we found biallelic *PALB2* mutations, designating PALB2 as FANCN. Interestingly, investigations of *FANCI* and *FANCN* have shown that all known group 3 proteins (BRCA2/FANCD1, BRIP1/FANCI, PALB2/FANCN) are breast cancer susceptibility genes. This recent emergence of new FA genes not only facilitated further understanding of a major DNA repair pathway, but also makes connections to tumorigenesis and cellular aging (Neveling et al., *Z Gerontol Geriatr* 2007).

P04.145

Role of Helicobacter Pylori in gastric adenocarcinoma : Special emphasis on gender, androgen receptor and angiogenic factors

S. Arbabi Bidgoli¹, M. Djamali Zavarhe², M. Soleimani¹, S. Sajadi¹;

¹Faculty of Pharmacy, Islamic Azad University (IAU), Tehran, Islamic Republic of Iran, ²Department of Pathology, College of Medicine, Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran.

H. pylori increase the risk of gastric cancer which has higher incidence in men globally. Due to animal studies male gastric tissues respond more rapidly to *H. pylori* but the underlying roles of sex hormones and angiogenic factors remained unclear in both genders. We studied the roles of *H. pylori* on tissue levels of Androgen Receptor (AR), uPA, MMP9 and TP as three major angiogenic and prognostic markers in gastric cancer. Malignant and non malignant tissues of 72 gastric adenocarcinoma cases who underwent surgery from 2004-2007 were analyzed by immunohistochemical methods. Higher prevalence of *H. pylori* in males, lack of AR expression in normal cells of females and lower expression of AR in tumoral cells of females ($p=0.03$) were the first significant differences between two genders. *H. pylori* infection was evaluated as a relative risk factor of AR expression in males (OR=5) and females (OR=3) that means most of AR (+) tumors had history of *H. pylori* infection in their normal cells. Although females showed higher uPA expression ($p=0.007$) but *H. pylori* negative tumors showed higher risk of tumoral uPA (OR=1.13), MMP9 (OR=1.24) and TP expression (OR=1.12) in males. By recording the strong role of AR and *H. pylori* infection on the expression of tumoral uPA and other angiogenic factors in women (OR=11) we concluded that *H. pylori* plays inconsistent roles in two genders by inducing different unknown genes but AR plays similar roles in both genders by increasing the tissue levels of angiogenic factors.

P04.146

High frequency of MLH1 and MSH2 mutations among familial gastric cancer patients

A. S. Tsukanov¹, A. N. Loginova¹, N. I. Pospekhova¹, T. A. Muzaffarova¹, L. N. Lubchenko², M. P. Nikulin², A. V. Karpukhin¹;

¹Research Centre For Medical Genetics, Moscow, Russian Federation, ²Cancer Research Centre, Moscow, Russian Federation.

Mutations of CDH1 gene are associated with familial diffuse gastric cancer. MLH1 and MSH2 mutations are associated generally with hereditary non-polyposis colon cancer syndrome that may include gastric cancer. So MLH1 and MSH2 mutations predispose to gastric cancer. However a frequency of MLH1 and MSH2 mutations among patients with familial gastric cancer unselected on cancer type or familial history is unknown.

We investigated the sample of 30 patients with familial gastric cancer on mutations of CDH1, MLH1 and MSH2 genes. The structure of our sample was near to a distribution of different familial gastric cancer types in the population and includes 8 families with diffuse gastric cancer. There were 5 germline MLH1 and MSH2 mutations among 30 patients (16,6%). Mutations have been found in families with gastric cancer only as well as in the families with both gastric and colon can-

cer cases. There were no mutations in CDH1 gene. Thus, a frequency of MLH1/MSH2 mutations associated with familial gastric cancer is higher in comparison with the CDH1 gene mutations ($P=0,026$).

P04.147

Telomere function in giant cell tumors of bone

S. Gebre-Medhin¹, Y. Jin¹, T. Jonson¹, K. Broberg², N. Mandahl¹, F. Mertens¹;

¹Department of clinical genetics, University hospital, Lund, Sweden, ²Department of occupational medicine, University hospital, Lund, Sweden.

BACKGROUND: Giant cell tumor of bone (GCT) is a locally aggressive tumor accounting for 1/20 of all bone tumors. Morphologically, GCTs show osteoclast-like giant cells mixed with mononuclear putative neoplastic cells. Cytogenetically, GCTs often show telomeric associations (tas) paralleled by an otherwise normal karyotype. It remains to be established whether tas in GCT represent deregulation of *cis*-regulatory or *trans*-regulatory mechanisms at the telomere, or a combination thereof, or are caused by other yet unknown mechanisms.

METHODS: DNA was extracted from fresh frozen biopsies of 20 GCTs for telomere length analysis. From the same 20 cases, RNA was extracted for quantitative RT-PCR analysis concerning the expression levels of four genes (*TERT*, *TRF1*, *TRF2* and *POT1*) involved in telomere function. FISH analysis was performed to evaluate the frequency of telomere-negative chromosome ends.

RESULTS: No correlation between presence of clonal chromosome aberrations and telomere length in tumor cells could be detected. At FISH analysis there was a correlation between frequency of tas and number of telomere-negative chromosome ends. Expression of *TERT*, *TRF1*, *TRF2* and *POT1* was found in all tumors. Analysis regarding the correlation between expression levels of individual genes and cytogenetic and clinical features is ongoing.

CONCLUSION: In view of our preliminary data, it is unlikely that the high frequency of tas could be explained by altered expression levels of any of the investigated genes. However, it can not be ruled out that altered function at the protein level of *TERT*, *TRF1*, *TRF2* or *POT1* is involved in tas formation.

P04.148

Overexpression of wild-Type p53 suppresses Cathepsin B (CSTB) in glioblastoma cells

M. Heidari, M. Safari, O. Seyedi;

Tehran University/Medical Sciences, Tehran, Islamic Republic of Iran.

The tumor suppressor protein *p53* plays critical role in modulating cellular functions such as cell cycle arrest and apoptosis. Due to its function in growth inhibition as well as contribution of its mutated form in >50% of human tumors particularly a significant proportion of glioma cases, *p53* is considered a fundamental tumour suppressor gene. In order to investigate potential *p53* target gene(s), we employed overexpression of wild-type *p53* via recombinant adenovirus (Ad-GFP-*P53*) which encodes green fluorescent protein and *p53* separately, and cDNA AFLP approaches in U87 glioblastoma cells. In response to overexpression of wild-type *p53*, cDNA AFLP results revealed the suppression of *cathepsin B* (*CSTB*) gene which encodes a protease but not in infected cells with Ad-GFP which does not express *p53* and mock control. Semi-quantitative RT-PCR analysis confirmed the activation of *CTSB* gene in cells containing Ad-GFP and mock control however; its transcriptional activity was suppressed in infected cells with Ad-GFP-*P53*. In addition, computational analysis detected several potential *p53* DNA target sequences within introns of *CTSB* genes. Taken together our results suggested that *CTSB* gene might be directly regulated by *p53* protein as a transcription regulatory protein in glioblastoma.

P04.149

MGMT and p15 promotor methylation - prognostic parameters for TMZ chemotherapy response?

S. Wemmer¹, R. Ketter¹, M. Bettscheider¹, S. Al², K. Kammers³, J. Rahnenführer³, W. Steudel¹, S. Urbschat¹;

¹Department of Neurosurgery, Saarland University, Homburg, Germany, ²Institute of Immunology, National Public Health Laboratory, Luxembourg, Luxembourg, ³Department of Statistics, Technical University Dortmund, Dortmund, Germany.

Glioblastomas are the most frequent and malignant brain tumors in adults. Surgical cure is virtually impossible and despite of radiation and chemotherapy the clinical course is very poor. Epigenetic silencing of

MGMT has been associated with a better response to TMZ-chemotherapy. We were also able to show that TMZ increases the median survival time of patients with tumors harbouring deletions on 9p within the region for p15 and p16.

The aim of our current study was to investigate the methylation status of p15, p16, 14^{ARF} and MGMT and correlate these results with the clinical data.

DNA was isolated from fresh frozen GBM biopsies (n=27) and modified by sodium bisulfite. Promotor methylation of p15, p16, p14^{ARF} and MGMT was analyzed by MS-PCR. Only patients with a KPS >70, radiation and TMZ-chemotherapy after radical tumor resection were included.

We observed promotor hypermethylation of MGMT in 56%, and of p15 in 37% of the tumors, whereas hypermethylation of p16 and p14^{ARF} were rare.

Interestingly, hypermethylation of p15 emerged as a significant predictor of a shorter overall survival (16,9 vs. 23,8 months, $P=0,025$; Log-rank test), whereas MGMT hypermethylation had no effect on median overall survival (22,5 vs. 22,1 months, $P=0,49$; Log-rank test). In the presence of other clinically relevant factors (age, KPS, sex, MGMT), p15 hypermethylation remains the only significant predictor ($P=0,021$; Cox regression).

Although these results need to be confirmed in larger series, our retrospective study suggests that p15 hypermethylation can act as an additional prognostic factor for survival in glioblastomas.

P04.150

Genetic basis in Gorlin Syndrome

N. Alonso^{1,2}, **S. Ciria**^{1,2}, **J. Mendioroz**³, **M. L. Martínez-Frías**³, **P. Unamuno**⁴, **R. González-Sarmiento**^{1,2};

¹Unidad de Medicina Molecular-Departamento de Medicina. Universidad de Salamanca, Salamanca, Spain, ²Centro de Investigación del Cáncer, Salamanca, Spain, ³CIAC. Instituto de Salud Carlos III, Madrid, Spain, ⁴Servicio de Dermatología. Hospital Universitario de Salamanca, Salamanca, Spain.

Gorlin syndrome is an autosomal dominant disorder characterized by multiple developmental abnormalities and predisposition to suffer tumours. SHH receptor gene Patched1 has been directly related to Gorlin syndrome. It represses Smoothed, which transduces SHH signal to activate transcription factor GLI family.

We have analyzed PTCH1 gene in 64 unrelated patients with Gorlin syndrome, using PCR, heteroduplex and automatic sequencing. We found 25 different mutations, 10 of them are reported for the first time: IVS2(-2)delAGTTGGAGGACGAGTA; IVS5(-56) T>G; IVS6(+1)G>A; IVS11(+20)delGAG; g.417insA; g.726delCA; g.1421insG; p.W851X; p.P1050P and g.2517delC. We also searched for PTCH in 38 patients by MLPA. We found 9 patients with amplifications and 3 cases with deletions. Moreover, in cases without abnormalities in the PTCH1 locus, we have analyzed new candidate genes in the SHH pathway: We found 3 mutations (p.H262H; p.R509W; p.R531C) in GLI1 gene. The 2 missense mutations have been screened in 200 healthy controls. R509W was found in one healthy subject, while R531C was not. GLI2 analysis showed new intronic and silent mutations. We found 3 new missense mutations in CDON gene (p.I75V; p.E162K; p.A686V) and 2 new missense changes in BOC gene (p.E915H and p.Q959K). All of them have been screened in 50 healthy controls resulting as polymorphisms. Suppressor of Fused, EGFR and KCTD11 genes do not present pathogenic mutations in patients with Gorlin syndrome. In conclusion, 20.3% of patients with Gorlin syndrome present mutations in PTCH1 gene. We also conclude R531C mutation in GLI1 seems to be pathogenic and responsible for Gorlin syndrome.

P04.151

Glutathione S-transferase (GSTM1) polymorphism in Serbian head and neck tumour patients

J. M. Milasin, **B. Ilic**, **D. Jelovac**, **M. Pesic**, **A. Boro**, **V. Konstatinovic**, **M. Vukadinovic**;

School of Dentistry, Belgrade, Serbia.

Susceptibility to head and neck tumours in a particular individual may depend in part on the metabolic balance between Phase I enzymes, such as cytochromes P450 (CYPs), and Phase II enzymes, such as glutathione S-transferases (GSTs). Impaired detoxification of carcinogens found in tobacco smoke appears to increase the risk for tobacco associated cancers. Glutathione S-transferases (GSTs) are involved in

the metabolism of a wide range of carcinogenic chemicals. In humans, cytosol GSTs are divided into several classes, and polymorphisms of these enzymes are associated with variations in enzyme activity which in turn may affect the concentration of activated carcinogenic chemicals in the body. We have investigated the association between the polymorphism in one of the cytosolic GSTs gene (GSTM1) and susceptibility to oral squamous cell carcinoma (OSCC) and basal cell carcinoma (BCC) of the skin. For that purpose 45 SCC, 42 BCC and 40 control specimens have been subjected to PCR analysis of the GSTM1 gene. The frequency of GSTM1 null homozygous genotype was as follows: 48% in BCCs, 44% in SCCs and 20% in controls. The deletion of the GSTM1 gene was more frequent in SCC, than in controls ($p=0.017$) and the same was true for BCCs ($p=0.016$).

Although cytosolic glutathione S-transferase (GST) enzymes occupy a key position in biological detoxification processes, GSTM1-1 gene is deleted in a high percentage of the healthy human population, with major ethnic differences. We found a significant difference in genotype frequencies between the two tumour groups and healthy controls.

P04.152

Molecular Assessment of Chimerism after Allogeneic Hematopoietic Cell Transplantation: Clinical utility in monitoring cell lineage engraftment

R. Domiati-Saad;

Baylor University Medical Center, Dallas, TX, United States.

Allogeneic hematopoietic cell transplantation (HCT) is a treatment option for a variety of hematopoietic malignancies as well as nonmalignant diseases. Monitoring of chimerism by molecular techniques has been widely utilized in the routine clinical setting. Chimerism analysis is usually performed on DNA extracted from unfractionated blood or bone marrow samples. Analysis of lineage-specific leukocytes might be useful in predicting the clinical outcome and might play a critical role in the management of HCT patient. We have used an Analyte Specific Reagent on a Beckman capillary electrophoresis platform to assess the dynamics of chimerism within the individual leukocytes subsets in 83 hematopoietic cell transplant patients after myeloablative and nonmyeloablative regimens. Magnetic anti-CD3, anti-CD15 and anti-CD19 beads were used to capture T cells, myeloid cells and B cells, respectively, from peripheral blood and bone marrow samples prior to isolation of DNA. Twelve different polymorphic short tandem repeats (STR) loci were amplified in a single multiplex reaction. Chimerism analysis performed on specific cellular lineages was most useful in early detection of relapse than unfractionated whole blood analysis due the increased sensitivity in the enriched cell subpopulations. Determination of the level of donor T cells appears to be critical for successful engraftment and could predict graft rejection.

Hepatoblastoma: *in vivo* and *in vitro* models for the analysis of Wnt/ β -catenin and IGFs pathways

M. Salvatore¹, **A. Antoccia**², **G. Azzalin**³, **R. Devito**⁴, **A. Di Mas**⁵, **C. La Rocca**⁶, **S. Lorenzetti**⁶, **G. Macino**³, **A. Magrelli**³, **A. Mantovani**⁶, **F. Maranghi**⁶, **C. Tanzarella**², **S. Tai**⁶, **R. Tassinari**⁶, **F. Tosto**¹, **M. Viganotti**¹, **D. Taruscio**¹;

¹Istituto Superiore di Sanità, Dept. of Cell Biology and Neuroscience, Rome, Italy, ²University "Roma Tre", Rome, Italy, ³University "Sapienza", Rome, Italy, ⁴Bambino Gesù Hospital, Rome, Italy, ⁵Istituto Superiore di Sanità, Dept. of Food Safety and Veterinary Public Health, Rome, Italy.

Hepatoblastoma (HB) is the most important paediatric liver cancer (1% in children aged 6mo-3yr). HB is a multi-factorial condition including both genetic and environmental factors.

Environmental factors may contribute to HB pathogenesis; exposure to phthalates (i.e. diethyl-2-hexyl-phthalate-DEHP), present in PVC-based devices, are suggested as a risk factor in the highly susceptible subpopulation of premature and low-birth weight newborns. DEHP interacts with nuclear receptors, thus interfering with a number of signalling pathways.

To investigate the role of phthalate exposure, animal and cell line studies are in progress to characterize the effects of DEHP, in comparison with benzofuran, a HB inducer in aged mice. Furthermore, histological and immuno-histochemical valuation will be performed on frozen and paraffin-embedded human tissues from HB patients. To elucidate molecular mechanism(s) of HB pathogenesis we will focus on *i)* the role of Wnt/ β -catenin and IGF pathways, and *ii)* its possible early diagnostic

and/or prognostic markers, human cell lines and tissues from mice treated with DEHP and BF.

β -catenin and APC gene mutational analysis, modulation of gene expression analysis, genomic post-transcriptional regulation analysis through microRNA and protein expression patterns are in progress.

We assessed *i)* the *in vitro* cytotoxicity of DEHP and BF in the HB cell line HuH6, *ii)* the *in vitro* differential expression of two microRNAs, *iii)* the differential protein expression in some gene products of the Wnt/ β -catenin signalling pathway.

Influence of the focal adhesion protein leupaxin on invasion and metastasis in TRAMP prostate carcinomas

S. Beckemeyer¹, S. Schweyer², P. Burfeind¹, S. Kaulfuß¹;

¹Institute of Human Genetics, Göttingen, Germany, ²Department of Pathology, Göttingen, Germany.

In a recent study we showed that leupaxin expression could be detected in 21% of human prostate carcinomas (PCa). Down-regulation of leupaxin expression using RNAi resulted in apoptosis of more than 50% of androgen-dependent LNCaP PCa cells and in a significant reduction of invasiveness and migratory ability of androgen-independent PC-3 and DU145 PCa cells.

To analyse the role of leupaxin in progression and invasion of PCa *in vivo* we bred transgenic mice expressing prostate-specific leupaxin with TRAMP mice to generate double transgenic heterozygous mice. The transgenic adenocarcinoma of the mouse prostate (TRAMP) model develops, as a consequence of transgene SV40 T/t antigen expression, progressive prostate cancer that is invasive and capable of metastatic spread. Histopathological analysis showed that at the age of 22 weeks 91% of double heterozygous mice display a poorly differentiated tumor. In addition, 65% of these mice developed metastasis to the lymph nodes. In single heterozygous TRAMP mice only 50% showed a well differentiated tumor while none of them developed metastasis. Furthermore, our recent studies could demonstrate that the expression of the cell-cell-adhesion molecule catenin delta 1 (p120CTN) negatively correlated with the expression of leupaxin. No expression of p120CTN could be detected in progressive and invasive prostate tumors of double transgenic TRAMP/leupaxin mice. In conclusion, the results of our studies indicate that leupaxin expression enhances the progression of PCa towards a more aggressive and metastatic tumor and that the loss of p120ctn expression due to leupaxin overexpression represents one possible cause of the invasive behavior.

P04.155

Does nonsense-mediated RNA decay support TP53 haploinsufficiency as the cause of tumour development in Li-Fraumeni syndrome?

K. Prochazkova¹, M. Mrhalova², A. Augustinikova², D. Sumerauer³, A. Puchmajerova¹, R. Kodeř, Z. Sedlacek¹;

¹Department of Biology and Medical Genetics, Charles University - Second Medical School and University Hospital Motol, Prague, Czech Republic, ²Department of Pathology and Molecular Medicine, Charles University - Second Medical School and University Hospital Motol, Prague, Czech Republic, ³Department of Paediatric Haematology and Oncology, Charles University - Second Medical School and University Hospital Motol, Prague, Czech Republic.

Li-Fraumeni syndrome (LFS) is characterised by predisposition to a broad spectrum of cancers. The syndrome is associated with germline TP53 mutations, usually missense. The aberrant protein produced from the mutated TP53 allele is expected to cause tumour development. However, a possibility remains that haploinsufficiency of the normal TP53 allele could also be responsible for the phenotype. We analysed two LFS families with nonsense germline TP53 mutations. Nonsense-mediated RNA decay (NMD) eliminates transcripts with premature termination codons (PTC). In LFS families with nonsense mutations NMD could thus influence phenotype, because the removal of mutated transcripts would lead to the absence of the aberrant protein. TP53 alleles were analysed in normal tissues (lymphocytes, adrenal gland) and in tumours of both families on DNA and RNA levels. In normal tissues the transcripts of mutated alleles were eliminated, similar to some of the tumours. This may support the notion that TP53 haploinsufficiency,

and not the mutated protein, could be responsible for tumour development in LFS. However, in some tumours both types of transcripts (or only mutated transcripts) were present. This could reflect either differences in NMD between different tissues, or global inactivation of NMD in tumours. In quest to distinguish between these possibilities we tested expression of several genes (U2AF35, RPL3, TM1, PTB2, PTB1, ABCC4) with PTC-containing alternative transcripts, which should undergo NMD under physiological conditions. However, these analyses were inconclusive, mainly because the patterns of removal of some transcripts described in the literature could not be replicated. Supported by grants MSM0021620813 and MZ000064203.

Molecular basis of the Li-Fraumeni syndrome: an update from the French LFS families

G. Bougeard¹, R. Sesboué¹, S. Baert-Desurmont¹, S. Vasseur¹, C. Martin¹, L. Brugières², A. Chompret³, B. Bressac-de Paillerets⁴, D. Stoppa-Lyonnet⁵, C. Bonaïti-Pellié⁶, T. Frébourg¹, & The French LFS working group⁷;

¹Inserm U614 and Department of Genetics University hospital, Rouen, France, ²Department of Pediatric Oncology, Institut Gustave Roussy, Villejuif, France, ³Department of Medicine, Institut Gustave Roussy, Villejuif, France, ⁴Department of Genetics, Institut Gustave Roussy, Villejuif, France, ⁵Department of Genetics, Institut Curie, Paris, France, ⁶Inserm U535, Villejuif, France, ⁷-, -, France.

Extensive analysis of TP53, based on complete sequencing of the 11 exons and QMPSF analysis to detect genomic rearrangements, in 474 French families suggestive of LFS, as defined by the Chompret criteria, led us to identify in 82 families (17%) a germline alteration of TP53. Most of the alterations corresponded to missense mutations (67%) and we identified in 4 families (5%) genomic deletions. These results represent a definitive argument demonstrating that LFS results from TP53 haplo-deficiency. Nevertheless, this does not explain the remarkable TP53 germline mutation spectrum characterized by the predominance of missense mutations. The different tumour spectrum observed between TP53 wt/mt and wt/- mice led us to compare the mean ages of tumour onset between patients harbouring either TP53 missense mutations or other types of alterations. We found a significant difference, missense mutations being associated with a 9-year earlier tumour onset, confirming that missense mutations not only inactivate p53 but also have an additional oncogenic effect. The observation of a later age of tumour onset associated with null mutations led us to perform TP53 analysis in patients suggestive of LFS, but with a first tumour being diagnosed after 40 years of age and we had the surprise to identify germline TP53 mutations in such families. Germline alterations of TP53 that lead exclusively to loss of function are therefore associated with a later age of tumour onset and the presence of such mutations should be considered in atypical LFS families with tumours diagnosed after 40 years.

P04.157

Genetic analysis of tumor cell-free DNA in patients with lung cancer

E. Hirmerová¹, A. Panczak¹, V. Kebrdlová¹, A. Hořínek^{1,2}, A. Slováková³, A. Bortlová³, M. Mareš³, J. Homolka³, J. Štekrová¹, M. Kohoutová¹;

¹Inst Biol Med Genetics, 1st Med Fac, Charles Univ, Prague, Czech Republic, ²3rd Dept Medicine, 1st Med Fac, Charles Univ, Prague, Czech Republic, ³1st Dept TBC Resp Dis, 1st Med Fac, Charles Univ, Prague, Czech Republic.

Cell-free DNA (cfDNA) circulating in plasma was found in healthy individuals, but its concentration can increase in patient with cancer. In these, total plasmatic cfDNA is the mixture of DNA from normal and tumor cells. Genetic analysis of tumor cfDNA in plasma could be a non-invasive tool for early diagnostics and other study of pulmonary tumors. The concentration of total cfDNA was measured by quantitative real-time PCR. We analysed total cfDNA by using time-release PCR with primers for short tandem repeats (STR) located at tumor suppressor genes TP53, APC, and FHIT: diTP53, D5S346, D5S318, D5S299, D5S82, D3S1300, D3S1560. We have studied loss of heterozygosity (LOH) or microsatellite instability by using capillary electrophoresis. DNA from peripheral nucleated blood cells from the same patient served as a control. We have analysed cfDNA of patients with lung cancer (n = 33), with other pulmonary non-tumor diseases (17), and control group of healthy individuals (29). We have proved simultaneous presence of LOH in multiple STR loci in majority of lung cancer patients in contrast

to both control groups; therefore, the presence of multiple LOH in a sample of cfDNA could predicate lung cancer. LOH of D5S299 had the highest sensitivity, and D5S346 (both in the vicinity of APC gene) had the highest specificity of all used primers. In the lung cancer group, there were two patients where one of two alleles of D5S82 or D5S318, respectively, completely disappeared; this was not seen in any individual in both control groups.

M6P/IGF 2R is mutated in human endometrial adenocarcinomas and lung cancer

J. Pavelic;

Rudjer Boskovic Institute, Zagreb, Croatia.

The M6P/IGF 2 receptor has been shown to be mutated in a number of human cancers and to suppress cancer cell growth, indicating it as a tumor suppressor. The aim of this study was to determine if the M6P/IGF 2R is a target for mutation in human endometrial and lung cancers, tumors where perturbation of level of IGF's peptides seems to be implicated in neoplastic growth by autocrine/paracrine mechanisms. The tumors were analyzed for loss of heterozygosity (LOH). In those with LOH at one M6P/IGF 2R locus, the remaining allele was screened for mutation in ligand binding region by direct sequencing of PCR products. Among 10 informative adenocarcinoma samples 4 had LOH at M6P/IGF 2R locus. Of them, two samples harbored the mutation in the remaining allele as well. Of 46 endometrial adenocarcinomas 16 had LOH at one IGF 2R locus. The remaining allele in 8 of these samples contained also the mutation in the IGF 2 binding domain. As IGF 2R mediate activation of the growth inhibitor TGF- β and clearance of growth promoter IGF 2, whose down and up regulation are involved in malignant transformation, it is reasonable to believe that dysfunction of IGF 2R by mutation, could also contribute to tumor development.

Candidate gene screening for melanoma susceptibility

C. Badenas^{1,2}, J. Puig Butille², M. Harland³, Z. Ogbah⁴, R. Cervera², J. Malvey^{5,2}, M. Milà^{1,2}, T. Bishop³, S. Puig^{5,2};

¹Biochemical and Molecular Genetics Service, Hospital Clinic, Barcelona, Spain, ²Centro Investigación Biomédica en Enfermedades Raras (CIBERER), ISCIII, Barcelona, Spain, ³Genetic Epidemiology Division, St. James's University Hospital, Leeds, United Kingdom, ⁴Fundacio Clinic per a la Recerca Biomedica, Barcelona, Spain, ⁵Dermatology Department, Melanoma Unit, Hospital Clinic, Barcelona, Spain.

Melanoma is a multifactorial and polygenic disease. The main risk factors are number of nevi, familial predisposition and skin phototype related to ultraviolet radiation exposition. Ten percent of cases are detected in a familial setting, being then inherited as an autosomal dominant trait. Two high susceptibility genes have been implicated: *CDKN2A/p14ARF* and *CDK4*. Mutations are detected in 20-60% of families. Nevertheless, sporadic melanoma accounts for 90% of cases. The molecular basis of melanoma predisposition in such patients has not been well characterized.

Aim: i) to determine the real implication of *CDKN2A* and *CDK4* in sporadic melanoma and to evaluate the clinical differences between mutation carriers and non-carriers. ii) Genotyping of 265 SNPs (located in 38 genes) to look for low susceptibility genes implicated in melanoma and nevus predisposition.

696 melanoma patients have been screened for *CDKN2A* and *CDK4* mutations. SNP genotyping has been carried out in 260 melanoma patients using the GenomeLab SNPstream Genotyping System.

Sixteen sporadic Melanoma patients are *CDKN2A* mutation carriers (2.3%). Mutations are more frequent in multiple melanoma (MPM) than in single primary patients (SPM) (12.2% vs 1%, p=0.000). Age at onset is lower in mutation carriers than non-carriers (36.63 vs 50.63 y.o, p=0,001). A148T variant has been detected in 14.6% of patients with MPM and in 7.2 of SPM (p=0.02), suggesting that A148T could act as a low susceptibility allele to melanoma predisposition. Results of SNP genotyping are being analyzed and data will be discussed.

Germline mutations of CDKN2A in multiple and familial melanoma Brazilian kindreds

A. L. R. Avila^{1,2}, J. P. D. Neto³, G. Landmann², D. M. Carraro¹;

¹Laboratory of Genomic and Molecular Biology of Treatment and Investigation Center of Hospital A.C. Camargo, Sao Paulo, Brazil, ²Department of Pathology of Hospital A.C. Camargo, Sao Paulo, Brazil, ³Department of Cutaneous Oncology of Hospital A.C. Camargo, Sao Paulo, Brazil.

Background: Melanoma is hereditary in approximately 10% of cases. Familial melanoma is described as a family in which either 2 first-degree relatives are diagnosed with melanoma, or families with 3 melanoma patients (irrespective of degree of relationship). *CDKN2A* is the first identified and the most important melanoma susceptibility gene. The mutation spectrum in the Brazilian population is unknown.

Aim: Report our experience in screening of mutations of *CDKN2A* gene in Brazilian kindreds with clinical diagnosis of Familial Melanoma. This study is part of the Melanoma Genetics Consortium, (GenoMEL) in Latin America.

Methods: Patients with multiple or familial clustering of Melanoma were genetically tested. Families were identified applying the GenoMEL diagnosis criteria. Point mutations in *CDKN2A* gene were screened by denaturing high performance liquid chromatography (DHPLC) followed by direct sequencing.

Results: Genomic DNA of 12 patients with clinical diagnosis of familial melanoma was obtained from peripheral blood samples. *CDKN2A* gene was divided into 9 fragments covering the 4 exons with substantial parts of intron regions. Blood sample was collected from one adult healthy control that not presented mutation in *CDKN2A* gene and it is used as a reference for DHPLC experiment.

P04.161

MC1R polymorphisms, phenotype and UVB radiation sensitivity in melanoma risk patients

P. Aguilera¹, C. Carrera¹, G. Salerni¹, F. Cuellar¹, Z. Ogbah², J. A. Puig-Butille², M. Lecha³, J. Malvey¹, S. Puig¹;

¹Melanoma Unit, Barcelona, Spain, ²Melanoma Unit, Genetic Service, Barcelona, Spain, ³Photobiology and Phototherapy Unit, Dermatology Service, Barcelona, Spain.

Background: UV radiation (UVR) plays an important role in melanocytic tumours development. History of intense intermittent sun-exposure, phenotypic characteristics encoding melanocortin-1 receptor gene (*MC1R*) and the presence of multiple nevi are risk markers to develop malignant melanoma. Familial melanoma represents 10% of all melanomas and it is supposed that genetic burden in these patients plays a more important role than environmental factors.

Objective: to study in different melanoma-risk patient settings the association between phenotypic characteristics, number of nevi, UVR sensitivity and polymorphisms in *MC1R*.

Methods: two groups of high risk melanoma patients were studied (N=32):

Group 1: Dysplastic nevus syndrome (DNS) patients (N=23).

Group 2: Melanoma patients belonging to familial melanoma (N=9).

UVB sensitivity, phenotypic and genotypic characterization were performed.

Results: patients from DNS had a higher UV-B photosensitivity (reduced UV-B minimal erythema dose) compared with patients from familial melanoma group (mean 88mJ/cm² ± 26 vs 122 mJ/cm² ± 26; p<0,005). In both groups a high percentage of *MC1R* polymorphisms were detected (at least 1 polymorphism in 75% of patients in group 1 vs 78% in group 2). However, a different percentage of red hair type polymorphisms (RHP) was observed in the 2 groups (20% in group 1 vs 66% in group 2, p<0,01).

Conclusions: Patients affected by DNS presented high UV-B sensitivity, similar to North European populations or patients with photodermatoses. Similar percentage of *MC1R* polymorphisms were detected in our both samples, however, RHPs were strongly associated with familial melanoma, an unexpected result in our Mediterranean area.

HER-2/*neu* Amplification in Paraffin Embedded Tissue Sections of Meningioma Patients

O. Ozer¹, F. I. Sahin¹, F. Aydemir², O. Ozer³, Z. Yilmaz¹, N. Altinors²;

¹Baskent University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey, ²Baskent University Faculty of Medicine Department of Neurosurgery, Ankara, Turkey, ³Baskent University Faculty of Medicine Department of Pathology, Ankara, Turkey.

Meningiomas arise from the meningoendothelial cells and are one of the most common tumors of the central nervous system. About 90% of meningiomas are benign. They are histologically classified as benign (Grade1), atypical (Grade2) and anaplastic (Grade3) according to World Health Organization (WHO) 2007 classification of brain tumors, which also correlates with disease prognosis. Numerical and structural chromosome abnormalities have been reported in meningiomas. HER-2/*neu* gene is located on 17q11.2-q12 chromosome region and encodes an epidermal growth factor receptor. HER-2/*neu* gene amplification and/or over expression have been detected in some human cancers and studied most widely in breast carcinomas. Previous studies have shown the importance of HER-2/*neu* gene amplification on the prognosis of meningioma cases. In this study, we aimed to detect HER-2/*neu* gene copy number in archive materials of 55 meningioma patients by fluorescent *in situ* hybridization (FISH). The patients included in the study have been operated in the neurosurgery department of our hospital between 1999 and 2002. Tissue samples were classified histologically according to WHO 2007 guidelines. We found HER-2/*neu* gene amplification in 7 (12,73%) patients. Another 2 patients had only one signal for the HER2-*neu* region. We confirmed this finding by a second hybridization with chromosome 17p13.1 (p53) probe. According to our results, HER-2/*neu* amplification could be regarded as an additional genetic factor playing role in meningioma pathogenesis together with known chromosomal abnormalities.

P04.163

Methylenetetrahydrofolate reductase gene (MTHFR) 677C>T polymorphism in Serbian oral squamous cell carcinoma and basal cell carcinoma patients

R. Milicevic¹, B. Ilic², D. Jelovac³, J. Milosevic³, T. Damjanovic⁴, M. Vukadinovic², V. Konstantinovic², J. Milasir²;

¹Pediatric Clinic, Nis, Serbia, ²School of Dentistry, Belgrade, Serbia, ³School of Dentistry, Belgrade, Serbia, ⁴School of Medicine, Belgrade, Serbia.

Enzyme methylenetetrahydrofolate reductase (MTHFR) regulates intracellular folate metabolism through conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which in turn play an important role in cancerogenesis because of its involvement in DNA methylation and nucleotide synthesis. A common genetic polymorphism in the MTHFR gene - C677T is associated with thermolability and decreased enzyme activity. Reduced MTHFR activity may decrease the methylation of homocysteine to methionine, resulting in DNA hypomethylation. The contribution of MTHFR polymorphisms to the susceptibility to various types of cancer is controversial. We investigated a possible association of MTHFR polymorphisms 677C>T and increased risk for oral squamous cell carcinoma (OSCCs) and basal cell carcinoma (BCCs).

PCR- RFLP analysis of the MTHFR gene was performed on DNA obtained from 40 SCC and 35 BCC patients and 400 healthy individuals. The following genotype frequencies were found: 25% (CC), 67.5% (CT) and 7.5% (TT) in squamous cell carcinomas; 34.3% (CC), 57.2% (CT) and 8.5% (TT) in basal cell carcinoma patients. Genotypes in controls were: 40% (CC), 46 (CT)% and 14% (TT). A statistically significant difference ($p < 0.05$) was found in the genotype frequencies between the two tumour groups and the control.

P04.164

MTR A2756G polymorphism confer a risk for colorectal cancer in Romanian patients?

M. L. TOMA, D. Cimponeriu, P. Apostol, M. Stavarachi, M. Cojocar, L. Belusica, I. Radu, D. Usurelu, L. Gavrilă;

Institute of genetics Bucharest, Bucharest, Romania.

Introduction: Epidemiologic and mechanistic evidences suggest that folate is involved in colorectal neoplasia. MTR, an essential enzyme in folate metabolism, catalyzes the remethylation of homocysteine to methionine. The A2756G polymorphism was implicated in modification

of plasma homocysteine level.

Aim: The goal of this study was to analyses the association between MTR A2756G polymorphism and colorectal cancer in Romanian patients.

Means & methods: Blood samples were obtained, after informed consent, from individuals with colorectal cancer (M:F=53:40), and healthy persons (M:F=55:45). Genomic DNA was extracted from peripheral blood leucocytes using commercial kits and the MTR A2756G polymorphism was assessed by PCR RFLP.

χ^2 test has been used for statistical analysis ($p < 0.05$ was considered significant).

Results: This polymorphism respect Hardy-Weinberg equilibrium in both case and control groups ($\chi^2 = 0,195$, $p = 0,658$; $\chi^2 = 0,541$, $p = 0,461$).

The procentual distribution of A2756G AA:AG:GG in patients and controls was 63,4:33,4:3,2 and 67: 31:2 respectively. In our study, the frequency of genotype GG was appropriate that in other European series (approximately 3 percent).

For MTR polymorphism, distribution of genotype frequencies and allele frequencies don't differed significantly between cancer patients and control ($X^2 = 0,269$, $p = 0,603$; respectively $X^2 = 0,364$, $p = 0,54$).

Conclusions: In this study, we find no association between MTR A2756G polymorphism and colorectal cancer Romanian patients. Thus, this potential link must be evaluated between in much powerful studies.

P04.165

Paraganglioma in a patient with multiple endocrine neoplasia type 1: Preservation of the *MEN1* gene heterozygosity and detection of the somatic point mutation in the wild-type allele

A. Sakurai¹, A. Murakami², K. Sano¹, S. Uchino², Y. Fukushima¹;

¹Shinshu University School of Medicine, Matsumoto, Japan, ²Noguchi Thyroid Clinic, Beppu, Japan.

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominantly inherited disorder characterized by hyperplastic and neoplastic disorders in endocrine organs such as parathyroid, anterior pituitary and endocrine pancreas. Development of pheochromocytoma in patients with MEN1 is very rare and there have been only a handful of case reports. Paraganglioma in MEN1 has not been reported in English literature. Involvement of *MEN1* gene in pheochromocytoma/paraganglioma has not been examined and molecular mechanism of development of such tumors remains elusive. Here we report a patient with MEN1 who developed retroperitoneal paraganglioma. The patient, a 63-year-old Japanese woman, was referred to us because of retroperitoneal tumor. She had been diagnosed as having MEN1 (primary hyperparathyroidism and pituitary tumor) and genetic testing had revealed a heterozygous mutation in exon 10 of the *MEN1* gene (c1546-1547insC). The tumor was surgically resected and that, pathologically diagnosed as paraganglioma, was applied to genetic analysis. In addition to the germline mutation in exon 10, a somatic frameshift mutation (c1217delA) was identified in exon 9 of the *MEN1* gene in DNA prepared from the tumor; this mutation was not seen in DNA prepared from peripheral mononuclear cells. Allele specific amplification and subsequent sequence analysis revealed that these two mutations exist on the different allele, indicating both alleles are functionally lost in tumor cells. This was further confirmed by immunostaining study. This is the first report which demonstrates causal relationship between inactivation of the *MEN1* gene and development of paraganglioma.

P04.166

High frequency of the heterozygous p.1171V mutation of the NBS1 gene in larynx cancer and multiple primary tumors

I. M. Ziolkowska¹, M. Maria Mosor¹, M. Wierzbicka², M. Rydzanicz¹, M. Pernak-Schwarz¹, J. Nowak¹;

¹Institute of Human Genetics, Poznań, Poland, ²K. Marcinkowski University of Medical Sciences, Poznań, Poland.

The higher incidence of multiple primary tumors (MPT) is a significant problem in head and neck tumor treatment. Recent studies suggest that carriers of heterozygous mutations in the NBS1 gene have an increased risk of malignant tumor development. The aim of our research was to assess the frequency of NBS1 mutations in patients with larynx cancer only (LC) and with MPT. The MPT group consisted of patients with one cancer localized in the larynx (primary or second)

and another at another site. DNA from 175 patients with LC and 104 patients with MPT was analyzed using the single-strand conformation polymorphism (PCR-SSCP) method and direct sequencing. We found 9 carriers of the p.I171V mutation among these 279 cancer patients and only 1 carrier among 500 population controls (0.2%). Four carriers of the p.I171V mutation were detected among 175 LC patients (2.3%) and 5 among 104 patients with MPT (4.8%). The frequencies of the p.I171V mutation carriers in LC and MPT patients were significantly higher than in controls (OR=11.7, CI 1.3-105.2, p=0.0175 and OR=25.2, CI 2.9-218.2, p=0.0007; respectively). In 1 individual with LC, a novel molecular variant c.1222A>G (p.K408E) was identified. No carriers of p.R215W or 657del5 NBS1 mutations were found in the present study. These findings imply that heterozygous carriers of the p.I171V mutation are prone to the development of larynx cancer and may, in addition, display an increased risk of second tumors at other sites.

P04.167

CpG island methylator phenotype in primary neuroblastomas is associated with poor survival

E. Grau, S. Oltra, F. Martínez, C. Orellana, A. Canete, M. Hernandez, V. Castel, Hospital Universitario La Fe, Valencia, Spain.

Hypermethylation of CpG islands (CGIs) is an epigenetic phenomenon that contributes to carcinogenesis. We have determined the methylation pattern of several genes involved in distinct biological pathways in neuroblastoma (NB), one of the most common pediatric solid tumors. 82 primary NB tumors were studied by methylation specific PCR (MSP) for twenty genes. Three of them were excluded (MGMT, SYK and GSTP) because showed no evidence of promoter hypermethylation. CpG island methylator phenotype (CIMP) status was defined as hypermethylation of more than 50% from the 17 genes analyzed. We found that some genes as TMS1, CASP8, THBS1, CCND2, RASSF1A, BLU, EMP3 or DR4 are more frequently methylated in NB cases with a poor prognosis. CIMP status was significantly associated with disease stage (P=0,0002), risk group (P=0,00004), age at diagnosis (P=0,0007), N-myc amplification (P=0,005) and 1p deletion (P=0,003). By a Kaplan-Meier analysis, the 27 CIMP+ cases showed significantly poorer disease-free survival (DFS) (P=0,0084) and overall survival (OS) (P=0,0062) than the 55 CIMP- cases. However, Cox regression analysis failed to demonstrate that CIMP was an independent factor to the remaining variables, except for the clinical stage. We conclude that CIMP status could strongly influence on OS in NB tumors, being a better prognosis factor than the other high-risk variables except for the disease stage. Thus the presence of CIMP may lead to a poor prognosis by induction of CGIs methylation.

P04.168

DCX expression in bone marrow after induction correlates with reduced survival in high-risk neuroblastoma patients

S. Oltra, E. Grau, C. Orellana, F. Martínez, C. Fernández, A. Cañete, V. Castel, Hospital Universitario La Fe, Valencia, Spain.

Background: Detection of minimal residual disease (MRD) in bone marrow (BM) and peripheral blood (PB) is crucial for follow-up in high-risk neuroblastoma patients and might impact on survival.

Methods: Relative quantification of DCX and TH was studied by quantitative reverse transcriptase polymerase chain reaction (QRT-PCR) using Assays on Demand from Applied Biosystems (Oltra et al., 2005, *Diagn Mol Pathol.* 14: 53-57). We studied DCX and TH expression in 87 high risk neuroblastoma patients (78 stage 4 and 9 stage 3) treated according cooperative national protocols in Spain.

Results: The frequency of DCX and TH detection at diagnosis in BM was 75,3% and 76,7%. After induction chemotherapy the frequency of both markers decreased to 37,8% and 28,9%. In PB samples the frequency of DCX and TH was 58,3% and 50%, respectively, at diagnosis and 12,5% and 15,6% after induction.

Only the DCX expression in BM after induction chemotherapy showed a statistically significant predictive value. Five years overall survival (OS) and event-free survival (EFS) were significantly reduced in patients with DCX expression in BM after induction (p<0,002).

Conclusions: DCX expression in BM after induction chemotherapy showed a statistically significant impact on OS and EFS in high risk neuroblastoma patients. In contrast, DCX expression in BM or PB at diagnosis did not show a disease prognostic value. TH expression did

not show prognostic value in PB and BM at these treatment points.

P04.169

Long-term persistence of clonal TCR and/or BCR gene rearrangements in patients with Nijmegen breakage syndrome

K. H. Chrzanowska¹, H. Gregorek¹, K. Dzierżanowska-Fangrat¹, M. Nowak¹, A. W. Langerak²;

¹The Children's Memorial Health Institute, Warsaw, Poland, ²Erasmus MC, University Medical Center, Rotterdam, The Netherlands.

Background: Nijmegen breakage syndrome (NBS), caused by mutations in the *NBN* gene, is an autosomal recessive chromosomal instability syndrome associated with high cancer risk. The NBN protein is a component of the MRE11/RAD50/NBN complex involved in processing DNA double-strand breaks. It is therefore particularly important to study abnormal recombination events in NBS patients, given the inherited predisposition to develop lymphomas and leukemias.

Objectives: The aim of this study was a longitudinal analysis of T-cell receptor (TCR) and immunoglobulin/B-cell receptor (BCR) gene rearrangements in peripheral blood mononuclear cells (PBMC) in NBS patients, and their correlation with eventual lymphoma development. **Patients and methods:** A total of 50 NBS patients (all carrying the 657del5 mutation on both alleles of the *NBN* gene) were periodically monitored for clonality of TCR and BCR gene rearrangements in PBMC by multiplex PCR-heteroduplex analysis. The same method was also used for molecular analysis of lymphoma tissues. Identity of clonal blood and/or tissue rearrangements was determined by direct sequencing.

Results: Seventeen NBS patients showed long-lasting clonal TCR and/or BCR rearrangements in PBMC, and identical clones persisted up to 4 years. Seven of these patients developed lymphomas, and in some of them clonal blood rearrangements preceded diagnosis of lymphoma with identical clonality by 2 years.

Conclusions: NBS patients often show clonal TCR and/or BCR gene rearrangements in PBMC. However, the clinical significance of this phenomenon requires further investigation.

This study was supported by grant No 2 P05A 118 29 from the Polish Ministry of Science and Higher Education.

Analysis of the 3'-UTR region of COX-2 gene in NMSC patients after transplantation

R. Brentonigo¹, M. Gomez Lira¹, G. Tessar², S. Mazzola¹, L. Naldi², G. Remuzzi³, L. Boschiero⁵, A. Forn⁶, C. Rigiu⁷, S. Piaserico⁸, G. Girolomoni⁹, A. Turco¹;

¹Departments of Mother and Child, Section of Biology and Genetics, University of Verona, Verona, Italy, ²Department of Biomedical and Surgical Sciences, Section of Dermatology and Venereal Diseases, University of Verona, Verona, Italy, ³Centro Studi Gruppo Italiano di Studi Epidemiologici in Dermatologia, Bergamo, Italy, ⁴Department of Nephrology, Ospedali Riuniti di Bergamo, Bergamo, Italy, ⁵Kidney Transplantation Center, University of Verona, Verona, Italy, ⁶Division of Cardiac Surgery, University of Verona, Verona, Verona, Italy, ⁷Department of Nephrology, University of Verona, Verona, Italy, ⁸Department of Dermatology, University of Padua, Padua, Italy.

Near up to 40% of transplant recipients experience non-melanoma skin cancer (NMSC). Various risk factors, including immunosuppressive treatment, infection with papilloma virus, and exposure to UV radiation contribute to the enhanced cutaneous carcinogenesis in this patients. UV radiation can promote carcinogenesis by its ability to induce formation of prostaglandins, which may then function as tumor promoters, or may enhance initiation because of their ability to act as oxidants. Cyclooxygenase-2 (COX-2) is the key enzyme in the production of prostaglandins. High levels of COX-2 has been reported in various epithelial cancer, including those of the skin. Expression of COX-2 are in part regulated by the 3'UTR which modulates the stability of the transcript. One polymorphism (8473T>C) in the 3' UTR region has been reported in association with breast and lung cancer risks.

This study was designed to investigate if polymorphism 8473T>C or other polymorphisms in the 3'UTR region can contribute to NMSC after transplantation. Genotyping of polymorphism 8473T>C in 150 patients and 180 controls demonstrated no significant differences, also stratifying by kind of tumor (p value>0.2). Moreover no appreciable difference were noted in functional analysis to test influence of C or T variant. Screening for new polymorphisms was performed in 30 NMSC and 30

controls, by heteroduplex analysis. We analyzed sequences containing binding sites for stabilization elements and putative sequences of microRNAs binding sites. One polymorphism was found (rs4648290) which is located in a microRNA binding site. Genotyping of this variant is ongoing and functional effects will be analyzed.

Copy Number Alterations of *HER2* and *EGFR* Genes in Non-Small Cell Lung Cancer (NSCLC)

M. Ozdemir¹, P. Uludag¹, A. Uludag¹, B. Durak¹, N. Buyukpinarbasil², E. Tepeli³, S. Artan¹;

¹Eskisehir Osmangazi University, Medical Faculty, Department of Medical Genetics, Eskisehir, Turkey, ²Istanbul Yedikule Chest Disease Hospital, Department of Pathology, Istanbul, Turkey.

PURPOSE: Epidermal Growth Factor Receptor (EGFR) and HER2 are the members of EGFR family. They are transmembrane proteins with tyrosine kinase activity. EGFR and HER2 amplification and/or overexpression have been reported in several types of cancer. The study was performed to correlate copy number variations of HER2 and EGFR genes with histopathological features of NSCLC samples. **MATERIALS-METHODS:** Copy number status of the genes was assessed using FISH in 100 archival materials. **RESULTS:** 75 % of the samples successfully analysed by FISH. HER2 amplification was only detected in high grade tumors whereas EGFR amplification was significantly seen in high grade (16/75) tumors but also less frequently detected in low-grade samples. Both of the gene amplifications were detected in histologically proved squamous cell and adenocarcinoma tumors in about equal frequencies. Amplification of EGFR also correlated with smoking. **CONCLUSION:** The amplification of EGFR and HER2 in NSCLC patients may play important role in the pathogenesis of lung carcinoma.

P04.172

Studying Amplification Status of *HER2/NEU* and *EGFR* Oncogenes in Non-Small Cell Lung Cancers by Real-Time PCR Technique

M. H. Muslumanoglu¹, D. Uzun¹, O. Cilingir¹, M. Ozdemir¹, N. Buyukpinarbasil², E. Tepeli³, S. Artan¹;

¹Eskisehir Osmangazi University, Medical Faculty, Department of Medical Genetics, Eskisehir, Turkey, ²Istanbul Yedikule Chest Disease Hospital, Department of Pathology, Istanbul, Turkey.

AIM: Family members of Epidermal growth factor receptor, EGFR and Her2/neu oncogenes, code transmembran proteins which exhibit tyrosine kinase activity. The family members play major roles in signal transducing pathways. Amplification /overexpression of these protooncogenes have been identified in various cancer types including NSCLC. The study was performed to correlate copy number variations of HER2 and EGFR genes with histopathological features of NSCLC samples, smoking status and family histories of the cases. **MATERIALS-METHODS:** DNAs were extracted from formalin-fixed, paraffin-embedded sections obtained from 100 patients with NSCLC and amplification levels of HER2 and EGFR were assessed by real-time PCR. **RESULTS:** The HER2/neu and EGFR gene amplifications were measured quantitatively in 18% and 26% of tumors, respectively. HER2 and EGFR amplifications were significantly detected in high grade tumors and HER2 gene amplification was only seen in tumors of smoking cases. Amplification of EGFR also correlated with smoking. **CONCLUSION:** The amplification of EGFR and HER2 in NSCLC patients may play important role in the pathogenesis of lung carcinoma. Real-time PCR is easy to operate and deserves widespread application for detection of HER2 and EGFR gene copy number variations.

P04.173

Participation of OCT3/4 and β -Catenin during dysgenetic gonadal malignant transformation

G. Queipo, I. Palma, S. Kofman-Alfaro;

Hospital General de Mexico-Facultad de Medicina Universidad Nacional Autónoma de México SDEIPTID05-1, Mexico City, Mexico.

Gonadoblastoma (GB) is an *in situ* germ cell tumor, 30% of patients GB develops in dysgerminoma/seminoma. GB almost exclusively affects a subset of patients with Disorders of sex development (DSD), in which tumor development is associated with the presence of an extra Y-chromosome (either normal or abnormal), or with molecular

evidence for Y-derived sequences. GB in dysgenetic gonads and its counterpart, carcinoma *in situ* (CIS) in well-differentiated testicular tissue, may be the earliest stages in the development of malignant germ cell tumors (GCTs). Although the mechanisms that trigger neoplastic progression are still unknown, several pathways have been proposed. Abnormal OCT3/4 expression is the most robust risk factor for malignant transformation. This transcription factor regulates the pluripotency of embryonic stem cells and is necessary for the survival and migration of primordial germ cells and has been associated with the germ cell neoplastic process. OCT3/4 and β -catenin might both be involved in the same oncogenic pathway, both genes are master regulators of cell differentiation and overexpression of either gene may result in cancer development. The mechanism by which β -catenin participates in GB transformation is not completely clear. In an effort to elucidate the participation of β -catenin and E-cadherin, as well as OCT3/4, in the GB oncogenic pathways, we analyzed those molecules in seven patients with mixed gonadal dysgenesis and GB. Proposing that the proliferation of immature germ cells in GB may be due to an interaction between OCT3/4 and accumulated β -catenin in the nuclei of the immature germ cells.

An inherited mitochondrial DNA disruptive mutation preferentially selected in oncocytic tumor cells

G. Gasparre¹, L. F. Pennisi², L. Iommarini², A. M. Porcellini², M. Lang¹, G. Ferrari¹, I. Kurelac¹, A. Ghelli², E. Bonora¹, C. Ceccarelli², M. Rugolo³, N. Salfi², G. Romeo¹, V. Carelli²;

¹Unità Operativa Genetica Medica, Bologna, Italy, ²Dipartimento di Scienze Neurologiche - University of Bologna, Bologna, Italy, ³Dipartimento di Biologia Evoluzionistica Sperimentale, University of Bologna, Bologna, Italy, ⁴Dip. Sc. Chirurgiche Specialistiche ed Anestesiologiche-Policlinico Sant'Orsola Malpighi, Bologna, Italy, ⁵U.O. Anatomia e Istologia Patologica-Policlinico Sant'Orsola Malpighi, Bologna, Italy.

Oncocytic tumors are characterized by cells with aberrant mitochondrial hyperplasia. Somatic mutations in mitochondrial genome (mtDNA) affecting respiratory chain complex I subunits have been previously reported in this type of neoplasia. We report the first case of inherited frameshift complex I mutation in the ND5 gene associated with a specific tumor phenotype.

The mtDNA was sequenced in microdissected areas from an oncocytic nasopharynx tumor and in different non-neoplastic tissues from the patient and two of his siblings in order to confirm inheritance of the mutation. Immunohistochemical analysis for complex I subunits was performed on tumor tissue to study protein expression and results confirmed by western blot. Quantification of the mutation load in mitochondria and of the total mtDNA copy number in the tissues analyzed for the patient and his siblings was performed. The oncocytoma harbors a frameshift homoplasmic (all mtDNA copies mutated) ND5 mutation which correlated with lack of expression of another mitochondrially coded complex I subunit (ND6). Conversely, oncocytic cells expressing ND6 show heteroplasmy for the ND5 mutation and a de novo homoplasmic pathogenic ND1 mutation. Such cells also present a lower degree of mitochondrial hyperplasia as shown by mtDNA copy number. The ND5 mutation is heteroplasmic in all normal tissues of the patient and his siblings indicating a shift to homoplasmy only in the tumor.

Since shift to homoplasmy of ND1 and ND5 mutations occurs exclusively in tumor cells, we conclude that complex I mutations may have a selective advantage and accompany oncocytic transformation.

Functional gene polymorphisms of 16 factors that influence risk for oral cancer: A multivariate regression analysis of their effect

C. Yapijakis¹, Z. Serefoglou¹, D. Avgoustidis¹, A. Vylliotis¹, E. Critselis¹, S. Spyridonidou¹, E. Nkenke², F. W. Neukam², E. Patsouris¹, E. Patsouris¹, E. Vairaktaris¹;

¹University of Athens Medical School, Athens, Greece, ²University of Erlangen Medical School, Erlangen, Germany.

Introduction: Functional DNA polymorphisms in genes of factors related to angiogenesis, inflammation and thrombosis have been associated with increased predisposition for oral squamous cell carcinoma (OSCC) by genetic association studies performed by our group and others. This study examined the possible combinatory effect of 16

such gene polymorphisms in predicting the occurrence of OSCC in Europeans.

Methods: 330 Greeks and Germans were studied, consisting of 162 OSCC cases and 168 healthy controls of comparable age, gender, and ethnicity. A series of multivariate logistic regression models, adjusted for age and gender, was constructed in order to assess the contribution of homozygous or heterozygous variant polymorphic genotypes upon overall, early and advanced stages of OSCC development. The studied polymorphisms included *IL1b*(+3953C/T), *IL-4*(-590C/T), *IL-6*(-174G/C), *IL-8*(-251A/T), *IL-10*(-1082A/G), *TNF-α*(-308G/A) and *TNF-β*(+252G/A), *MMP-1*(-1607 1G/2G), *MMP-3*(-1171 5A/6A), *MMP-9*(-1562C/T), *TIMP-2*(-418C/G), *VEGF*(+936C/T), *GPI-α*(+807C/T), *PAI-1*(4G/5G), *ACE*(intron 16D/I) and *TAF*(+325C/T).

Results: The contribution of *TNF-α* and *IL-6* polymorphisms was consistent and robust in almost all models constructed. Furthermore, when the mode of inheritance of each variant allele was taken into account in a multivariate logistic regression model, five polymorphisms emerged as primary predictors for all OSCC stages: *TIMP-2*(OR=26.33; 95%CI=12.39-55.95), *TNF-α*(OR=15.27; 95%CI=7.30-31.96), *IL-6*(OR=8.33; 95%CI=3.95-17.58), *IL-8*(OR=3.54; 95%CI=1.69-7.43) and *IL-10*(OR=2.65; 95%CI=1.28-5.46).

Conclusions: The highly significant contribution of 5 out of 16 studied factors in the occurrence of OSCC was revealed. Based on these findings and previous reports, possible interactions of the implicated factors leading to OSCC development, as well as an algorithm of risk estimation will be discussed.

P04.176

P53 and bcl-2 in the pathogenesis of oral squamous cell carcinoma

B. Popovic¹, I. Novakovic², B. Jekic², D. Jelovac¹, B. Ilic¹, V. Konstantinovic¹, J. Milasin¹;

¹School of Dentistry, Belgrade, Serbia, ²School of Medicine, Belgrade, Serbia.

The imbalance between the rate of cell proliferation and apoptosis in tumour tissue is due to numerous genetic and epigenetic factors. Two of the most important cancer genes, contributing to pathogenesis of oral squamous cell carcinoma (OSCC) are p53 and bcl-2. Mutated p53 gene is associated with the inability of the cell to repair DNA lesions or to induce apoptosis. Consequently, increased expression of the antiapoptotic marker bcl-2 in tumour cells is expected. Based on this regulation pathway, in the present study we analyzed the association between the presence of mutated p53 gene and expression of bcl-2 protein. Mutational analysis of exons 5-8 of p53 was done by SSCP followed by sequencing. Expression of bcl-2 was analyzed by immunohistochemistry. According to results of mutational and immunohistochemical analyses, performed on 28 specimens of OSCCs, 60% of samples showed simultaneously the presence of mutated p53 gene and expressed bcl-2 oncoprotein. Independently of p53 status, the expression of bcl-2 was detected in 68% cases. Both analyzed markers showed an increased rate of mutation/expression in tumors of higher clinical stages.

The positive association between changes in p53 and bcl-2, point at deep deregulation of apoptosis which is in agreement with the increased proliferative potential of OSCCs.

Routine analysis of these markers in tumour samples obtained after surgery might be valuable in the assessment of tumour aggressiveness.

P04.177

Intratumoral patterns of clonal evolution in Ductal Pancreatic Adenocarcinoma by multicolour interphase fluorescence *in situ* hybridization (iFISH).

M. L. Gutiérrez¹, L. Muñoz-Bellvis², J. M. Sayagues¹, O. Bengochea³, M. M. Abad³, A. Orfao¹;

¹Servicio General de Citometría, Centro de Investigación del Cáncer, Universidad de Salamanca, Salamanca, Spain, ²Unidad de Cirugía Hepática, Biliar y Pancreática, Hospital Universitario de Salamanca, Salamanca, Spain, ³Departamento de Anatomía Patológica, Hospital Universitario de Salamanca, Salamanca, Spain.

Introduction. Pancreatic ductal adenocarcinoma (PDAC) is a fatal disease with an almost uniform 5-year mortality rates. Understanding the molecular mechanisms involved in tumor development and progression are a prerequisite to improve early diagnosis and therapy. How-

ever no study has been reported so far in which the clonal evolution of tumor cells has been systematically analyzed at the intratumoral cell level.

Materials and methods. Chromosomal abnormalities for 46 chromosomal regions distributed across the most frequently altered chromosomes were studied in 29 PDAC patients using multicolor interphase FISH techniques.

Results. All cases displayed numerical/structural abnormalities for at least one of the 24 chromosomes analyzed. Chromosome 17 was the most frequently altered (27/29 cases), followed by chromosomes 18 (23/29), 8 and 9 (24/29), and chromosome Y (17/21); in contrast, chromosome 22 was the less frequently altered. Of note, monosomy 9/9p was positively associated with 17p and 18q deletions. Overall, only 3 (7%) of the 29 cases analyzed had a single tumor cell clone while most cases (93%) displayed two or more clones. The most frequent ancestral tumor cell clones were characterized by deletion of 9p, 17p, 18q and Y nulismy.

Conclusions. Our results show that, as in other tumors, progression of PDAC is a multi-step process in which neoplastic cells develop genome-wide instability evidenced at the intratumoral cell level leading to the emergence of multiple clonal populations with different chromosome abnormalities within the same tumor. This study also provides evidence about different patterns of intratumoral clonal evolution which had not been previously reported.

P04.178

Genetic variation and haplotype structures of the gene encoding human thymidylate synthase, a pharmacogenetic marker in fluoropyrimidine-treated cancer patients

M. Baiget, L. Paré, E. del Rio, P. Gallano, E. Tizzano, J. Salazar;

Genetics. Hospital Sant Pau, Barcelona, Spain.

Thymidylate synthase (TS) activity is an important determinant of response to chemotherapy with fluoropyrimidine prodrugs and its expression is largely determined by polymorphic features in the 5' UTR region of the TS gene that can modify the number of the functional USF protein binding sites. DNA was extracted from peripheral blood from 587 caucasian cancer patients. Genotyping was performed by PCR amplification of the repeat region followed by automated sequencing

Results:

# Functional USF binding sites	Genotypes*	Colorectal cancer N (%)	Breast cancer N (%)
1	2RGC/2RCC	0 (0.0)	1 (0.6)
	2RCC/3RGCC	3 (0.7)	0 (0.0)
2	2RGC/2RGC	75 (17.8)	40 (24.1)
	3RGCC/3RGCC	44 (10.6)	13 (7.8)
	2RGC/3RGCC	103 (24.5)	45 (27.1)
	2RCC/3RGGC	2 (0.5)	0 (0.0)
	2RGC/3RGCC+ins6pb	4 (1.0)	1 (0.6)
	3RGCC/3RGCC+ins6bp	3 (0.7)	2 (1.2)
3	3RGGC/3RGCC	75 (17.8)	25 (15.1)
	2RGC/3RGGC	73 (17.3)	27 (16.3)
	2RGC+ins4bp/3RGGC	1 (0.2)	0 (0.0)
	3RGGC/3RGCC+ins6bp	3 (0.7)	0 (0.0)
4	3RGGC/3RGGC	32 (7.6)	12 (7.2)
	2RGG/3RGGC	1 (0.2)	0 (0.0)
	2RGC/4RGGGC	1 (0.2)	0 (0.0)
	3RGGC/4RGGCC	1 (0.2)	0 (0.0)
		Total N: 421	Total N: 166

In bold: novel allele. *According to Lincz et al. Int. J. Cancer 2007; 120:1930-34.

We define the genotypes of the 5'UTR region of the TS gene in a large cohort of caucasian cancer patients and we determine the number of functional USF binding sites that can be used as a pharmacogenetic marker in patients treated with fluoropyrimidines. The recently described 2RCC allele was also found in 6 patients, in all cases in heterozygous form. We identify a novel allele containing a 4bp insertion (cgcc) in the inverted repeat sequence located 2bp prior to the ATG start codon.

Molecular genetic analysis of apparently sporadic pheochromocytomas and paraganglioma in Czech patients

Z. Musil¹, J. Vesela¹, A. Krepelova^{1,2}, A. Panczak¹, J. Widimsky³, T. Zelinka³, A. Puchmajerova², M. Simandlova², Z. Frysak⁴, J. Vaclavik⁴, M. Kohoutova¹;

¹Institute of Biology and Medical Genetics of the First Faculty of Medicine, Prague, Czech Republic, ²Institute of Biology and Medical Genetics, 2nd Faculty of Medicine and Teaching Hospital at Motol, Prague, Czech Republic, ³3rd Medical Department - Clinical Department of Endocrinology and Metabolism, 1st Faculty of Medicine, Prague, Czech Republic, ⁴3rd Clinical Department, Faculty of Medicine and Faculty Hospital, Palacky University, Olomouc, Czech Republic.

Pheochromocytoma is a tumor arising in adrenal or extra-adrenal sites and occurs as a sporadic form or, less frequently, in familial setting as a part of inherited syndromes. Paraganglioma of the head and neck occurs mostly sporadically and also in syndromic or non-syndromic familial settings. To date, four susceptibility genes for pheochromocytoma have been reported that included *RET* proto-oncogene, *VHL* tumor suppressor gene, and recently identified genes *SDHB* and *SDHD* for succinate dehydrogenase subunit B and D, respectively. Mutations in these genes can predispose an individual to pheochromocytoma and/or paraganglioma. All these genes were analyzed to investigate possible genetic cause of pheochromocytoma and paraganglioma in population of Czech patients. Among 147 patients two novel germline (missense) mutations were found in the *VHL* gene. Further, one novel coding single nucleotide polymorphism and one inversion, both in *SDHB* gene, were detected. In one case of isolated pediatric onset of neuroblastoma and paraganglioma we detected a novel splice site mutation in *SDHB* gene. In addition, in one examined patient with paraganglioma we detected mutation of the start codon in *SDHD* gene. Supported by the grant project MSM0021620808

Carriers of germline c.1710+1355G>C substitution in the PML gene are at an increased risk of gastrointestinal cancer

P. Plevova^{1,2}, S. Walczyskova¹, I. Jeziskova¹, A. Krepelova³, K. Langova⁴, E. Silhanova¹;

¹Department of Medical Genetics, Faculty Hospital, Ostrava, Czech Republic, ²Medical Faculty, Palacky University, Olomouc, Czech Republic, ³Institute of Genetics, 2nd Medical Faculty, Charles University, Prague, Czech Republic, ⁴Institute of Biophysics, Palacky University, Olomouc, Czech Republic.

Introduction: *PML* (promyelocytic leukemia) is a tumor suppressor gene. We studied occurrence of c.1710+1355G>C (p.A570+232>P570+232) substitution in alternatively spliced exon 7b of the *PML* gene in cancer patients.

Patients and methods: Sporadic and hereditary breast, colon and stomach cancer and multiple colon polyposis patients were included into the study. The control group included 100 non-cancer patients. The c.1710+1355G>C substitution was analyzed in genomic DNA using restriction analysis. Its occurrence in each cancer versus control groups was correlated using chi-square test.

Results: c.1710+1355G>C was found in 7 of 64 (11%) non-*BRCA1/2* breast cancer (p=0,683), none of 24 *BRCA1/2*-associated breast cancer (p=0,276), 15 of 57 (26%) non-HNPCC colon cancer or multiple polyposis (p=0,003), none of 6 HNPCC-associated colon cancer (p=0,988, chi-square test with Yates correction), 2 of 3 stomach cancer patients (p=0,025, chi-square test with Yates correction) and 9 of 100 (9%) controls.

Conclusion: Our results suggest that germline carriers of the c.1710+1355G>C substitution in alternatively spliced exon 7b of the *PML* gene might be at an increased risk of gastrointestinal cancer or polyposis.

The 8q24 rs10505470 variant is not associated with prostate cancer risk in patients from the Republic of Macedonia

N. Matevska¹, D. Petrovski², S. Dzikova², S. Banev², V. Georgiev², A. Sikole², A. J. Dimovski¹;

¹Faculty of Pharmacy, Skopje, The former Yugoslav Republic of Macedonia,

²Faculty of Medicine, Skopje, The former Yugoslav Republic of Macedonia.

Recent compelling evidence demonstrates chromosome 8q24 as a prostate cancer (PC) susceptibility locus. Multiple variants within three adjacent regions at 8q24 have been identified to impact the risk of PC. Most commonly assessed variants are rs1447295 (region1), rs16901979 (region2) and rs6983267 (region3). Although regions 1 and 3 are close together, they are separated by a recombination hot-spot among individuals of European ancestry. Hence, all three neighboring regions seem to contribute independently to the PC risk, and the combined effects of SNPs across regions follow a multiplicative model. In order to examine the association between the PC risk and all three regions of 8q24 we designed a case-control study of randomly selected PC patients and controls without history of any malignant disease. Herein, we present the results of the association of PC risk and rs10505470 variant which is known to be in strong LD with rs6983267 in region 3. The rs10505470 genotypes were determined using custom designed TaqMan SNP genotyping assay on a Real-time PCR analyzer (MxPro 3005P). We did not observe a difference in overall allelic frequencies and genotype distribution ((A allele 0.518 for patients; 0.516 for controls); (AA 28.24%, AG 47.06%, GG 24.71% for patients; AA 27.60%, AG 47.92%, GG 24.48% for controls)). Furthermore there was no significant difference after stratification of patients in subgroups according to age and Gleason score. Our findings led us to conclude that rs10505470 variant is not implicated with PC risk, time of onset or PC aggressiveness in Macedonian population.

Alpha-methylacyl-CoA racemase, a novel specific biomarker for prostate cancer

R. O. Dumache¹, B. G. Bumbacila¹, A. Anghel¹, F. Miclea², M. Puiu³;

¹Victor Babes' University of Medicine and Pharmacy, Faculty of Medicine, Biochemistry Department, Timisoara, Romania, ²Victor Babes' University of Medicine and Pharmacy, Faculty of Medicine, Urology Department, Timisoara, Romania, ³Victor Babes' University of Medicine and Pharmacy, Faculty of Medicine, Medical Genetics Department, Timisoara, Romania.

Alpha-methylacyl-CoA racemase, abbreviated in data bases as AM-ACR or P504S, is a 382 amino acid protein that plays a critical role in peroxisomal and mitochondrial beta oxidation of branched chain fatty acid and bile acid intermediates, dihydroxycholestanic acid and trihydroxycholestanic acid, molecules. Specifically, it catalyses the conversion of (R) α -methyl branched chain fatty acyl CoAs to their (S) stereoisomers, because only stereoisomers with the 2-methyl group in the (S) position can be metabolized by peroxisomal oxidases, the first enzymes in the β oxidation pathway. It is well known that the main sources of branched chain fatty acids are the dairy products and red meat pork and beef, the consumption of which has been associated with an increased risk for prostate cancer in men, in multiple studies. We evaluated the AMACR gene expression in 32 patients aged 55 to 80, with total PSA values in a range of 2 to 40 ng/ml. 26 patients were diagnosed positive for prostate intraepithelial carcinoma and they had PSA values greater than 11 ng/ml. In these 26 men, we found by using PCR and micro array techniques on needle biopsies that they had an over expressed gene for AMACR, too. The other 6 patients with total PSA values smaller than 11 ng/ml, had normal expression of the AMACR gene.

According to our results, we propose the use of AMACR as an important marker of prostate cancer in Urology Clinics beside PSA and morphopathological diagnostic.

P04.183

CAG repeat number in androgen receptor gene and prostate cancer

S. Trivodalieva¹, N. Matevska², A. Dimovski², G. D. Efremov¹, D. Plaseska-Karanfilska¹;

¹Macedonian Academy of Sciences and Arts, Research Centre for Genetic Engineering and Biotechnology, Skopje, The former Yugoslav Republic of Macedonia, ²Faculty of Pharmacy, Farmacogenetic laboratory, Skopje, The former Yugoslav Republic of Macedonia.

Prostate cancer (PC) is the second leading cause of cancer deaths among men. The effects of androgens on prostatic tissue are mediated by the androgen receptor (AR) through the androgen receptor-androgen complex. The 5' end of exon 1 of the AR gene includes a polymorphic CAG triplet repeat that varies in number between 10 to

36 in the normal population. The length of the CAG repeats is inversely related to the transactivation function of the AR gene. There is controversy over an association between short CAG repeat numbers in the AR gene and prostate cancer. The aim of this study was to evaluate the possible effect of short CAG repeats in the AR on prostate cancer risk in Macedonian males. We studied 66 PC patients, 46 patients with benign prostatic hyperplasia (BPH), 104 male patients with colon cancer (CC) and 152 males from the general population. The CAG repeat number was determined by fluorescent PCR amplification of exon 1 of AR gene followed by capillary electrophoresis on ABI PRISM 310 Genetic Analyzer. The mean CAG repeat length among PC patients was significantly lower (21.4 ± 2.6) in comparison to the BPH patients (22.7 ± 2.2 ; $p=0.007$), CC patients (22.6 ± 3.1 ; $p=0.008$) and males from general population (22.3 ± 2.8 ; $p=0.029$). We found a significantly higher percentage of short CAG repeats (≤ 21) in PC patients (56.1%) than in BPH patients (21.7%; $p=0.0002$). Our results suggest that short CAG repeats are associated with an increased prostate cancer risk in Macedonian men.

P04.184

The Galician splicing mutation p.R71G in the BRCA1 gene is not found at an increased frequency in Galician prostate cancer patients

L. Facha¹, A. Carballo², A. Blanco¹, P. Peleteiro², O. Lortes¹, M. Magdalena¹, C. Ruíz-Ponte¹, A. Gómez², Á. Carracedo¹, A. Vega¹;

¹Fundación Pública Gallega de Medicina Xenómica-SERGAS, Grupo de Medicina Xenómica-USC, CIBER-ER, Santiago de Compostela, A Coruña, Spain, ²Servicio Radioterapia, Hospital Clínico de Santiago de Compostela, Santiago de Compostela, A Coruña, Spain.

The Breast Cancer Linkage Consortium and other family-based ascertainment have suggested that male carriers of *BRCA* mutations are at increased risk of prostate cancer. However, several series looking at the frequency of *BRCA* mutations in unselected patients with prostate cancer have not confirmed this finding. In the Galician population, one splicing founder mutation p.R71G in the *BRCA1* gene is present in more than 50% of the breast/ovarian cancer families with mutations. To assess the contribution of p.R71G to prostate cancer morbidity we conducted a case-control study in prostate cancer patients. Blood specimens from 257 unselected Galician men with prostate cancer were screened for the presence of the common Galician founder mutation in *BRCA1*. As a control group 250 Galician male volunteers without prostate cancer were genotyped. We found that mutation p.R71G was completely absent in our cohort. Therefore, our result suggests that the contribution of *BRCA1* germline mutations in prostate cancer morbidity is probably negligible.

P04.185

Study of GSTM1, GSTT1 polymorphisms and CAG microsatellite repeat length of the androgen receptor gene in Iranian prostate cancer patients

Z. Ousati - Ashtiani¹, M. Modarressi¹, H. Ayat², B. Sabah Gouliani³, M. Aarabi², S. M. Hasheminasabi¹;

¹Department of Medical Genetics, Medical Sciences/University of Tehran, Tehran, Islamic Republic of Iran, ²Department of Urology, Medical Sciences/University of Tehran, Tehran, Islamic Republic of Iran, ³Bistoon, Ultrasound Clinic, Tehran, Islamic Republic of Iran, ⁴Department of Reproductive Genetics and Biotechnology, Reproductive Biotechnology Research Center, Avesina Research Institute, ACECR, Tehran, Islamic Republic of Iran.

Androgens which act through androgen receptors (ARs) are required for growth and normal prostate function. ARs are important for development and progression of prostate cancer. AR gene contains CAG repeats and it has been hypothesized that, shorter alleles of the CAG repeat are associated with an increased risk of prostate cancer. Ethnic variation in CAG repeat length may contribute to variable prostate cancer risks in different populations. Genetic polymorphism of metabolic enzymes such as Glutathione S-transferases is involved in metabolism of numerous potential prostate carcinogens. The frequencies of homozygous carriers of GSTT1, GSTM1 deletions vary significantly within ethnic groups and may be contributed to prostate cancer risk. To evaluate whether these polymorphisms are associated with an increased risk in Iranian prostate cancer patients, DNA from 110 pathologically-confirmed prostate cancer patients, 96 age-matched men with BPH individuals were extracted and amplified by polymerase chain reaction

(PCR). PCR products were examined by electrophoresis, sequencing. Statistical analysis of results was carried out using t-test and chi² methods. The mean number of CAG repeat in prostate cancer patients was significantly smaller than BPH groups (19.9 vs. 21.9 $P<0.0001$). The frequencies of GSTT1 and GSTM1 positive genotypes were higher in patients (65.5%, 54.9%) than BPH group (59.1, 52.3). Our results showed that CAG repeat polymorphism in AR gene is significantly associated with higher prostate cancer risk, suggesting that it may act as a risk modifier to cancer patients in Iranian population. GSTT1 and GSTM1 positive genotypes also may be contributed to prostate cancer susceptibility in Iranian patients.

P04.186

TMRSS2/ERG4 fusion gene is a novel hormone refractory marker of prostate cancer

T. V. Kekeeva¹, Y. Y. Andreeva², G. A. Frank², D. V. Zaletaev^{1,3}, M. V. Nemtsova^{1,3};

¹Moscow medical academy, Moscow, Russian Federation, ²Moscow Herzen Oncological Research Institute, Moscow, Russian Federation, ³Medical Genetic Research Centre, Moscow, Russian Federation.

Recurrent gene fusions involving oncogenic ETS transcription factors (including ERG, ETV1, and ETV4) have been identified in a large fraction of prostate cancers. The most common fusions contain the 5' untranslated region of TMRSS2 fused to ERG. TMRSS2-ERG gene fusion leading to the androgenic induction of the ERG proto-oncogene expression is a highly prevalent oncogenic alteration in prostate tumor cells. To assess the role of TMRSS2-ERG alteration in prostate cancer onset and/or progression, we have evaluated the status of fusion transcripts in 72 whole-mount prostatectomy specimens of patients with pT1-T4 prostate cancer stage. We tested for the presence of TMRSS2:ERG, TMRSS2:ETV1 and TMRSS2:ETV4 gene fusion product, using RT-PCR and direct sequencing. Overall, 36 of 72 (50%) patients exhibited TMRSS2-ERG fusion transcripts in prostate cancer samples. There are no TMRSS2:ETV1 and TMRSS2:ETV4 fusion transcripts in adenocarcinoma specimens. TMRSS2-ERG expression was correlated with prostate cancer stage. We observed significantly difference between hormone ablation therapy patients group and group without hormone therapy ($p=0.02$). Patients without TMRSS2-ERG expression are shown no response to hormone treatment.

TMRSS2-ERG is the most common genetic aberration so far described in human malignancies. Furthermore, its clinical application as a hormone resistant biomarker is promising perspective for prostate cancer therapy scheming.

Mitochondrial implication in Prostate Cancer: Mitochondrial gene expression

M. López de Heredia^{1,2}, J. Abril¹, R. Cléries³, L. González^{1,2}, M. Nadal¹, M. Gómez-Zaera¹, V. Nunes^{1,4,2};

¹Centro de Genética Médica y Molecular, IDIBELL, L'Hospitalet de Llobregat, Spain, ²Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER) U-730, ISCIII, L'Hospitalet de Llobregat, Spain, ³Servicio de Epidemiología, ICO, Hospital Duran i Reynals, L'Hospitalet de Llobregat, Spain, ⁴Unidad de Genética. Departamento de Ciencias Fisiológicas II, UB-IDIBELL, L'Hospitalet de Llobregat, Spain.

Prostate cancer (PCa) is one of the most common cancers among male population in the world, being responsible for 6% of all deaths by cancer in males. In spite of its relevance and the progressive increase in the number of cases detected, the mechanisms that account for its genesis and development are unknown. Genomic studies have suggested that genes from mitochondrial respiratory chain, Krebs cycle and the glutathione reductase anti-oxidant system may be involved in PCa. In order to broaden our knowledge on the mitochondrial role in PCa carcinogenesis and progression, we have analyzed in paired samples (normal-tumor) from PCa patients, the presence of mutations in mitochondrial genome (by direct sequencing); mtDNA amount (by quantitative PCR); and mRNA expression of genes with mitochondrial functions encoded either by mitochondrial genome (*MT-ND2*, *MT-ND4*, *MT-ND6*, *MT-CYB*, *12S*, *16S*, *MT-CO2*, *MT-ATP6*) or by nuclear genome (*COX11*, glutathione reductase/*GSR*, citrate sintase/*CS*, aconitase/*ACO2*).

We have observed that in spite of the presence of mutations in mtDNA,

there are no changes in the amount of mtDNA. We have also observed a significance decrease in the expression of mitochondria-encoded genes *MT-12S*, *MT-CO2* and *MT-ATP6*.

P04.188

Identification of novel molecular targets for arresting prostate cancer cell proliferation.

S. F. Gaudi¹, F. Carlini¹, D. De Orsi¹, S. Paradisi¹, G. Bozzuto¹, L. Toccaceli¹, G. Formisano¹, A. Weisz², R. Arcieri¹, S. Vella¹;

¹Istituto Superiore di Sanità, Roma, Italy, ²Seconda Università degli Studi di Napoli, Naples, Italy.

Retroelements (RE) represent a significant portion of the human genome (45 %) and play a key role in the regulation of gene expression in mammals. RE can act as insertional mutagens altering the coding integrity of genes and, particularly the gene coding for reverse transcriptase (RT) is typically expressed at high level in transformed cells and tumor.

A large body of published data supports the conclusion that retrotransposons are biologically active elements and indicates that retrotransposition is an ongoing process in mammalian genomes and can trigger the onset of several pathologies including cancer. Active LINE-1 transcripts have been detected in murine embryonal carcinoma cells and in human testicular cancers, while only basal levels of RT activity have been revealed in terminally differentiated cells and tissues.

Studies developed in our research groups over the last years have shown that the commercially available RT inhibitor, Abacavir, widely used in AIDS therapy, is able to modulate cell growth and differentiation in prostate cancer cell line (PC3).

ABC, respectively at 10 and 100 µg/ml, is able to reduce proliferation, migration and invasion. We studied genome wide expression profile on PC3 cells treated with ABC and we identified genes involved in RNA regulation and expression. Further immuno-fluorescence experiments revealed a critical involvement of nucleolus as target of ABC action.

Finally, we discuss new approaches to treatment, including recently discovered molecular targets that might provide more effective treatment strategies with the potential for less toxicity.

P04.189

PTCH1 gene polymorphisms and risk of non melanoma skin cancer after organ transplantation

A. Begnini¹, G. Tessari², M. Gomez Lira¹, L. Naldi², G. Remuzzi², L. Boschiero², A. Formi², C. Ruggi², S. Piaserico², G. Girolomonfi², A. Turco¹;

¹Section of Biology and Genetics, Department of Mother and Child and Biology-Genetics, University of Verona, Verona, Italy, ²Section of Dermatology, Department of Biomedical and Surgical Science, University of Verona, Verona, Italy.

Organ transplant recipients (OTR) are at higher risk of non melanoma skin cancer (NMSC), particularly basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). Risk factors for NMSC in OTR include skin type, ultraviolet light exposure, immunosuppression, human Papilloma virus infections, and genetic susceptibility.

PTCH1 is a negative regulator of the Hedgehog pathway, that provide mitogenic signals to basal cells in skin. PTCH1 gene mutations are responsible for nevoid basal cell carcinoma syndrome (NBCCS or Gorlin syndrome), and also occur in sporadic forms of BCC. Associations have been demonstrated between PTCH1 polymorphisms and BCC susceptibility in non transplanted recipients.

This study was designed to investigate if known polymorphisms of PTCH1 gene contribute, individually or as haplotypes, to NMSC risk after transplantation, and to identify novel genetic polymorphism in the proximal 5' regulatory region of the gene.

We analyzed the frequencies of three PTCH1 gene SNPs (rs2297086, rs2066836, rs357564) in 273 Northern Italian OTR patients (120 cases and 153 controls).

Single locus and haplotype frequency analysis showed no significant associations.

Screening for polymorphisms was performed by heteroduplex analysis in 30 cases and 30 matched controls.

Two polymorphisms, -198A>G and -195G>C, were identified in the 5' flanking region. Both variants were in linkage disequilibrium and showed a frequency of 0.5% (2/400) in 200 tested individuals.

These results seem to exclude an important role of the PTCH1 gene in NMSC susceptibility after organ transplantation. Further studies on a larger sample are warranted to confirm these findings.

P04.190

Molecular genetic and clinical survey of Swiss PTEN hamartoma tumor syndrome patients

M. Plasilova¹, N. Boesch¹, C. Egenter¹, B. Röthlisberger², H. Mueller¹, K. Heini-mann¹;

¹Research Group Human Genetics, Division of Medical Genetics UKBB, Center of Biomedicine, University Children's Hospital, Basel, Switzerland, ²Center of Laboratory Medicine, Cantonal Hospital Aarau, Aarau, Switzerland.

PTEN hamartoma tumor syndrome (PHTS) is a condition caused by germline mutations in the PTEN (phosphatase with tensin homology) tumor suppressor gene which encodes a phosphatase with lipid and protein specificity, a negative regulator of the phosphoinositol 3-kinase (PI3K) pathway. PHTS includes Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba syndrome (BRRS), Proteus syndrome (PS), and Proteus-like syndrome, the first two being the most prevalent conditions. Here we present the results of a molecular genetic and clinical survey on 12 Swiss PHTS patients (10 CS, 2 BRRS) and their relatives referred during the past 4 years. All patients were subjected to DNA sequencing of the coding (incl.exon/intron boundaries) and the promoter region, and to gene dosage analysis. In the coding region of PTEN, heterozygous germline mutations were identified in five CS patients and one BRRS patient. The majority of the PTEN mutations were found to be either nonsense point mutations or frameshift deletions. In addition, one heterozygous splice site mutation and one missense mutation were observed. Based on these findings, the mutational spectrum and clinical manifestations in both, PTEN mutation carriers and those without detectable genetic alterations will be presented. In particular, the clinical overlap between CS and BRRS PTEN mutation carriers will be discussed.

P04.191

Evaluation of exon 2 and exon 6 mutations of PTEN gene in patients with gastric cancer

Gastric cancer (GC) is still one of the most frequent causes of cancer-related deaths in all overworld. Molecular mechanism of GC has not been well described. In recent years, the pathogenesis of GC related to the basis of the molecular and genetic changes have been investigated in the different populations. These changes can be classified as activation of oncogenes, the inactivation of tumor suppressor genes, the reduction of cellular adhesion, the reactivation of telomerase and the presence of microsatellite instability. A novel tumor suppressor gene, PTEN (phosphatase and tensin homologue deleted on chromosome ten), has recently been described and mapped to chromosome band 10q23.3 region. In the present study, we evaluated the frequency of exon 2 and exon 6 mutations of PTEN gene in the normal (n=47) and tumor tissues (n=47) of the patients with GC, by using SSCP and sequencing techniques. The frequency of mutations in exon 2 and exon 6 of the PTEN gene in tumor and normal tissue DNAs were compared and the results were compared with the other results published for the other population in the literature.

P04.192

High throughput, nanofluidic real-time PCR analysis of gene expression in tumor samples

E. Ortenberg¹, S. Liu-Cordero¹, J. Hurlley¹, T. Morrison¹, J. Cho¹, M. Kopczynski¹, C. Brennan¹, K. D. Munnally¹;

BioTrove, Inc., Woburn, MA, United States.

Understanding biological complexity arising from patterns of gene expression and gene function requires accurate and precise measurement of RNA levels across large numbers of genes simultaneously. We demonstrate a novel highly parallel, nanofluidic system capable of performing 3072 real-time polymerase chain reactions (rt-PCR), based on Sybr Green detection, in a miniaturized through-hole array format.

The system has shown accuracy, precision and dynamic range in the thirty-three nanoliter reaction volumes identical to the same reactions performed in 100-fold larger volumes typical for rt-PCR in 384-well microplates. A 64-fold increase in analytical throughput relative to 384-well microplates simplified quantification of message RNA, resulting in unprecedented throughput and sensitivity suitable for detection of low abundance nucleic acids as well as low consumable costs. We show the utility of this system for studying two different areas of cancer biology. First, the expression of over 500 kinase genes was screened in three types of tumor tissues and the biological significance of regulated genes in regulating the cell cycle was confirmed. Second, we studied its utility for screening for DNA methylation as a biomarker for tumor detection.

P04.193

Setting up of a questionnaire by the genetic counselor to optimize the collection of data during the first consultation of cancer genetics

A. Combes¹, K. Baudry-Samb¹, P. Pujol¹, J. Duffour², I. Coupier^{1,2};

¹CHU Arnaud de Villeneuve, Montpellier, France, ²CRCL Val d'Aurelle, Montpellier, France.

Persons presenting a hereditary predisposition for cancer are addressed to a consultation of cancer genetics because of their personal and family history of cancers. During consultation a family pedigree is drawn, genetic counselor collects information to evaluate hereditary predisposition. All this information is difficult to obtain if the patients are not informed of the questions which will be asked to them during consultation.

The aim of this study is to optimize the collection of information using a questionnaire targeting essential data during this first consultation.

This questionnaire was addressed to all patients making an appointment for a first consultation. It gathers personal and medical information, in both parental branches over three generations. Questionnaires were assessed according to two criteria : their return and filling up rates.

The return rate is 82 % (110/134). The mean filling up rate is 74 % and for more than 86 % of questionnaires, the amount of information is very satisfactory (questionnaires supplemented in 60, 80 and 100 %).

The questionnaire has a double interest, for the patients and for the medical team. The patients collected a lot of information on their family before their consultation. For the medical team, data necessary for the realization of the family pedigree are gathered in a more precise and quicker manner.

Considering the good return and filling up rates of this questionnaire, we decided to insert it into the daily practice of our consultations.

P04.194

Analysis of the molecular-genetic alterations in the genes VHL, RASSF1, and FHIT in clear cell renal carcinomas

D. S. Mikhaylenko^{1,2}, A. M. Popov³, R. V. Kuryim⁴, D. V. Zaletayev^{1,2};

¹Research Centre for Medical Genetics RAMS, Moscow, Russian Federation, ²Institute of Molecular Medicine of Sechenov Moscow Medical Academy, Moscow, Russian Federation, ³Medical Radiological Research Center RAMS, Obninsk, Russian Federation, ⁴Clinic of Urology of Sechenov Moscow Medical Academy, Moscow, Russian Federation.

Clear cell renal carcinoma accounts approximately 75% patients with kidney cancer and characterized by alterations of the genes *VHL*, *RASSF1*, *FHIT*. We have conducted the molecular-genetic study of mutations, loss of heterozygosity, methylation of the *VHL* gene as well as allelic deletions of the genes *RASSF1* and *FHIT* in 123 clear cell renal carcinomas for the development of renal cancer prognostic criteria. *VHL* mutations were detected by SSCP and subsequent sequencing; methylation was tested by methylsensitive polymerase chain reaction. Loss of heterozygosity was analyzed using STR-markers D3S1317 and D3S1038 (*VHL*), D3S1568 and D3S966 (*RASSF1*), D3S1234 and D3S1300 (*FHIT*). *VHL* somatic mutations were observed in 31.7% samples, 84.6% of them were identified for the first time. We have detected *VHL* allelic deletions in 27.9% informative cases, and aberrant methylation - in 14.6% heterogeneous tumor samples. *VHL* inactivating events were presented in 53.8% patients with stage I, and could be responding for early gene inactivation. *RASSF1* and *FHIT* allelic deletions were observed in 27.5% and 35.6% informative cases, correspondingly. Loss of heterozygosity of two or three analyzed genes in

primary tumor was associated with metastases in the regional lymph nodes and/or distant metastases (P = 0.036, OR = 1.49, 95% CI: 1.01-2.33). Results of this investigation could be used for selection of prognostic molecular markers of clear cell renal cancer.

Under-representation of the RET sequence variants G691S and S904S in patients with a common C618R RET proto-oncogene mutation

V. Neocleous¹, V. Anastasiadou^{2,1}, M. Pantzaris¹, N. Skordis², L. A. Phylactou¹;

Medullary thyroid carcinoma (MTC) occurs in a sporadic or as an autosomal dominant hereditary form. Inherited forms of MTC are related to mutations in the RET proto-oncogene. Identification of polymorphic variants that increase susceptibility and variations in pathological phenotypes is a frequent question that is addressed in medical genetics. In various studies which resulted to conflicting results a number of polymorphisms within the RET proto-oncogene were proposed to act as low penetrance predisposing alleles. In the present study, in order to test for the contributory role of the polymorphisms G691S and S904S, in the development of MEN2A, we looked for an association of these RET haplotypes in hereditary MEN2A cases and in controls from individuals of Greek Cypriot origin.

Screening for the polymorphic variants G691S/S904S was performed in 226 Greek Cypriots who served as controls and in 6 unrelated Greek Cypriot patients diagnosed with MEN2A with the C618R mutation. In controls, the allelic frequencies of G691S/S904S polymorphisms were found in the heterozygous state in 102/226 (45 %) individuals, and in the homozygous state in 11/226 (~5 %). In all cases, these polymorphisms were in co-segregation. This allelic frequency for the polymorphisms G691S/S904S of the RET gene in the Greek Cypriot population is the highest reported so far among normal individuals. Moreover, only 1/6 (16.66 %) patients with MEN2A had the G691S/S904S polymorphisms in the heterozygous state. This under-representation of the G691S/S904S polymorphic variants in MEN2A patients, might suggest a possible synergistic and protective effect exercised by these polymorphisms.

Variants in the retinoblastoma gene: neutral polymorphism or pathogenic change?

C. J. Dommering¹, A. H. van der Hou², S. M. Imho³, A. C. Mol³, M. Burton², Y. J. Vos², H. J. Meijers-Heijboer¹;

Retinoblastoma is a malignant neoplasm of the developing retina, occurring mostly in early childhood. The birth prevalence is between 1 in 15.000 and 1 in 20.000. Hereditary (40% of cases) as well as non-hereditary (60% of cases) retinoblastoma (RB) result from inactivation of both alleles of the tumor-suppressor gene *RB1*, located on chromosome 13q14. In hereditary RB, the mutated gene is transmitted in an autosomal dominant way, usually with almost complete penetrance. We have performed DNA-mutation scanning (sequencing of exon 1, 15 and the *RB1*-promoter, DGGE analysis of the other exons and MLPA analysis for large deletions and duplications) in 411 RB-patients and found causative *RB1*-mutations in 173/197 (88%) bilateral/familial patients and 18/214 (8.4%) in unilateral non-familial cases. Most mutations are nonsense changes or small insertions or deletions causing frameshifts. However, for some changes it is not immediately clear if they are pathogenic mutations or just neutral variants. These include missense changes, synonymous changes, small in-frame deletions and intronic variants at other sites than the invariable splice donor and acceptor sequences. These variants cause serious problems in genetic counselling of RB patients and their family. We will discuss several variants with unknown significance in the *RB1*-gene, 15 missense changes, 11 intronic variants, 2 synonymous changes in 1 in frame deletion, and illustrate ways to substantiate their pathogenicity.

P04.197**Mutation in siRNA target sequence can impair RNAi mediated inhibition of E1A gene expression in HEK 293**

H. Vosgha, M. Behmanesh, M. Sadeghizadeh;

Tarbiat Modares University, Tehran, Islamic Republic of Iran.

RNA interference (RNAi) has emerged as an effective method for silencing gene expression in eukaryotic cells. It has tremendous potential as both a research tool and a therapeutic strategy. The key player in RNAi is small RNA (~ 22nt) termed siRNA. So in this report we used the E1A specific siRNA coding plasmid under U6 snRNA promoter to suppress E1A gene expression. Then these constructs were transfected into the HEK 293 cancerous and successfully transfected cells colonies were selected based on Neomycin antibiotic resistance. Changes in E1A gene expression were analyzed using RT-PCR technique. Final findings showed no obvious difference in E1A gene expression level in suppression and control groups upon transfection with constructed plasmids. In order to deduce the rationale behind no suppression of the E1A gene expression, we analyzed the PCR amplified sequence of the siRNA target region of the E1A gene using sequencing technique. The findings illustrated certain mutations in this region. It has been established previously that in RNAi process, occurrence of any mutation in mRNA sequence of target gene at the siRNA binding site might cause impaired interference in gene expression. Therefore even a single mutation in mRNA sequence cause inhibition of interference.
